INSTRUCTIONS TO ABSTRACTORS,

GIVING THE

NOMENCLATURE AND SYSTEM OF NOTATION

ADOPTED IN THE ABSTRACTS.

---

1. Before beginning to write an abstract, it is desirable to read through the whole of the original paper, in order to form a judgment as to its importance, and as to the scale on which the abstract should accordingly be made.

2. The abstract should mainly consist of the expression, in the abstractor's own words, of the substance of the paper.

3. The abstract should be made as concise as possible, consistently with a clear and accurate statement of the author's results or theories, due regard being paid to their import.

4. If an abstract of a paper on the same subject, either by the author of the paper abstracted, or by some other author, has already appeared, note should as a rule be made of this fact. Important references to the researches of others quoted by an author should be reproduced in the abstract. Always employ figures instead of Roman numerals for references, thus:—*Annalen*, **221**, 92, instead of ccxxi, 92.

5. If an abstractor is acquainted with papers previously published by other authors containing statements either practically identical with, or opposed to, those in the paper abstracted, and to which no reference is made, he should notice their agreement or contradiction in a foot-note.

6. As a rule, details of methods of preparation or analysis, or generally speaking of work, may be omitted, unless such details are essential to the understanding of the results, or have some independent value.

Nomenclature.

7. Employ names such as *sodium chloride*, *potassium sulphate*, *ethyl acetate*, and use the terminals *ous* and *ic* only in distinguishing compounds of different orders derived from the same elementary radicle; such, for instance, as mercurous and mercuric chloride, sulphurous and sulphuric acid.

8. Term compounds of metallic and alcoholic radicles with the group OH, *hydroxides* and not hydrates; for example, potassium hydroxide, phenyl hydroxide, the name hydrate being reserved for compounds supposed to contain water of combination or crystallization. Compounds such as CH_3ONa, C_2H_5ONa, $C_7H_{15}ONa$, &c., should be termed sodium methoxide, ethoxide, heptyloxide, &c.

9. Apply the term *acid* only to compounds of hydrogen with negative radicles, such as HNO_3, H_2SO_4, H_3PO_4, and denote the oxides which form acids by names such as sulphuric anhydride, carbonic anhydride. Term salts containing an amount of metal equivalent to the displaceable hydrogen of the acid, *normal* and not neutral salts, and assign names such as hydrogen sodium sulphate, hydrogen disodium phosphate, &c., to the acid salts. Basic salts are as a rule best designated merely by their *formulæ*.

10. Use names such as *methane*, *ethane*, &c., for the normal paraffins or hydrocarbons of the C_nH_{2n+2} series of the form $CH_3 \cdot [CH_2]_5 \cdot CH_3$, &c. The isomeric hydrocarbons are usually most conveniently represented by names indicating their relation to methane; for example, $CH_3 \cdot CH_2 \cdot CH_2 \cdot CH_3$ = propylmethane; $CH_3 \cdot CH(CH_3)_2$ = isopropylmethane or trimethylmethane; or, although less frequently, by names such as diisopropyl.

11. Term the hydrocarbons C_2H_4 and C_2H_2 *ethylene* and *acetylene* respectively (not ethene and ethine). Distinguish the homologues of ethylene, whenever possible, by names indicating their relation to it, such as methylethylene, dimethylethylene, &c., denoting the di-derivatives of the form $C_nH_{2n+1} \cdot CH{:}CH \cdot C_nH_{2n+2}$ as α-, and those of the form $CH_2{:}C(C_nH_{2n+1})_2$ as β-compounds, thus: $CH_3 \cdot CH{:}CH \cdot CH_3$ = α-dimethylethylene; $CH_2{:}C(CH_3)_2$ = β-dimethylethylene. Similarly, use names such as methylacetylene and dimethylacetylene for the homologues of acetylene of the form $CH{:}C \cdot C_nH_{2n+1}$ and $C_nH_{2n+1} \cdot C{:}C \cdot C_nH_{2n+1}$. Adopt the same *allene* for the hydrocarbon $CH_2{:}C{:}CH_2$, and indicate the relation which its homologues bear to it in the same manner as pointed out for acetylene.

12. Distinguish all alcohols, that is, hydroxyl-derivatives of hydrocarbons, by names ending in *ol*; such as quinol, catechol, resorcinol, saligenol, glycerol, erythrol, mannitol, instead of hydroquinone, pyrocatechin, resorcin, saligenin, glycerin, erythrite, mannite. Compounds which are not alcohols, but which are at present distinguished by names ending in *ol*, may be represented by names ending in *ole*, if a systematic name cannot be given. For example, write indole instead of indol: furfuraldehyde instead of furfurol; fucusaldehyde instead of fucusol. Ethers derived from phenols, such as $C_6H_5 \cdot OCH_3$, &c., hitherto called anisol, anethol, &c., may be distinguished by names ending in *oïl*, as anisoïl and anethoïl.

Alcohols should be spoken of as mono-, di-, tri-, or n-*hydric*, according to the number of OH groups.

13. Compounds analogous to the acids of the lactic series containing the group OH should be termed *hydroxy*-derivatives, and not oxy-derivatives; for example, hydroxyacetic and not oxyacetic acid. Compounds containing the analogous groups C_2H_5O, C_6H_5O, $CH_3 \cdot COO$, &c., should in like manner be termed ethoxy-, phenoxy-, acetoxy- derivatives. Thus

ethoxypropionic acid instead of ethyl-lactic acid; 3 : 4 diethoxybenzoic acid instead of diethylprotocatechuic acid; and acetoxypropionic acid instead of acetyl-lactic acid. Terms such as diethylprotocatechuic acid should be understood to mean a compound formed by the displacement of hydrogen-atoms in the hydrocarbon radicle of protocatechuic acid by ethyl, viz., $C_6H(C_2H_5)_2(OH)_2{\cdot}COOH$, and not $C_6H_3(OC_2H_5)_2{\cdot}COOH$, just as dibromoprotocatechuic acid is understood to be the name of a compound of the formula $C_6HBr_2(OH)_2{\cdot}COOH$.

14. The term *ether* should be restricted to the oxides of hydrocarbon radicles, and the so-called compound ethers should be represented by names similar to those given to the analogously constituted metallic salts (comp. 12).

15. Compounds of the radicle SO_3H should, whenever possible, be termed *sulphonic* acids, or failing this, *sulpho-compounds*: as benzenesulphonic acid, sulphobenzoic acid, and not sulfi-compounds. Compounds of the radicle $SO_2{\cdot}NH_2$ should be termed sulphonamides.

16. Basic substances should invariably be indicated by names ending in *ine*, as aniline, instead of anilin, the termination *in* being restricted to certain neutral compounds, viz., glycerides, glucosides, bitter principles, and proteids, such as palmitin, amygdalin, albumin. The compounds of basic substances with hydrogen chloride, bromide, or iodide should always receive names ending in *ide* and not *ate*, as morphine hydrochloride and not morphine hydrochlorate.

Notation.

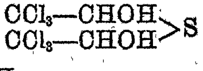
17. Equations should *be omitted* unless essential to the understanding of the results; they, as a rule, should *not* be written on a separate line, but should "run on" with the text.

18. To economise space, it is desirable: 1, that *dots* should be used *instead of dashes* in connecting contiguous symbols or radicles, whenever this does not interfere with the clearness of the formula; 2, that formulæ should be shortened by the judicious employment of the symbols Me for CH_3, Et for C_2H_5, Pr^{α} for $CH_2{\cdot}CH_2{\cdot}CH_3$, Pr^{β} for $CH(CH_3)_2$, Ph for C_6H_5, Ac for $CO{\cdot}CH_3$, and Bz for $CO{\cdot}C_6H_5$; and 3, that formulæ should be written *in one line* whenever this can be done without obscuring their meaning. For example:

$CCl_3{\cdot}CH(OEt)_2$ instead of

$$CCl_3{-}CH{<}\begin{array}{l}OC_2H_5\\OC_2H_5\end{array}$$

$[CCl_3{\cdot}CH(OH)]_2S$ instead of

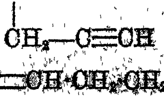


$$\begin{array}{l}CCl_3{-}CHOH\\CCl_3{-}CHOH\end{array}{>}S$$

$CH_2 \vdots CH_2$ instead of $CH_2{=}CH_2$

$CH \vdots CH$ instead of $CH{\equiv}CH$

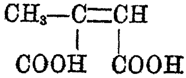
$CH \vdots C{\cdot}CH_2{\cdot}CH_2{\cdot}C \vdots CH$ instead of



$$\begin{array}{l}CH_2{-}C{\equiv}CH\\|\\CH_2{-}C{\equiv}CH\end{array}$$

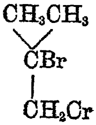
$CHMe \vdots CHPr^{\alpha}$ instead of $CH_3{\cdot}CH{=}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_3$

COOH·CH : CMe·COOH instead of



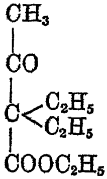
$$CH_3{-}\underset{COOH}{C}{=}\underset{COOH}{CH}$$

CH₂Br·CBrMe instead of

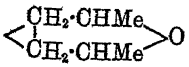


$$\begin{array}{l}CH_3CH_3\\ \quad\vee\\ \ CBr\\ \ \ |\\ CH_2Cr\end{array}$$

CEt₂Ac·COOEt instead of

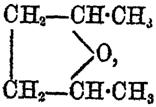


$$\begin{array}{l}CH_3\\ |\\ CO\\ |\\ C<^{C_2H_5}_{C_2H_5}\\ |\\ COOC_2H_5\end{array}$$



$$<^{CH_2·CHMe}_{CH_2·CHMe}>O$$

instead of

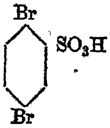


$$\begin{array}{l}CH_2—CH·CH_3\\ |\qquad\quad >O,\\ CH_2—CH·CH_3\end{array}$$

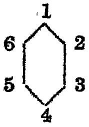
CHPh(OBz)·CH(OBz)·COOEt instead of
$C_6H_5·CH(O·CO·C_6H_5)·CH(O·COC_6H_5)·COOC_2H_5$.

19. In representing the constitution of benzene-derivatives, as a rule, merely indicate the relative positions of the radicles in the symbol of benzene by figures, instead of by means of the hexagon symbol, for example:—

Paradibromobenzenesulphonic acid, $C_6H_3Br_2·SO_3H$[Br : SO_3H : Br = 1 : 2 : 4] instead of



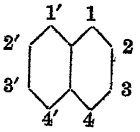
the figures always being used in the order



Relatively to the position 1, the positions 2 and 6 should always be spoken of as *ortho*-positions, 3 and 5 as *meta*-positions, and 4 as the *para*-position. It is better, however, in speaking of the derivatives of benzene, to express their constitution by giving them names such as 1 : 2 dibromobenzene, 1 : 3 dibromobenzene, &c., rather than by terming them ortho- or meta-dibromobenzene, &c.

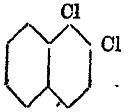
20. Moreover, in representing the constitution of derivatives of other "closed-chain" hydrocarbons do not, as a rule, employ graphic formulæ, but merely indicate the position of the radicles introduced in the following manner:—

In the case of naphthalene, express the position of the radicles introduced in place of hydrogen relatively to the carbon-atoms common to the two "rings," and number the positions in the one ring 1, 2, 3, 4, and those in the other 1′, 2′, 3′, 4′ in the order shown by the annexed symbol:—

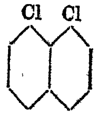


The dichloronaphthalenes, for example, are spoken of simply as 1 : 2 dichloronaphthalene, or dichloronaphthalene[Cl : Cl = 1 : 2], &c., thus:—

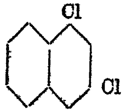
1 : 2 dichloro-
naphthalene =



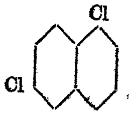
1 : 1′ dichloro-
naphthalene =



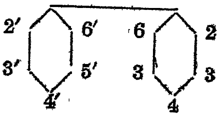
1 : 3 dichloro-
naphthalene =



1 : 3′ dichloro-
naphthalene =



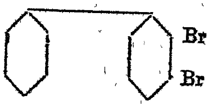
In the case of diphenyl, indicate the position of the radicles relatively to the carbon-atom of one C_6 group which is associated with the other C_6 group, and number the positions in the one group by the figures, 2, 3, 4, 5, 6, and the corresponding positions in the other group by the figures 2′, 3′, 4′, 5′, 6′. as shown by the following symbol:



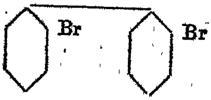
Thus the mono-derivatives, the bromodiphenyls, for example, are represented as

Bromodiphenyl [Br = 2]
" [Br = 3]
" [Br = 4]

and the two dibromodiphenyls

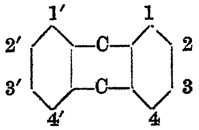


and



are respectively dibromodiphenyl [Br : Br = 2 : 3] and dibromodiphenyl [Br : Br = 2 : 6].

In the case of anthracene, employ the following symbol, and indicate the position of the radicles relatively to the central C_2-group:



Examples:

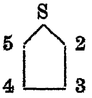
Alizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 2].
Quinizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 4].
Anthraflavic acid, $C_6H_3(OH) : C_2O_2 : C_6H_3(OH)$ [OH : OH = 2 : 3′].
Purpurin, $C_6H_4 : C_2O_2 \cdot C_6H(OH)_3$ [OH : OH : OH = 1 : 2 : 4].

In speaking of compounds such as these, their constitution may be represented by the names

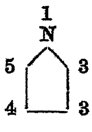
1 : 2 Dihydroxyanthraquinone = Alizarin.
1 : 4 „ = Quinizarin.
2 : 3′ „ = Anthraflavic acid.
1 : 2 : 4 Trihydroxyanthraquinone = Purpurin.

Always include the letters and figures indicating the constitution of derivatives of closed-chain hydrocarbons in square brackets.

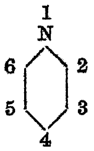
21. *In the case of thiophen*, express the position of the radicles introduced relatively to the sulphur-atom by numbers, as shown by the following symbol:



In the cases of pyrroline and pyridine, indicate the position relatively to the nitrogen-atoms as shown by the following symbols:

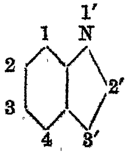


Pyrroline.

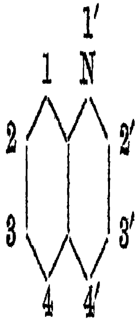


Pyridine.

In the case of indole, positions should be numbered as shown in the following symbol:—



In the case of quinoline, express the positions relatively to the carbon-atoms common to the two rings, and number the positions in the carbon ring 1, 2, 3, 4, and those in the nitrogen ring 1′, 2′, 3′, 4′ in the order shown by the annexed symbol:—



The Editor's decision, in all matters connected with the Abstracts, must be considered final.

JOURNAL

OF

THE CHEMICAL SOCIETY.

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN BRITISH AND FOREIGN JOURNALS.

General and Physical Chemistry.

Absorption-spectrum of Oxygen. By G. D. LIVEING and J. DEWAR (*Phil. Mag.* [5], 26, 286—290).—The absorption-spectrum of oxygen under pressure is examined by forcing it into a steel tube 165 cm. long, furnished with quartz windows at each end. At 85 atmos., bands were observed extending into the ultra-violet (λ 2664), beyond which the light appeared to be entirely absorbed. At 140 atmos., the bands were darker and the light ceased at λ 2704. A Rowland's grating failed to resolve the bands into lines, a result which agrees with Ångström's observation that the band a little above D in the solar spectrum is resolved into lines when the sun is high, but is continuous when the sun is near the horizon. On reducing the pressure, the band A was the last to disappear (at 20 atmos.). The bands appear to be identical with those of the solar spectrum which Ångström observed to be equally strong whether the atmosphere was moist or dry. Some of them are also identical with those observed by Olszewski with liquid oxygen. The point at which absorption of the ultra-violet begins is the same as that for ozone. Compounds of oxygen (carbonic anhydride and nitrous oxide) showed no absorption under pressure. In another experiment, a tube 18 m. long was used. At the ordinary pressure, the absorption of A was just visible. At 90 atmos., a general absorption in the red occurred extending to one-third the distance between A and B. The oxygen in this experiment was equal in quantity to that contained by a similar column extending to the limit of the atmosphere, but the absorption is much greater. Daylight, when observed through the tube, appeared to have a blue tint similar to that of liquid oxygen.

H. K. T.

Metallic Spectra. By J. TROWBRIDGE and W. C. SABINE (*Phil. Mag.* [5], 26, 342—353).—The authors have undertaken the re-examination of metallic spectra with a view to determine wave-lengths with greater accuracy. The apparatus used consisted of Rowland's grating with accessories arranged as previously described (*Phil. Mag.* [5], **16**, 197). Spectra of all orders are in focus at the same time, thus allowing a comparison of the different spectra and diminution of error. The photographic plate was also curved so that the distances between the lines were closely proportional. Solar and spark spectra were taken on different halves of the plate, the wave-lengths of the metallic lines being obtained by interpolation with the assistance of Rowland's tables of wave-lengths. In order to correct displacement due to vibration, the violet of the third spectrum was photographed along with the solar spectrum, and the wave-lengths obtained as before; the correction in some cases was as much as 20 millimetres. The noise of the spark discharge was found to be the cause of the vibration. A table of results is given. H. K. T.

Degree of Oxidation of Chromium and Manganese in Fluorescent Mixtures. By L. DE BOISBAUDRAN (*Compt. rend.*, **107**, 468—471).—Chromium oxide combines with aluminium oxide more readily the lower the temperature to which the latter has previously been heated. The colour of the product varies from rose to green as the quantity of chromium oxide added increases, the intermediate proportions yielding grey products. Presence of a trace of alkali somewhat facilitates combination, but the effect of the alkali varies with the relative proportions of the chromium and aluminium oxides and the alkali. When a precipitated mixture of chromium and aluminium oxides containing some alkali is heated, a small quantity of chromate is formed. If the quantity of chromium is very small, a large proportion of alkali prevents its union with the alumina.

Careful quantitative experiments failed to detect any loss of oxygen when the chromium and aluminium oxides are strongly heated, and hence there is no evidence that any chromous oxide is formed. The chromium in rubies is in all probability present in the state of chromic oxide. The rose-coloured compound seems to be the cause of the fluorescence, since the brilliancy of the latter increases with the intensity of the rose colour. C. H. B.

Electromotive Force of Amalgams. By S. LINDECK (*Ann. Phys. Chem.* [2], **35**, 311—331).—The author points out that experiments on the E.M.F. of amalgams containing varied proportions of mercury, immersed in an electrolyte such as sulphate of zinc or dilute sulphuric acid, have been made by Crova (*Ann. Chim. Phys.* [3], **69**, 458), Gaugain (*Compt. rend.*, **42**, 430), and Hockin and Taylor (*J. Soc. Tel. Eng.*, **8**, 282). The latter observers found that very minute traces of zinc or cadmium made a considerable difference in the E.M.F. of mercury. For example, an amalgam consisting of 1 part of zinc to 23·6 million parts of mercury in sulphate of zinc was found to be more positive than pure mercury by 0·01 volt, and an amalgam consisting of 1 part of cadmium in 5·7 million parts of mercury was found to be more positive by 0·09 volt than the pure metal.

The author has experimented with amalgams of zinc, cadmium, lead, tin, and silver, and constructed a series of curves in which the percentage of either of these metals contained in the mercury is taken as abscissa, and the corresponding change of potential difference as ordinate.

From the comparison of these curves he draws the following conclusions, which are in accordance with the results obtained by Taylor and Hockin:—

(1.) The higher the position of a metal in the electromotive series the more will the addition of a slight trace of it to pure mercury raise the position of the latter in the series.

(2.) A further addition of metal produces very little effect, and the amalgam containing a mere trace of the metal occupies approximately the same position in the series as a bar of amalgamated metal.

(3.) The amalgam of silver and mercury, in whatever proportions, occupies practically the same position in the series as that occupied by pure mercury. G. W. T.

Electromotive Force of Selenium. By S. KALISCHER (*Ann. Phys. Chem.* [2], **35**, 397—399).—The author points out that the method described in von Uljanin's paper (Abstr., 1888, 883) of preparing selenium sensitive to the production of E.M.F. by the action of light had been described by him two years ago (Abstr., 1887, 693). He states that in the paper by Fritts, quoted by von Uljanin as well as by himself, there is no question of an E.M.F. caused by the exposure of selenium to light, as he had already pointed out. Righi, in a recent paper, states that he has obtained a current from a selenium cell in the dark, and suggests that the reason that other observers have not noticed this is that they have attributed the whole E.M.F. to the action of light. Kalischer states that he had tried to obtain an effect of this kind, but without result, and he says that it does not appear from Righi's description that daylight was totally excluded in his experiments. He points out, moreover, that the method of observation of the effect of light would preclude any interference from such an effect if it existed, and that the E.M.F's. observed are therefore entirely due to light, and not the resultants of these and of effects of the kind which Righi states that he has obtained. G. W. T.

Irreciprocal Conductivity. By W. W. H. GEE and H. HOLDEN *Phil. Mag.* [5], **26**, 126—149).—Currents up to a given strength can be passed through strong sulphuric acid, but on attempting to pass a stronger current, the decomposition nearly ceases. The size of the electrodes has a considerable influence. If a current be passed from a large to a small electrode and then reversed, the current is almost completely arrested. The obstruction after reversal is at the anode, for if the cathode be exchanged for a large plate, the resistance is not removed, whilst if the anode be changed the current again passes. If the anode be increased, a greater current is required to produce insulation. Tables are given showing the current density at the anode required to give insulation under different conditions. The insulating condition is due to a resistance at the anode, and may conveniently be regarded as due to a film of badly conducting material. The film disappears very quickly if the current is broken, and instantly if it is reversed; the film is also removed by wiping. The film cannot be produced if the acid contains more than 70 per cent. of water. With increase of temperature, increase of current is required to produce insulation. Swan lamp filaments gave the same results as platinum, but other forms of carbon were disintegrated. Films could not be obtained with phosphoric or nitric acids, nor with potassium hydroxide. Solutions of soap did not give films, but a solution of sodium benzoate showed irreciprocal conductivity exactly like solid soap. The formation of the resisting film is probably due to the concentration of the acid at the anode, the oxygen under the above conditions becoming entangled in the film. An upper limit has been found at which the disturbing effect of the oxygen again comes into play. H. K. T.

Apparatus for determining the Conductivity of Electrolytes. By W. OSTWALD (*Zeit. physikal. Chem.*, **2**, 561—567).—A description of the modification of Kohlrausch's apparatus, which the author has found most useful, and also of a thermostat for work at constant temperature. H. C.

Specific Heats at High Temperatures. By W. SUTHERLAND (*Phil. Mag.* [5], **26**, 298—305).—The author has recalculated the results of Hirn's experiments (*Ann. Chim. Phys.* [4], **10**) on the specific heats of alcohol, ether, carbon bisulphide, and carbon tetrachloride at high temperatures from the experimental data, and obtains formulæ agreeing closely with those of Regnault at low temperatures. Hirn used an empirical formula connecting the times and temperatures, and then got the rate of cooling by differentiation. The values for alcohol at high temperatures obtained as above do not join on continuously with those of Regnault, hence there must be a point of inflection (at 50—80°) in the curve. This agrees with the point of inflection observed by Regnault at 70—80° in the total heat curve for alcohol.

The author has also found that the supposed inaccuracy of Regnault's specific heats of water at high temperatures (Velten, *Ann. Phys. Chem.* [2], **31**) does not exist. A single column of data (weight of hot water) has been wrongly copied out, whilst the results are correctly calculated from the data. H. K. T.

Specific Heats of Saline Solutions. By E. MATHIAS (*Compt. rend.*, **107**, 524—527).—The specific heat of any saline solution in which the number of equivalents, n, of the solvent is at least 25 for each equivalent of the substance dissolved, is accurately represented by the expression—

$$\gamma_n = \frac{a+n}{b+n}c,$$

c being the specific heat of the solvent, whilst a and b are constants. Two experiments are sufficient to determine the value of these constants. If e is the equivalent of the solvent we may take $\gamma_0 = ac/b$ and $E = eb$, and the first expression then becomes—

$$E\gamma_0 + nec = \gamma_n(E + ne),$$

that is to say, when a saline substance forms a dilute solution, Wœstyn's law is applicable to the solution, and it would seem as if the dissolved substance had acquired in the liquid state a new equivalent E, and a new specific heat γ_0, both of which are independent of the degree of dilution. C. H. B.

Heat of Combustion of Acids of the Oxalic and Lactic Series. By Louguinine (*Compt. rend.*, **107**, 597—599).—The determinations were made by means of the calorimetric bomb:—

	Per gram.	Per gram-molecule.	Difference.
Malonic acid......	2006·05 cal.	208650 cal.	147434 cal.
Succinic acid.....	3017·7 „	356089 „	155583 „
Pyrotartaric acid..	3876·3 „	511672 „	160246 × 3 cal.
Suberic acid......	5703·5 „	992409 „	151629 × 2 „
Sebacic acid......	6414·2 „	1295668 „	

The difference between oxalic and malonic acids is 148650 cal., and it would seem that oxalic, malonic, and succinic acids form one truly homologous series, and suberic and sebacic acids another, whilst pyrotartaric acid occupies an anomalous position, and probably differs from the others in constitution. The conversion of itaconic acid and its isomerides into pyrotartaric acid by hydrogenation, and the analogous conversion of fumaric and maleic acids into succinic acid, would develop about +34000 cal. in each case. The differences between the heats of combustion of homologues in the series of alcohols and hydrocarbons are not so regular as in the series of acids.

The heat of combustion of hydroxyisobutyric acid is 473689 cal., and the difference between this and the heat of combustion of lactic acid (144189 cal.) is less than the usual difference between homologues, but hydroxybutyric acid is not a true homologue of lactic acid.

The accuracy of the determinations made with the calorimetric bomb makes it possible to determine the differences between the heats of combustion of isomerides of the same chemical function, whereas with the older methods these differences were within the limits of the experimental errors. C. H. B.

Heats of Combustion of some Organic Substances. By I. Ossipoff (*Zeit. physikal. Chem.* 2, 646—649).—The experiments were performed with Berthelot's calorimetric bomb. The heats of combustion of the following substances were found to be per gram-molecule—

	At const. vol.	At const. pressure.
Stilbene, $C_{14}H_{12}$	1771·704 Cal.	1773·331 Cal.
Nononaphthene, C_9H_{18}	1380·748 „	1383·188 „
Isononaphthene	1381·719 „	1384·159 „

Comparing the heats of combustion of the nononaphthenes with that of diamylene, 1579 Cal., it is found that the differences do not follow Berthelot's rule, that two consecutive homologues should differ in their heats of combustion by about 150 Cal. But with reference to the heat of combustion of amylene itself, 804·4 Cal., one-fourth of the difference, 579 Cal., would be in pretty good agreement with the rule. Since the calculated heat of combustion, according to the equation $C_9H_{18} + 27O = 9CO_2 + 9H_2O$ is 1476 Cal. ($C = 97$, $H_2 = 67$), the heats of formation of nononaphthene and of isononaphthene would be 92·81 and 91·84 Cal.

The following heats of combustion were also determined:—Sorbic acid, $C_7H_8O_2$, 728·950 Cal.; terebic acid, $C_7H_{10}O_4$, 789·210 Cal.; cinnamic acid, $C_9H_8O_2$, 1028·452 Cal.; atropic acid, $C_9H_8O_2$, 1042·586 Cal.

H. C.

Heat of Combustion of Camphoric Acids. By W. LOUGUININE (*Compt. rend.* **107**, 624—626).

	Per gram.	Per gram-molecule.
Dextro-camphoric acid	6202·9 cal.	1240580 cal.
Dextro-camphoric anhydride	6824·14 „	1241994 „
Lævo-camphoric acid (from feverfew)	6227·7 „	1245540 „
Lævo-camphoric acid (from valerian)	6211·3 „	1242260 „
Racemo-camphoric acid	6261·3 „	2504560 „

The conversion of camphoric acid into sebacic acid by hydrogenation should develop +14,000 cal. The combination of camphoric anhydride with water is accompanied by a very slight thermal disturbance, a result which explains the ease with which the acid is converted into the anhydride.

The heats of combustion and therefore the heats of formation of the dextrogyrate and lævogyrate acid are practically identical, but the heat of combustion of racemo-camphoric acid is 18440 cal. greater than the sum of the heats of combustion of the optically active varieties.

C. H. B.

Method of determining Vapour-tensions at Low Temperatures. By J. WALKER (*Zeit. physikal. Chem.*, 602—605).—Three sets of Liebig bulbs are employed, the first two containing the solution to be examined, and the third distilled water. These are connected with a U-tube, containing pumice moistened with concentrated sulphuric acid. The apparatus is kept at constant temperature, and air drawn through the whole for some time by means of an aspirator. The relative decrease in the vapour-tension, produced by the salt in the solution, is then equal to the loss in weight of the third bulb, divided by the increase in weight of the U-tube.

An experiment takes on an average about 22 hours. The weight of water absorbed by the sulphuric acid will then be from 1 to 3 grams, if the temperature is from 18° to 25°. Details of experiments with this apparatus show that it gives very satisfactory results. H. C.

Vapour-tensions of Alcoholic Solutions. By F. M. Raoult (*Compt. rend.*, **107**, 442—445).—From the author's previous experiments, he deduced the law that 1 mol. of any non-saline solid dissolved in 100 mols. of any volatile liquid reduces the vapour-tension of the latter by a constant fraction of its value; the mean value of the fraction being 0·0105 (Abstr., 1887, 207). This law was not applied to salts in aqueous solution, because of the disturbing influence of the more or less complete dissociation of the salt. It seemed not improbable, however, that this influence would disappear with other solvents such as alcohol. New experiments have shown that in the case of lithium bromide and chloride, calcium chloride, and sodium ethoxide, the reduction of the vapour-tension is not constant if they are regarded as existing in solution in the anhydrous condition. If, however, it is assumed that these salts exist in the liquid in the form of alcoholates of the same composition as those which crystallise from the solution, namely, $LiCl + 5EtOH$, $LiBr + 5EtOH$, $CaCl_2 + 3EtOH$, and $NaEtO + 3EtOH$, then the law holds good, at least in dilute solutions, for saline as well as non-saline substances, and the value of the fraction is 0·0104. C. H. B.

Water of Crystallisation of the Alums. By H. Lescœur and D. Mathurin (*Bull. Soc. Chim.*, **50**, 33—43).—Experiments made with pure potassium alum gave the following results:—(1) The saturated solution of alum at 20° has a maximum tension of about 15·4 mm., or 0·89 with regard to the tension of water, which explains why alum does not deliquesce; (2) alum (with 24 mols. H_2O) at 20° has a tension of 4·6 mm., or 0·265 with regard to the tension of water; (3) the addition of a trace of water (0·12 mol.) increases the tension very considerably, showing that the hydrate contains 24 mols. H_2O and not more. Observations were also made at 70° and 100°; at 100° a hydrate with 6 mols. H_2O is formed.

Similar experiments made with potassium chrome-alum show that there are two hydrates, the one with 24 mols., the other with 12 mols. H_2O. The latter is readily obtained by keeping the ordinary salt over sulphuric acid until of constant weight: it is a lilac-coloured powder which does not lose its colour at 75°.

Ammonium alum has two hydrates with 24 and 6 mols. H_2O respectively (compare Maumené, *Bull. Soc. Chim.*, **46**, 261 and 807; and de Boisseau, *Bull. Soc. Chim.*, **47**, 494). N. H. M.

Electrolytic Method of Liquefying Gases. By H. N. Warren (*Chem. News*, **58**, 127—128).—Strong hydrochloric acid is introduced into a combustion tube, bent at right angles, so as to cover two small platinum plates fused into the closed end of the tube; a plug of asbestos, saturated with concentrated sulphuric acid, is placed at the bend, the open and shorter arm is then fused up and immersed in a freezing mixture. On the passage of a current through the plates, gas is evolved and liquefies at the other end; but on removing the tube from the freezing mixture and discontinuing the current, the liquefied hydrogen chloride is re-absorbed by the water. The experiment may then be repeated. Other compound gases behave in a similar manner. When acidified water is decomposed in this apparatus, and a platinum plate covered with platinum-black has been fused in the short end, explosions occur there, at intervals, and small quantities of water form, containing hydrogen peroxide, and having an ozonised odour. With chromic acid and water, the blue oxide of chromium is obtained. The method has also been applied to the liquefaction of oxygen and hydrogen, and the latter is said to have been "decidedly liquefied."

D. A. L.

Compressibility of Hydrogen, Oxygen, Nitrogen, and Air at very High Pressures. By E. H. AMAGAT (*Compt. rend.*, **107**, 522—524).—The author's results at pressures approaching 3000 atmospheres differ considerably from those obtained by Natterer, the differences being variable both in direction and magnitude. As a rule, it was found that the pressure required to produce a given contraction of volume was much greater than that stated by Natterer. The following table gives the volume at 15°, under various pressures, of a mass of gas which occupied unit volume at 15° and 760 mm.:—

Atmospheres.	Air.	Nitrogen.	Oxygen.	Hydrogen.
750	0·002200	0·002262	—	—
1000	0·001974	0·002032	0·001735	0·001688
1500	0·001709	0·001763	0·001492	0·001344
2000	0·001566	0·001613	0·001373	0·001161
2500	0·001469	0·001515	0·001294	0·001047
3000	0 001401	0·001446	0·001235	0·000964

The following table gives the mean coefficients of compressibility between different limits of pressure:—

Pressure in atmos.	Air.	Nitrogen.	Oxygen.	Hydrogen.
750—1000	0·000411	0·000407	—	—
1000—1500	0·000268	0·000265	0·000258	0·000408
1500—2000	0·000167	0·000170	0·000160	0·000272
2000—2500	0·000123	0·000122	0·000115	0·000197
2500—3000	0·000093	0·000091	0·000091	0·000158

At very high pressures, oxygen, nitrogen, and air have practically the same coefficient of compressibility, and the value of this coefficient is of the same order of magnitude as in the case of liquids. Under 3000 atmos., the coefficient approaches closely to that of ether under normal pressure.

Adopting the usual coefficient of compressibility for glass, the sp. gr. of the four gases under 3000 atmos. referred to water as unity are—

	Oxygen.	Air.	Nitrogen.	Hydrogen.
Apparent	1·0972	0·8752	0·8231	0·0880
Real............	1·1054	0·8817	0·8293	0·0887

If the pressures are measured along the axis of abscissæ and the values of *pv* along the axis of the ordinates, the curves are almost right lines with a slight concavity towards the axis of the abscissæ.

C. H. B.

Isotonic Coefficient of Glycerol. By H. DE VRIES (*Ann. Agronom.*, **14**, 376—379).—By a method similar to that used in his previous researches (Abstr., 1888, 1153) the author finds the isotonic coefficient of glycerol to be 1·78, very near those of cane- and invert-sugar, and malic, citric, and tartaric acids, which lie between 1·88 and 2·02. The lowering of the freezing point, which has been shown by Raoult to be related to the isotonic coefficient, is 17·1° in the case of glycerol, and 18·5—19·5° in that of the other substances mentioned.

J. M. H. M.

Action of a Magnet on Chemical Action. By H. A. ROWLAND and L. BELL (*Phil. Mag.* [5], **26**, 105—114).—Two iron rods are embedded in insulating material, the point of one and the side of the other being laid bare by removing the insulation. The rods are placed in a beaker between the poles of an electromagnet, and connected with a galvanometer. They are acted on by various reagents. When perpendicular to the lines of force, no current is produced. When parallel, a current is produced, the sharp-pointed rod forming the negative element; soon afterwards reversal takes place. The direction of the current is independent of that in the magnet. Similar but much weaker effects are produced with nickel and cobalt. The action is greatest with substances which, like nitric acid, attack the iron without evolution of hydrogen. The reversal can be annulled by preventing motion in the liquid by means of gelatin or sand. The electromotive force varies from 0·0001 to 0·02 volt. The evolved hydrogen probably acts mechanically in reducing the current. The protection of the pointed end from the reagents is due to the increased energy required to remove the iron in opposition to magnetic attraction. No differential action is observed with plane surfaces, but where a point occurs, protection ensues, and the elevation increases in size.

H. K. T.

Accelerating and Retarding Influences in Chemical Processes. By W. MEYERHOFFER (*Zeit. physikal. Chem.*, **2**, 585—601).—The reaction $HBrO_3 + 6HI = HBr + 3H_2O + 6I$, which was studied by Ostwald, was observed to form an exception to the ordinary rule of mass action. The author has, therefore, further investigated this reaction, and the accelerating and retarding influence which certain acids and salts are found to exercise on it. He finds that the exception alluded to is due to a retarding influence set up by the liberated iodine, which, at any moment, is directly proportional to the amount of free iodine present. When a certain point is reached, the solution becomes saturated with iodine, which then separates in the solid form, again interfering with the regularity of the reaction. Allowing for these influences, it is possible to interpret the numbers given by Ostwald for the acceleration caused by different acids. The author further studies the influence of ferric salts in accelerating the reaction. He finds that in the action of both ferric chloride and bromide on hydriodic acid, iodine is liberated in quantity rapidly attaining a maximum, and proposes to make further special experiments of this nature in order to obtain some idea of the various influences at work during the reaction. H. C.

Nitration of Benzene. By J. GIERSBACH and A. KESSLER (*Zeit. physikal. Chem.*, **2**, 676—714).—This paper contains the results of a large number of experiments carried out under L. Meyer's direction, with the object of studying the nitration of benzene as one of the non-reversible chemical changes. Nitric acid of all strengths was employed, the solution in the case of the stronger acids being diluted with nitrobenzene in order to moderate the action and admit of the change being studied as a time reaction. The results prove beyond doubt that the nitration of benzene does not follow the ordinary law of mass action. Instead of the most favourable proportions for the reaction being those of equivalent quantities of benzene and nitric acid, it is found that, in any time, the more benzene there is in solution, the less nitrobenzene will be formed, or in other words, that the benzene exercises a retarding influence on the reaction. This influence is so great that if nitric acid be mixed with equivalent quantities of benzene and nitrobenzene, only 2 per cent. of the acid will be found to act in the same time that 20 per cent. would undergo change if only a fourth or fifth part of the benzene were employed.

Since the velocity of the reaction is found to be proportional to the square of the amount of nitric acid employed, it might be assumed in explanation of the above that nitration is caused not by the action of the acid, but by that of the anhydride. Two equivalents of acid would then be required to one of benzene, since $2HNO_3 = H_2O + N_2O_5$, and the reaction would be still further retarded by the water formed during nitration.

It is found that the admixture of an equivalent of water with the acid does not so greatly retard the action as the addition of an equivalent of nitrobenzene, but a comparison of equal volumes shows that the retarding influence of water is a much greater one than that of the nitrobenzene. H. C.

The Foundations of Chemistry. By T. S. HUNT (*Amer. Chem. J.*, **10**, 333—356).—The relations of gaseous, liquid, and solid species to temperature and pressure, together with the phenomena of allotropism, specific gravity, hardness, and of chemical indifference, are briefly reconsidered: all of these properties the author maintains are intimately related to and dependent on a principle of condensation that he has enunciated on previous occasions, as in his "New Basis for Chemistry." He comes to the conclusion that something radically different from the "fantastic arrangements supposed by the present highly complicated atomic hypothesis" must be devised before we can hope to explain adequately the dynamical and chemical history of matter, and that signs are not wanting that this hypothesis so generally accepted since Dalton's time, is felt by many to be no longer adequate, and is doomed to the same fate as the corpuscular, and seemingly also the undulatory theories of light. H. B.

Method of determining Molecular Weights by Reduction of the Freezing Point. By E. BECKMANN (*Zeit. physikal. Chem.*, 2, 638—645 and 715—743).—The first part of the paper is devoted to a description of the apparatus and method of experimenting, the author laying particular stress on the necessity of an air-jacket between the cooling apparatus and the vessel containing the solution, and also on the advisability of using a thermometer divided into hundredths of a degree. The substances examined were all organic, and, where possible, solutions in the three solvents, water, acetic acid, and benzene, were taken, the effect of varying the concentration of each solution being also studied.

An examination was made of a number of carbonyl and oximido-compounds. The former gave in all three solvents numbers agreeing very well with the theoretical for the molecular weights, the results being most accurate for the more dilute solutions. The oximido-compounds gave molecular weights varying very largely with the concentration of the solutions, the concentrated solutions in some cases giving double the molecular weight of the more dilute. This appears to point to the formation of double molecules of these compounds in concentrated solutions.

Chloral anhydride, hydrate and alcoholate, and acetal were examined in all three solvents. In benzene, normal values are obtained, as also for the hydrate and acetal in water. Acetic acid appears to effect a partial dissociation of the last three compounds; water converts the anhydride into the hydrate, and splits the alcoholate into its components. Aldehyde-ammonia, which is insoluble in benzene, is completely dissociated by acetic acid, but in water it gave a molecular weight three times greater than that ordinarily assumed, which remained practically constant for all concentrations examined.

A series of alcohols, phenols, and acids examined in benzene gave numbers altogether at variance with the commonly accepted molecular weights for the more concentrated solutions, ethyl alcohol in 32·45 per cent. solution giving, for instance, 318. The more dilute the solutions, however, the nearer do the numbers approximate to the true molecular weights. It appears, moreover, that the above behaviour is due to the presence of the hydroxyl group, for on displacing this by an alcohol or acid radicle, normal values are obtained in benzene for the compounds formed. The above irregularities also disappear if acetic acid is used as the solvent instead of benzene. The values for the molecular weights are then approximately normal, suffering only a slight increase with rising concentration. The bimolecular polymeride of ethyl cyanide, $(C_3H_5N)_2$, also exhibits irregularity in benzene, but in acetic acid it gives numbers agreeing with the above formula.

A few aromatic compounds were examined in benzene and acetic acid, and gave normal values.

Discussing the results obtained with varying concentrations, from the fact that the molecular weight is almost always found to rise with the concentration, the author concludes that the molecules of the dissolved substance exercise an attraction on one another as they are brought into closer contact. It is also probable that in most cases some action occurs between the molecules of the dissolved substance and the solvent. In accordance with the proposal of Arrhenius, the author also calculates the molecular weight from the depression given by one gram of substance in 100 c.c. of the solvent, instead of 100 grams. He finds that by so doing the effect of increasing concentration is much reduced. Another source of error is that, taking Van't Hoff's expression for the reduction of the freezing point (Abstr., 1888, 780), $0·02\ T^2/W$, as the concentration rises, T decreases, and therefore also the value of the above expression, which effects an increase in the molecular weight. This is, however, in part balanced by a simultaneous decrease in W, the latent heat of fusion of the solvent.

In using the cryoscopic method of determining molecular weights, water should on account of its dissociative properties only be used as solvent in the case of non-conductors. Benzene and other indifferent solvents, such as nitrobenzene, ethylene dibromide, and naphthalene, cannot be used in the case of hydroxyl compounds or substances with acid properties. The solvent of most general application, and the one to be chiefly recommended, is acetic acid. The concentration of the solution should, if possible, be such as to give a reduction of 1° to 2°, but it is very advisable to take observations for a number of different concentrations.

H. C.

Resistance to Light of Colouring Matters fixed in Tissues. By J. Joffre (*Bull. Soc. Chim.*, **49**, 860—862).—In examining the influence of light on coloured materials, certain precautions must be taken to render the experiments trustworthy. For example, a sample of material dyed with a very unstable colour; the fibres being completely saturated with the dye, might attain a shade which would offer a certain resistance to sunlight; in such a case it would be inferred that the dye was stable. If, however, the sample is compared with a material dyed by some other colouring matter, the proportion of dye in the fibre being the same in both, and transparent shades being employed, the instability of the sample would be at once perceptible.

It is equally essential that the two exposures should be simultaneous, not only because sunlight varies in intensity, but also because the condition of the atmosphere may influence the results. Of two samples of material exposed to the same light, one of which is placed in moist, the other in dry air, the former will lose its colour far more quickly than the latter.

F. S. K.

Apparatus for Fractional Distillation in a Vacuum. By S. B. Newbury (*Amer. Chem. J.*, **10**, 362—363).—The distilling flask is fitted with a stoppered separating funnel, whose drawn-out end reaches almost to the bottom of the flask; it serves to admit a very small but constant current of air to stop bumping, and also to introduce fresh fractions into the flask. Between the condenser and the receiver is another stoppered separating tube, which enables the receiver to be changed without admitting air to the whole apparatus. H. B.

Inorganic Chemistry.

List of Elementary Substances announced from 1877 to 1887. By H. C. Bolton (*Chem. News*, **58**, 188).—The names of 58 substances, announced as being elementary, together with their sources and the names of their discoverers, are given in tabular form.

Chlorine and Cyanogen. By E. Allary (*Bull. Soc. Chim.*, **49**, 865—867).—The author cites the isomorphism of potassium chloride and potassium cyanide as fresh evidence in support of the views of Brodie, Dumas, Lockyer, and others that chlorine is composed of two elements. If the atomic weight of chlorine is divided into two parts proportional to the atomic weights of carbon and nitrogen, the two constituents of chlorine would have the atomic weights 19·1 and 16·4 respectively. From the study of certain series of organic compounds, Dumas came to the conclusion that chlorine consists of two elements, the atomic weights of which are 19 and 16·5 respectively. If this view were correct, chlorine would probably be composed of fluorine and oxygen, and the oxygen is perhaps intimately united with $\frac{H}{2}$. Meyer's observation that oxygen is produced when chlorine is strongly heated, may be adduced in support of this theory.
F. S. K.

Apparatus for a Constant Supply of Chlorine. By A. Vosmaer (*Zeit. anal. Chem.*, **27**, 638—640).—The manganese dioxide is used in fragments of the size of peas, and is placed in a two-necked bottle, at the bottom of which there is a layer of broken glass or pumice. This stands in a water-bath. Hydrochloric acid is supplied from a reservoir at a higher level by a tube reaching to the bottom of the layer of glass, a T-piece and stopcocks allowing the same tube to serve for the removal of the manganese solution. The corks should be soaked in paraffin. Suitable drying apparatus can be attached, and will not require replenishing for a long time. The chlorine begins to come off when the temperature of the bath reaches 50°, and by means of a stopcock on the outlet its rate is completely under control. The evolution can speedily be arrested by closing the stopcock at the outlet of the drying apparatus and emptying the water-bath. The apparatus is then left full of chlorine, and is ready at any moment to give a supply of the gas completely free from oxygen.
M. J. S.

Dissemination of Sulphur and Phosphorus in Masses of Metal. By H. N. Warren (*Chem. News*, **58**, 177—178).—When sulphur is well mixed with excess of molten iron, and a rod cast from the mass is made the positive electrode of an electric circuit, in a bath of ferrous chloride, with a platinum or copper negative electrode, the metallic iron is dissolved and is precipitated on the negative electrode, whilst ferrous sulphide, FeS, remains attached to the positive electrode. In the same way, iron phosphide, Fe_4P, may be separated from a mass of the metal. Other metals of the iron group behave in a similar manner. The author regards the above compounds, FeS, Fe_4P, and the compound Fe_2Si, obtained by him, as the lowest forms of the respective iron sulphides, phosphides, or silicides, although ordinary analytical results may indicate still lower forms, owing to the intimate dissemination of these compounds throughout the mass of the metal. The sulphides of the metals of the second group are not disseminated in this way through the mass of the metal (compare Abstr., 1888, 555—556). D. A. L.

Preparation of Hydrogen Iodide. By A. ÉTARD (*Bull. Soc. Chim.*, **49**, 742—743).—In preparing hydrogen iodide from iodine and amorphous phosphorus, the author places the iodine in a flask provided with a bent neck and connected with the vessel containing the phosphorus and water by means of a bent tube. By turning the flask round the bent tube, fresh quantities of iodine can be added when requisite without admitting air into the apparatus. F. S. K.

Hydrogen Sulphide Apparatus. By J. H. J. DAGGER (*Chem. News*, **58**, 127).—The apparatus figured and described consists of two glass globes connected by india-rubber tubing. The acid is put in one of the globes, the ferrous sulphide (zinc or marble) in the other; they are fitted with tubes and corks and then fixed in a suitable position. D. A. L.

Apparatus for the Preparation of Hydrogen Sulphide. By P. CHANTEMILLE (*Bull. Soc. Chim.*, **50**, 170—171).—The iron sulphide is contained in an épouvrette, and the acid in an ordinary flask fitted with a doubly-bored cork, through the one hole of which is passed a tube reaching to the bottom of the flask, and closed at its upper end by an india-rubber tube and pinch-cock; the second hole is fitted with a short tube bent at right angles and fitted to the lower end of the épouvrette. The force of gas is increased or diminished by raising or lowering the flask. The gas is purified in the usual manner.
N. H. M.

Chydrazaïne or Protoxide of Ammonia. By E. J. MAUMENÉ (*Bull. Soc. Chim.*, **49**, 850—853).—*Chydrazaïne* is evolved when a solution of potassium permanganate (158 grams) and sulphuric acid (40 grams SO_3) is added to dried, crystallised ammonium oxalate (141·2 grams), the whole well mixed and gently heated until it begins to boil. The gaseous product is absorbed in hydrochloric acid and a neutral solution of the salt can thus be obtained. The *hydrochloride* is crystalline and very readily soluble in water, but only sparingly in alcohol. The sublimed salt has the composition $N_2H_8O,2HCl$, but the crystals dried by means of the anhydrous salt contain one-fifteenth of their weight of water. When a solution of the hydrochloride is mixed with platinic chloride, a *platinochloride* is obtained, the composition of which varies with the conditions of the experiment; with excess of the hydrochloride, a yellow salt is formed, the composition of which is approximately N_2H_6O,H_2PtCl_6, but if excess of platinic chloride is added, the proportion of platinum is sensibly increased. The *sulphate* is crystalline and soluble in water, but only very sparingly so in absolute alcohol; it forms a double salt with aluminium sulphate. The *nitrate* is crystalline. When a solution of the nitrate is evaporated, nitric acid, nitric peroxide, nitrogen, and a compound having the composition N_2H_2 are evolved.

F. S. K.

Action of the Electric Spark on Mixtures of Nitric Oxide with Hydrogen, with Methane, &c. By S. COOKE (*Chem. News*, **58**, 130—131).—Under the influence of sparks (from a coil capable of giving a 4-inch spark), with the eudiometer wires half an inch apart, a mixture of hydrogen and nitric oxide always explodes, provided the proportion of hydrogen to nitric oxide does not exceed 6 : 10; but with the wires closer together, or with a feeble coil, or if the pressure is diminished to 300 mm. of mercury, no explosion occurs. The carefully dried gases explode quite as readily as when they are not dried. The nature of the gaseous mixture after explosion varies very considerably, but there is little doubt that much of the nitric oxide is converted into oxygen and nitrogen. Explosions have also been obtained with nitric oxide and hydrogen sulphide; with nitric oxide and methane with the production of carbonic anhydride and oxygen: other hydrocarbons in proper proportions and suitable spark make an explosive mixture with nitric oxide. Carbonic and nitric oxides mixed do not explode under the influence of the spark, but combination goes on gradually with the production of carbonic anhydride and nitrogen.

D. A. L.

Decomposition of Nitric Oxide in Contact with Water and with Potash. By S. COOKE (*Chem. News*, **58**, 155—156).—Nitric oxide exposed in tubes over water in the dark undergoes gradual decomposition with the production of nitrous acid, nitrogen, and a little nitrous oxide. The change is always slow, but is more active at the commencement than at the end of an experiment; it is also accelerated by the presence of platinum and by heat, whilst admixture with hydrogen retards it. The action of potassium hydroxide on nitric oxide is also aided by platinum and heat (compare this Journal, 1877, ii, 37).

D. A. L.

Action of Hydrogen Sulphide on Arsenic Acid. By L. W. MCCAY (*Zeit. anal. Chem.*, **27**, 632—634; compare Brauner and Tomiček, Trans., 1888, 145).—When a slow stream of hydrogen sulphide is passed through an acidified solution of an arsenate at 70°, besides arsenic pentasulphide there is also formed some free thioxyarsenic acid, H_3AsO_3S. This, under the influence of mineral acids and heat, decomposes into free sulphur and arsenious acid, the latter of which then yields arsenic trisulphide with the hydrogen sulphide. A solution of thioxyarsenic acid may be obtained by passing hydrogen sulphide not in excess into a cold, dilute, acidified solution of potassium arsenate. If a larger quantity of hydrogen sulphide is employed, the excess may be removed either by immediate addition of copper sulphate or by a vigorous stream of air bubbles. An opalescence caused by free sulphur may be removed by shaking with asbestos. The clear, strongly acid liquid obtained, exhibits the following properties. It remains clear for a long time after addition of sulphuric or hydrochloric acid; it gives no immediate precipitate with hydrogen sulphide, but ultimately yields one. When boiled, it gives a precipitate of pure sulphur, without evolution of hydrogen sulphide or sulphurous anhydride. With hydrogen sulphide, the boiled and cooled liquid gives an immediate precipitate of arsenic trisulphide; it gives no precipitate with copper sulphate; with mercuric chloride it gives immediately a heavy yellowish-white precipitate; with silver sulphate it gives a heavy black precipitate, the filtrate from which contains no arsenious acid. The potassium thioxyarsenate of Bouquet and Cloëz agrees with this solution in all the above particulars.

M. J. S.

Barium Sulphite. By E. R. HODGES (*Chem. News*, 58, 128); G. S. JOHNSON (*ibid.*, 155).—Hodges' experiments led him to infer that barium sulphite is insoluble in hydrochloric acid; but Johnson proves it to be readily and completely soluble in that solvent. He, moreover, shows that pure aqueous barium chloride is not precipitated by sulphurous acid, but that in the presence of dissolved oxygen a precipitate of barium sulphate forms. D. A. L.

Solubility of Gypsum. By G. A. RAUPENSTRAUCH (*Chem. Centr.*, 1888, 821—822, from *Pharm. Centralhal.*, 29, 229—233).—The author finds that a saturated solution of gypsum is readily obtained, but supersaturation of the solution can only be obviated by shaking the solution for some time. The solubility of gypsum increases up to the temperature of 32°, between 32° and 38° it remains almost constant, and at higher temperatures than 38° decreases. Natural gypsum comports itself like artificial, provided it be pure. After heating, gypsum takes up water of crystallisation more or less rapidly, and shows the normal solubility again. J. W. L.

Ancient Mortar from a Roman Wall in London. By J. SPILLER (*Chem. News*, 58, 189).—While examining some mortar from a Roman wall, exposed when sinking the foundations of the new Post Office buildings in St. Martin's-le-Grand, the author found, after extracting as much silica as possible by means of dilute hydrochloric acid, that the residue yielded nearly 11 per cent. of silica to cold dilute sodium hydroxide. Under similar treatment with cold soda, builder's sand and pulverised flints yield a mere trace of silica in solution, whilst mortars 20, 100, and many hundreds of years old yielded quantities of silica increasing with the age of the mortar. The author suggests that perhaps the Romans used a puzzuolana in compounding their mortar, or perhaps this soluble silica or silicate is the direct result of long contact of plain sand and lime. The mortar from St. Martin's-le-Grand had the following composition per cent.:—Sand and brick, 46·48; acid-soluble, SiO_2 0·52; alkali-soluble, SiO_2 10·44, Al_2O_3 3·00, Fe_2O_3 0·48, CaO 20·02, MgO 0·76, CO_2 13·03, SO_3 0·37, NaCl trace, H_2O and loss 4·90. D. A. L.

Analysis of Money. By J. C. WELCH (*Chem. News*, **58**, 164—165).—The author has analysed some specimens of "manilla money" made in Birmingham. It is yellowish-red, reddish-yellow, brass or bronze-like in colour, and in shape like a G. They proved to be variable alloys of lead and copper with small quantities of iron, tin, zinc, antimony, and arsenic. Some contained pieces of originally unmolten metal, and some had a semi-fused appearance. Another coin resembling gold in colour contained per cent.: Cu, 62·58; Zn, 37·26; Fe, 0·11; Pb, 0·013, and had been silvered to pass for a *6d.*-piece. D. A. L.

New Hydrated Cupric Chloride. By E. CHUARD (*Chem. Centr.*, 1888, 887, from *Arch. sci. Phys. Nat. Genève* [3], **19**, 477).—A hydrated cupric chloride of the formula $CuCl_2 + 3H_2O$ crystallises from the solution of the green hydrate when cooled down to 0°. The existence of this compound explains the change in the colour of the solution which takes place when it suffers dilution, for the chloride of the green hydrate contains only 2 mols. H_2O, and by diluting or by cooling below 0°, the chloride with 3 mols. H_2O is formed, and gives a blue colour to the solution. The latter chloride again loses 1 mol. H_2O when the solution is boiled. J. W. L.

Purification of Mercury. By J. M. CRAFTS (*Bull. Soc. Chim.*, **49**, 856—860).—Mercury can be completely freed from lead, zinc, tin, and other impurities by placing it in a slightly inclined glass tube provided with a funnel at the lower extremity, and aspirating a gentle stream of air through the apparatus for about 48 hours. The oxides of the metals collect at the upper end of the tube, and after about 24 hours, as a rule, the surface of the mercury is quite clean and the operation is finished. Large quantities can be treated in this way, but mercury which has been used for amalgamating zinc contains such a large amount of impurity that this method cannot be suitably employed. Silver is not removed by this process.

A stream of pure air was passed through pure mercury contained in the apparatus described above, but even after 10 days' time no appreciable quantity of oxide was formed.

Platinum, in the form of thin foil, is not attacked by cold mercury, but when the latter is boiled, air being excluded, the platinum is gradually acted on. Only a small quantity is dissolved, as a large proportion separates in the form of a black powder, and almost the whole is simply held in suspension. The surface of the mercury remains bright, but when a stream of air is passed, the platinum collects at the surface after some time as a black powder, and on distilling the separated mercury only a very small quantity of platinum remains. F. S. K.

The average of the 26 results obtained by the electrolysis of the ammonium and potassium double salts is higher than the average of all the results. This is probably due to the fact that in oxidising the tin, the platinum vessel is always attacked to a slight extent, and that in dissolving the stannic bromide, a small portion may be lost by volatilisation. If, therefore, the average of the 26 experiments is taken as the most trustworthy result, the atomic weight of tin is 118·8034 ($O = 15·96$) or 119·1 ($O = 16$).

Experiments in which it was sought to determine the atomic weight by converting pure tin into stannic sulphide, and estimating the sulphur in the latter, did not give satisfactory results (118·676 as the average of eight experiments). It was also found that when the oxide is reduced with pure hydrogen, a small quantity of tin is always volatilised. F. S. K.

Action of Incandescent Platinum Wire on Gases and Vapours. By W. R. Hodgkinson and F. K. S. Lowndes (*Chem. News*, **58**, 187).—When a spiral of platinum wire is exposed to the action of chlorine in a glass globe and rendered incandescent by an electric current, a white glow is observed round the heated wire, the sides of the globe become covered with platinous chloride, and very fine crystals of platinum are formed on the wire. With bromine or iodine vapour, the flame round the wire is greatly increased, but only a very small quantity of platinous bromide or a trace of the iodide is formed, and no crystalline metal is produced. With dry silicon fluoride, crystals of silicon are deposited, and the top of the globe is deeply corroded, presumedly by the liberated fluorine. D. A. L.

Normal Platinum Chloride. By R. Engel (*Bull. Soc. Chim.*, **50**, 100—102).—Normal platinum chloride, $PtCl_4 + 4H_2O$, can be obtained by dissolving the calculated amount of platinum oxide in a solution of platinum chloride hydrochloride; the liquid is filtered and evaporated. The crystals are deliquescent like those of the hydrochloride. When dry hydrogen chloride is passed over the crystals heated at 50°, the hydrochloride is formed; at a lower temperature no combination takes place. N. H. M.

Mineralogical Chemistry.

Hexagonal Zinc Sulphide. By W. Stahl (*Chem. Centr.*, 1888, 943, from *Berg. Hütt. Zeit.*, **47**, 207—208).—The naturally occurring mineral, wurtzite, which has also been artificially prepared, has been noticed by the author as a product of the blast furnace of the Sophia smelting work in the Lower Harz. It forms clear, wine-yellow, shining, hexagonal crystals, mostly in tufts, with the faces $\infty P2$, $P2$, $2P2$, and $0P$. Cleavage in the direction R and ∞R. Hardness = 3—4, sp. gr. = 4·32; composition:—

Zn.	Fe.	Mn.	Pb.	S.
66·08	0·55	trace	0·31	32·88 = 99·82

J. W. L.

Arsenopyrite from Servia. By A. Schmidt (*Zeit. Kryst. Min.*, **14**, 573—574).—The specimen examined formed part of the collection of the Royal Hungarian Geological Survey at Budapest. It is stated to have come from the Luta Strana adit-level, Servia. The arsenopyrite occurs, with iron pyrites and zinc blende, in small prismatic crystals, on which were observed the forms ∞P, $0P$, $\frac{1}{24}\breve{P}\infty$, $\frac{1}{6}\breve{P}\infty$, the two last being new for this mineral. The axial ratio is computed to be $a : b : c = 0·686 : 1 : 1·170$. Analysis of this arsenopyrite gave the following results :—

Fe.	As.	Sb.	S.	Zn.	Insoluble.	Total.
34·58	42·38	0·14	21·71	0·46	0·22	99·49

The percentage of zinc is evidently due to an unavoidable admixture of blende. B. H. B.

Formation of Deposits of Oxides of Manganese. By F. P. Dunnington (*Amer. J. Sci.*, **36**, 175—178).—In view of the results of a series of 15 experiments, it appears possible that many deposits of manganese ore in calciferous rocks have been formed by the action of solutions of sulphates rather than of bicarbonates. An illustration of such action is perhaps afforded by the manganese deposits of Crimora, Augusta Co., Virginia. Wherever pyrites has been deposited, the outcrop is gradually converted into limonite by weathering, and the acid solution of ferrous sulphate which sinks into the underlying deposits, must carry with it all the manganese in the pyrites itself, and in any disintegrating silicates. As this solution is exposed to the air or meets with calcium carbonate, ferrous carbonate will be formed, whilst the manganese sulphate will remain in solution until exposed to the action of both air and calcium carbonate at the same time.

B. H. B.

Artificial Production of Hydrocerusite. The Composition of this Mineral and the Constitution of White Lead. By L. Bourgeois (*Bull. Soc. Chim.*, **50**, 83—85).—Hydrocerusite, $2PbCO_3, Pb(OH)_2$, is formed if a boiling solution of lead acetate (1 mol.) is treated with litharge ($1\frac{1}{2}$ mol.), and when cold, with carbamide (1 mol.). The liquid is then filtered and heated at about 130° for some hours, when a quantity of nacreous spangles separate which are washed with water. These have a sp. gr. = 6·14 at 15°, dissolve with effervescence in nitric and acetic acids, and give off water and carbonic anhydride at 400°, leaving a residue of massicot slightly coloured by a trace of minium.

White lead consists of a mixture of hydrocerusite and cerusite.

N. H. M.

Preparation of Pyromorphite and Mimetesite. By L. Michel (*Zeit. Kryst. Min.*, **14**, 619, from *Bull. soc. franç. min.*, **10**, 133).—The author mixes three equivalents of lead phosphate or arsenate, or a mixture of the two, with one equivalent of lead chloride in a porcelain crucible. He covers the mixture with a thin layer of lead chloride, and places the crucible in one of fireclay. Both are hermetically sealed, the intermediate space being filled with ignited magnesia. The crucibles are then heated to the melting point of gold, and slowly cooled. The cavities of the fused mass contain hexagonal prisms as much as 2 cm. in length and 1 mm. in width. The best results were obtained with the mixture corresponding with kampylite (Analysis 4), the prisms being well developed and perfectly transparent. The crystalline products obtained had the following compositions:—

	$Pb_3As_2O_8$.	$Pb_3P_2O_8$.	$PbCl_2$.	Total.	Sp. gr.
1	89·75	—	9·92	99·67	7·12
2	84·73	4·97	10·03	99·73	6·93
3	79·85	10·06	8·98	98·89	6·97
4	69·78	20·02	10·07	99·87	6·93
5	46·05	44·87	9·79	100·71	—
6	29·37	59·24	10·31	98·92*	—
7	19·43	68·98	10·12	98·53	—
8	10·21	79·67	9·71	99·59	—
9	—	89·87	10·14	100·01	—

On the addition of a small quantity of lead chromate, yellow or orange crystals are obtained. In rare cases, they are of a grass-green colour.

B. H. B.

Uranite from Madagascar. By E. JANNETTAZ (*Zeit. Kryst. Min.*, **14**, 608, from *Bull. soc. franç. min.*, **10**, 47).—The mineral examined forms greenish-yellow aggregates of crystals exactly similar in appearance to those of Autun. Analysis gave the following results:—

H_2O.	P_2O_5.	UO_3.	Fe_2O_3.	CaO.	Total.
22·08	14·93	55·08	1·36	6·51	99·96

These results correspond with the formula $(UO_2,Fe,Ca)_3P_2O_8 + 12H_2O$. Of the proportion of water, 9 per cent. is evolved at 65°.

B. H. B.

Baryto-celestine from Werfen in Salzburg. By E. HATLE and H. TAUSS (*Jahrb. f. Min.*, 1888, ii, Ref., 210, from *Tschermak's min. Mitth.*, **9**, 227—231).—The baryto-celestine accompanying the wagnerite of Werfen has hitherto been regarded as barytes. It forms druses, crystals 1·5 cm. thick, and radiated or granular masses. It is of a pink colour, and translucent, with a hardness of 3·5 and a sp. gr. of 4·17. Analysis gave 84·80 per cent. of barium sulphate and 15·05 of strontium sulphate. The formula is $4BaSO_4 + SrSO_4$.

B. H. B.

Arseniopleite, a New Swedish Mineral. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1888, ii, Mem., 117—122).—Numerous rare and new minerals occur with braunite and hausmannite at the manganese mine, Sjögrufvan, in the parish of Gryhyttan, Oerebro, Sweden. In November, 1887, the author discovered there another new mineral,

* 99·51 in the original paper.

which he names *arseniopleite* from the metal arsenic, and πλεῖον (more). The mineral occurs in intimate association with rhodonite in small veins in dolomite. It also occurs in the same rock in masses 0·5 to 1 cm. in thickness. Its colour is cherry-red. No crystals have been found. It is uniaxial and positive, and judging from the cleavage appears to crystallise in rhombohedral forms. Analysis gave the following results:—

As_2O_5.	MnO.	Fe_2O_3.	PbO.	CaO.	MgO.	H_2O.	Total.
44·98	28·25	3·68	4·48	8·11	3·10	5·67	98·27

Traces of Sb_2O_5 and Cl were observed. Arseniopleite is a basic arsenate, like olivenite. It resembles most closely diadelphite and synadelphite. It, however, contains no alumina. Its relation to the other hydrated arsenates occurring in Sweden may be seen from the following list:—

Chondroarsenite....	$(MnO)_5As_2O_5 + 2\frac{1}{2}H_2O$.
Xanthoarsenite	$(MnO)_5As_2O_5 + 5H_2O$ (Abstr., 1886, 25).
Hæmafibrite	$(MnO)_6As_2O_5 + 5H_2O$.
Polyarsenite	$(MnO)_4As_2O_5 + H_2O$ (Abstr., 1887, 347).
Allactite	$(MnO)_7As_2O_5 + 4H_2O$.
Diadelphite........	$(MnO)_8As_2O_5 + Al_2O_3(Fe_2O_3) + 8H_2O$.
Synadelphite	$(MnO)_5As_2O_5 + Al_2O_3(Fe_2O_3) + 5H_2O$.
Arseniopleite	$3(MnO,CaO,PbO,MgO)_3As_2O_5 + Mn_2O_3(Fe_2O_3) + 3H_2O$.

(Compare Abstr., 1887, 902.) B. H. B.

Treatment of Natural Silicates with Hydrochloric Acid as a means of Ascertaining their Structure. By E. A. SCHNEIDER (*Amer. Chem. J.*, **10**, 405—408).—Referring to the recent paper by Clarke (Abstr., 1888, 659), the author remarks that the weathering of minerals may be used for drawing conclusions as to their constitution, and suggests the carrying out of a number of experiments, substituting hydrochloric acid for the atmospheric carbonic anhydride, and accelerating its action by heating in sealed tubes in a water-bath, the mineral being finely powdered. H. B.

Minerals of the Tyrol. By A. CATHREIN (*Jahrb. f. Min.*, 1888, ii, Ref., 220—221, from *Tschermak's min. Mitth.*, 8, 400—413).—1. *The so-called Paragonite from the Zillerthal.*—The composition of this mineral is found to be that of talc, and not that of mica. It is as follows:—

SiO_2.	MgO.	FeO.	H_2O.	Total.
62·24	30·22	2·66	4·97	100·09

This talc is the matrix of the actinolite from this locality.

2. *A New Pseudomorph of Fassaite.*—This was found at Monzoni in association with crystals of grossular remarkable for the occurrence of the rare plane $4O\frac{4}{3}$, first observed by Bauer on garnet from Oravicza. The composition of the fassaite is as follows:—

ville. Some of the crystals were 2 inches in length, and in perfection, depth of colour, and transparency, rival those from St. Gothard.

6. *Aragonite Pseudomorph.*—A crystal from Pima Co., Arizona, originally consisted of aragonite, but had been almost entirely changed and impregnated by ferric and manganese oxides. It had an outer coating of white cacholong. B. H. B.

Artificial Formation of Mica. By C. Doelter (*Jahrb. f. Min.*, 1888, ii, Mem., 178—180).—In May, 1888, the author announced to the Royal Academy of Sciences of Vienna, that he had successfully produced mica artificially. From alumina-hornblende and augite he obtained biotite, and from pennine and glaucophane he obtained phlogopite, when these minerals were fused with magnesium fluoride and sodium fluoride at a red heat. In the same manner, biotite is obtained on fusing the silicate, $K_2Al_2Si_2O_8 + Mg_2SiO_4$, with sodium and magnesium fluorides. When ferrous silicate is substituted for the magnesium silicate, ferriferous biotites are obtained. Recently the author has obtained very excellent results by fusing garnet and andalusite with fluorides. Biotite, closely resembling that from Vesuvius, is obtained by fusing pyrope or almandine with sodium and magnesium fluorides. Very beautiful crystals of muscovite are obtained by fusing andalusite with potassium fluoride, silicon fluoride, and aluminium fluoride in the proportion of 4 : 3 : 1 at a low red heat. Curiously enough, the artificial mica usually exhibits a smaller axial angle than the natural. Zinnwaldite is obtained by fusing, at a dull red heat, andalusite with 4 parts of potassium fluoride, 3 of silicon fluoride, 2 of aluminium fluoride, and 1 of lithium carbonate.

B. H. B.

Chiastolite. By M. Rohrbach (*Chem. Centr.*, 1888, 942, from *Zeit. deut. geol. ges.*, **39**, 632—638).—The author again points out that the characteristic cross-like division of the coal-black substance has no connection with a twin-formation, but most probably with a crystalline "growth" which, according to the author's view, has been brought about as follows:—The primarily-formed black, prismatic crystals have grown on the ∞P faces more than on the edges, and, consequently, appear notched; the black, slate-like particles covering the crystals are pressed back from the faces, but on the edges they become enclosed by the substance of the crystals.

J. W. L.

Cordierite-gneiss from Connecticut. By E. O. Hovey (*Amer. J. Sci.*, **36**, 57—58).—Cordierite (or iolite), which has hitherto been found in America only as an accessory constituent in rocks, has been found at Guildford, near New Haven, with biotite, quartz, and some plagioclase constituting a true gneiss. This is the first time cordierite-gneiss is reported from America. B. H. B.

Occurrence of Piemontite. By B. Koto (*Zeit. Kryst. Min.*, **14**, 599—600, from *J. Coll. Sci. Tokyo*, **1**, 303).—In a former paper, the author described the occurrence of piemontite (manganese-epidote) with glaucophane-bearing rocks of the archæan-schist series. The dark-violet rocks are developed most typically in the vicinity of the town of Tokusima, on the island of Shikoku. Here piemontite occurs in association with fine quartz grains, forming a stratified rock, in which sericite, garnet, rutile, orthoclase, and specular iron ore occur as accessory constituents. In the glaucophane-schists, piemontite also occurs as an accessory constituent. An analysis of piemontite, isolated by means of Thoulet's solution, from Otakisan in the province of Awa, gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	Mn_2O_3.	CaO.	MgO.	Na_2O.	H_2O.	Total.
36·16	22·52	9·33	6·43	22·05	0·40	0·44	3·20	100·53

Piemontite-schist is widely distributed throughout Japan. Like glaucophane-schist, it occurs in the lowest portion of the chlorite-sericite gneisses of the archæan formation. B. H. B.

Origin of Primary Quartz in Basalt. By J. P. Iddings (*Amer. J. Sci.*, **36**, 208—222).—The basalts in the vicinity of the Rio Grande Cañon, Tewan Mountains, New Mexico, contain porphyritic rounded grains of crackled quartz, surrounded by light green shells of microscopic augites. Similar remarkable occurrences of free silica in a basic magma are met with in the lithophysæ of the rhyolitic obsidian from Obsidian Cliff, Yellowstone National Park, and from Cerro de las Navajas, Mexico. This anomalous association of primary igneous materials was most probably brought about by great pressure and aqueo-igneous action, induced by the influence of water-vapour absorbed in the molten glass. In order to show that the chemical composition of quartz-bearing basalts is not characteristic of a particular modification of rock magma, the author gives the following analyses:—

	I.	II.	III.	IV.	V.	VI.

B. H. B.

Peridotite of Iron Mine Hill, Cumberland, Rhode Island. By M. E. WADSWORTH (*Jahrb. f. Min.*, 1888, ii, Ref., 224—225, from *Bull. Mus. Comp. Zool. Harvard*, 7, 183).—The mean of a number of analyses of the iron ore, peridotite, from Iron Mine Hill, Cumberland, Rhode Island, was as follows:—

SiO_2.	Al_2O_3.	Fe_2O_3 + FeO.	MnO.	CaO.	MgO.	TiO_2.
22·87	10·64	44·88	2·05	0·65	5·67	9·99

Zn.	H_2O.	Total.
0·20	(3·05)	100·00

Under the microscope, the ore is seen to consist of magnetic pyrites, olivine, plagioclase, and actinolite. B. H. B.

The Badenweiler Ore Deposit. By A. WOLLEMANN (*Zeit. Kryst. Min.*, **14**, 624—628, from *Verh. phys. med. ges. Würzburg*, **20**, 39).—The ore deposit of Badenweiler traverses a highly siliceous sandstone, and is enclosed on the one side by granite and porphyry and on the other by Keuper marl, in which rocks numerous branches of the deposit are met with. After giving a geological sketch of the vicinity of Badenweiler, the author gives the results of his petrographical and chemical investigations of the crystalline rocks of the district. The somewhat coarse-grained granite of the Forstgärtchen contains oligoclase, orthoclase, and mica, analyses of which minerals are given. As further macroscopic constituents, quartz, hornblende, and orthite are met with, whilst magnetite, apatite, zircon, rutile, anatase, and epidote occur microscopically. The minerals found in the ore deposit include barytes (analysis given), quartz, fluorspar, brown-spar, zinc-blende, zinc silicate, galena, anglesite, linarite, cerussite, pyromorphite (three analyses given), yellow lead ore, and copper pyrites. From the last-named mineral, copper glance and copper indigo are produced in indistinct pseudomorphs. Other products of decomposition are chrysocolla, malachite, and limonite. The quartz appears to be younger than the barytes and fluorspar, after which it forms pseudomorphs. The memoir concludes with a discussion of the genesis of the ore deposit by lateral secretion. B. H. B.

Mineral Springs in the Admirals-gartenbad, Berlin. By R. FRESENIUS (*J. pr. Chem.* [2], **38**, 236—240).—On 24th January, 1888, the spring delivered 12·8 litres per minute; the temperature of the water was 15·2°, the air temperature being 5°. The water was perfectly clear, but deposited oxide and phosphate of iron on exposure to air; its sp. gr. at 17·5° was 1·021016; no micro-organisms were developed in the bacteriological research. The detailed analysis is as follows, all the carbonates being calculated as normal carbonate:—

	In 1000 parts by weight.
Sodium chloride	26·715139
Potassium chloride	0·139062
Lithium chloride	0·002197
Ammonium chloride	0·018855
Calcium chloride	0·520697
Magnesium chloride	0·644199
Sodium bromide	0·020943
Sodium iodide	0·000598
Calcium sulphate	0·297493
Strontium sulphate	0·037129
Barium sulphate	trace
Magnesium carbonate	0·245551
Ferrous carbonate	0·008097
Manganous carbonate	0·000160
Aluminium phosphate	0·000107
Aluminium silicate ($Al_2O_3,3SiO_2$)	0·002173
Calcium borate	0·005807
Silica	0·013925
	28·672132
Carbonic anhydride combined with the normal carbonates, to form bicarbonates	0·131754
Free carbonic anhydride	0·014010
	28·817896

The author compares this water with other waters as to its contents of sodium, calcium, and magnesium chlorides, sodium bromide, and sodium iodide. A. G. B.

Analysis of Roncegno-water. By M. Gläser and W. Kalmann (*Ber.*, 21, 2879—2881).—The quantity of water flowing from this medicinal spring, which has its source in the Tesobo Mountain, varies during the year. The analysis of a sample taken at the time of greatest flow is given below; one litre at 18° containing—

H_3AsO_4.	$FeSO_4$.	$Fe_2(SO_4)_3$.	$Fe_2(PO_4)_2$.	$Al_2(SO_4)_3$.	$MnSO_4$.
0·1531	0·0072	3·0980	0·0285	1·5572	0·1684

$CoSO_4$.	$NiSO_4$.	$ZnSO_4$.	$CuSO_4$.	$CaSO_4$.	$MgSO_4$.
0·0353	0·0862	0·0121	0·0306	1·9072	0·3657

K_2SO_4.	Na_2SO_4.	$NaCl$.	SiO_2.	Organic matter.
0·0400	0·3009	0·0043	0·1274	0·2280

Total solids, by direct estimation, 8·1440 grams.

A comparison with the analysis previously given (Abstr., 1888, 796) shows that the quantity of arsenic acid has decreased considerably (38·1 mgrm. per litre), whilst the other constituents are present in almost the same quantities as before. F. S. K.

Analyses of the Waters of some American Alkali Lakes. By T. M. Chatard (*Amer. J. Sci.*, **36**, 146—150).—The four analyses given represent the most important alkali lakes so far known. For determining the boric acid, Gooch's method (Abstr., 1887, 299) was found to be the most accurate. Of the four lakes, the most northern is Albert Lake (I), in south-east Oregon. The sample analysed was taken in September, 1887, 1 foot below surface, and 35 feet from the shore; sp. gr. 1·03117 at 19 8°. II. Big Soda Lake, near Ragtown, Churchill Co., Nevada; sample taken in 1881 at the depth of 1 foot; sp. gr., 1·0995 at 19·8°. III. Mono Lake, California, although of a composition favourable to utilisation, is practically inaccessible on account of its great altitude. The sample was taken in 1882 at the depth of 1 foot; sp. gr. 1·045 at 15·5°. IV. Owen's Lake, Inyo Co., California, is 17 miles long and 9 miles wide, its greatest depth being 51 feet. It is estimated to contain 22 million tons of sodium carbonate. The manufacture of soda at this point has been commenced. The sample was taken in September, 1886; sp. gr. 1·062 at 25°.

The analytical results were as follows, *a* being the composition in grams per litre, and *b* that per cent. of solid constituents:—

	I*a*.	I*b*.	II*a*.	II*b*.	III*a*.	III*b*.	IV*a*.	IV*b*.

Organic Chemistry.

Isoallylene. By G. Gustavson and N. Demjanoff (*J. pr. Chem.* [2], **38**, 201—207).—Isoallylene may be prepared by the action of zinc-dust on an alcoholic solution of dibromopropylene. The latter, best obtained by the action of potassium hydroxide on tribromhydrin, is allowed to drop slowly into the warm mixture of zinc-dust and 80 per cent. alcohol, contained in a flask. The isoallylene evolved is collected over water, in which it is very little soluble. 10 grams of dibromopropylene yield 900 to 1000 c.c. of the gas.

---

* 100·00 in the original paper.

Isoallylene is a colourless gas, smelling like normal allylene; it burns with a strongly luminous flame, and gives no precipitate with ammoniacal cuprous chloride or silver nitrate. With aqueous solutions of mercuric chloride or sulphate it gives a white precipitate. The gas from 10 grams of dibromopropylene was absorbed by 35 grams of bromine, the unaltered bromine dissolved in sodium hydroxide solution, and the colourless oil washed with water. It weighed 17 grams, the calculated yield being 18 grams, and had the formula $C_3H_4Br_4$. *Isoallylene tetrabromide* smells of camphor, and has the sp. gr. 2·729 at 0° and 2·658 at 18° (water at $0° = 1$); it solidifies when cooled to $-18°$, and melts below 0°; at the ordinary pressure it distils between 215° and 230° with partial decomposition. Normal allylene tetrabromide has the sp. gr. 2·690 at 0° and 2·652 at 18°, and does not solidify in a freezing mixture. That the two are not identical is conclusively proved by the fact that by the action of zinc-dust isoallylene is liberated from the one, and normal allylene from the other.

On heating sodium with an ethereal solution of isoallylene in a sealed tube at 100°, the sodium is converted into a white powder, which evolves normal allylene when treated with water. Favorsky has shown that this conversion of iso- into normal hydro-carbons by the action of sodium, is characteristic of the homologues of acetylene.

When passed into strong sulphuric acid, isoallylene is absorbed, and on dilution with water and addition of potassium hydroxide, acetone separates; this is a strong argument in favour of isoallylene being *dimethylenemethane*, $CH_2{:}C{:}CH_2$, thus (1) $CH_2{:}C{:}CH_2 + 2H_2SO_4 = CH_3{\cdot}C(HSO_4)_2{\cdot}CH_3$; (2) $CH_3{\cdot}C(HSO_4)_2{\cdot}CH_3 + H_2O = CH_3{\cdot}CO{\cdot}CH_3 + 2H_2SO_4$. If this is the case, the dibromopropylene from which isoallylene is obtained must be $CH_2Br{\cdot}CBr{:}CH_2$, and isoallylene tetrabromide must be $CH_2Br{\cdot}CBr_2{\cdot}CH_2Br$. A. G. B.

Cyanurates. By A. CLAUS and O. PUTENSEN (*J. pr. Chem.* [2], **38**, 208—229).—The amethyst-coloured crystals, obtained when cyanuric acid is mixed with ammoniacal copper sulphate, have the composition $(C_3N_3O_3H_2)_2Cu,2NH_3$. By digesting them with dilute ammonia, violet needles of the composition $(C_3N_3O_3H_2)_2Cu,3NH_3$ are obtained, and if strong ammonia is used a deep blue compound, $(C_3N_3O_3H_2)_2Cu,4NH_3$, is formed; but this last is very unstable, rapidly losing ammonia in the air. When the first of these ammoniacal copper cyanurates is digested with water, a basic copper cyanurate, $C_3N_3O_3(Cu{\cdot}OH)_3 + 3H_2O$, is formed. An acid copper cyanurate of the composition $(C_3N_3O_3H_2)_2Cu,C_3N_3O_3H_3,NH_3 + H_2O$ is formed when copper carbonate is digested with cyanuric acid and ammonia. The salt, $C_3N_3O_3HCu + 3H_2O$, is precipitated when sodium cyanurate is added to copper sulphate; and normal copper cyanurate, $(C_3N_3O_3)_2Cu_3 + H_2O$, crystallises when acid magnesium cyanurate is mixed with copper sulphate. The following cyanurates are also described: Acid magnesium cyanurate, ammoniacal cadmium cyanurate, ammoniacal zinc cyanurate, ammoniacal nickel cyanurate, cyanurates of nickel, cobalt, and manganese; tetramethylammonium cyanurate, and further, cyanurates of quinoline, quinine, cinchonine, strychnine, narcotine, and caffeïne. A. G. B.

Preparation of α-Dibromhydrin. By O. ASCHAN (*Ber.*, **21**, 2890—2892).—α-Dibromhydrin is best prepared as follows:—Phosphorus tribromide (650 grams) is dropped in quantities of from 10 to 20 grams at a time into pure, warm glycerol (500 grams), the whole being well shaken and cooled after each addition of bromide. The operation is at an end in from three to four hours. After keeping for 24 hours, the mixture is heated on the water-bath for about three hours, cooled, diluted with water (3 to 4 vols.), extracted with ether, and the extract washed with sodium carbonate solution and dried. After evaporating the ether, the residual oil is heated at about 200°, and then fractionated; the portion boiling at 208—218°, which constitutes about two-thirds of the whole, is finally distilled under reduced pressure. 500 grams of glycerol yield 135 grams of pure α-dibromhydrin. The requisite quantities of yellow phosphorus and bromine can be employed instead of phosphorus tribromide.

When α-dibromhydrin is treated with nitric acid of sp. gr. 1·48, the principal product is a liquid boiling at 78—79° (18 mm.), which contains bromine and nitrogen. It forms very stable, yellow, readily crystallisable salts. F. S. K.

Epichlorhydrin. By C. PAAL (*Ber.*, **21**, 2971—2973).—*Chloriodohydrin methyl ether*, $C_3H_5ClI·OMe$, is obtained by heating epichlorhydrin (1 mol.) with methyl iodide (1 mol.) at 190°, fractionating the product, and removing the free iodine with finely divided silver. The yield is about 20 per cent. of the theoretical quantity. It is a colourless oil with a pungent smell, exceedingly sensitive to light, and miscible with the ordinary solvents excepting water, in which it is insoluble. It boils at about 200° with partial decomposition, and is readily volatile with steam.

Chloriodohydrin ethyl ether, $C_3H_5ClI·OEt$, is prepared by heating epichlorhydrin with ethyl iodide at 200—220°, and purifying the product as described above. The yield is 30—50 per cent. of the theoretical quantity. It boils at 200—210° with slight decomposition and resembles the preceding compound.

Chloriodohydrin isopropyl ether, $C_3H_5ClI·OPr^{\beta}$, prepared in like manner, boils at 208—212° with partial decomposition and resembles the ethyl ether. The *normal propyl ether* boils at 200—210° with slight decomposition; it is relatively stable and less sensitive to light than the other ethers which, however, it resembles in other respects.

F. S. K.

Propyl-phycite. By A. FAUCONNIER (*Compt. rend.*, **107**, 629—630). —The action of hypochlorous acid on epichlorhydrin results in the assimilation of water, most probably because of the acidity of the liquid, and the "propyl-phycite" obtained by Carius by saponifying the product of this reaction, and described by him as a lower homologue of erythrol, is in reality ordinary glycerol. C. H. B.

Molecular Weight and Valency of Perseite. By MAQUENNE (*Compt. rend.*, **107**, 583—586).—When perseite is treated with boiling hydriodic acid, it is partly converted into resinous products of indefinite composition, and partly into a volatile liquid which can be separated into two fractions boiling at 100—110° and 190—200° respectively. The first is a heptine, isomeric with œnanthylidene, which boils at 102—105° after rectification over calcium oxide and over sodium; sp. gr. at 20° = 0·78. The second fraction is a dense red oil with a slight ethereal odour. It boils at 192—196° under ordinary pressure, and at 92—95° under a pressure of 40—50 mm., but decomposes to a considerable extent even when distilled in a vacuum. It consists mainly of heptyl iodide with a small quantity of heptine hydriodide.

The *dibenzoic acetal of perseite*, $C_{21}H_{24}O_7$, is obtained by the action of benzaldehyde on perseite in presence of alcohol saturated with hydrogen chloride. It forms confused, slender, microscopic needles which soften at 215°, but have no definite melting point, and are quite insoluble in water and almost insoluble in alcohol.

These results show that the formula previously attributed to perseite (Abstr., 1888, 807) is incorrect, and that perseite is really the next higher homologue of mannitol, and has the formula $C_7H_{16}O_7$. It is the first instance of a heptahydric alcohol and of a sugar containing 7 carbon-atoms. C. H. B.

Constitution of the Glucoses. By B. RAÝMANN (*Ber.*, **21**, 2841—2842).—The author considers that the aldehyde and ketone formulæ explain the chief reactions of the glucoses, and that the reactions which Tollens mentions (*Kurzes Handb. d. Kohlenhydrate*), as incompatible with the assumption that these compounds are aldehydes do not afford sufficient grounds for changing the formulæ.

N. H. M.

Oxidation of Arabinose with Nitric Acid. By H. KILIANI (*Ber.*, **21**, 3006—3009).—Calcium arabonate is obtained in considerable quantities when arabinose (1 part) is heated at 35° for about six hours with nitric acid of sp. gr. 1·2 (2 parts), the diluted solution boiled with excess of calcium carbonate, filtered, evaporated, and mixed with alcohol. This method can be suitably employed for the preparation of arabonic acid.

Calcium trihydroxyglutarate is obtained from arabinose as follows:—Arabinose (1 part) is digested at 35° with nitric acid of sp. gr. 1·2 (2·5 parts); after the evolution of gas has ceased, the solution is evaporated until free from nitric acid, the residual syrup dissolved in water (25 parts), boiled with calcium carbonate, and the hot solution filtered. The sparingly soluble, red calcium salt which separates is spread on porous plates, and by concentrating the mother-liquor, separating the salt, and repeating the process several times, 40—45 per cent. of the weight of the arabinose employed is obtained in the form of calcium trihydroxyglutarate. It is very similar to calcium saccharate in appearance and in its behaviour when heated with water. The *potassium* salt, $C_5H_6O_7K_2$, crystallises in large, colourless, monoclinic plates or prisms, is readily soluble, and is not converted into the acid salt when the aqueous solution is evaporated with acetic acid. Lead acetate and silver nitrate produce white precipitates in an aqueous solution.

Trihydroxyglutaric acid, $C_5H_8O_7$, obtained by decomposing the calcium salt with oxalic acid, crystallises from alcohol in colourless, microscopic plates, melts at 127°, and does not reduce Fehling's solution. The normal ammonium salt crystallises in slender needles and is very readily soluble. F. S. K.

Action of Nitrous Acid on Hexamethyleneamine. By F. MAYER (*Ber.*, 21, 2883—2890).—*Trimethylenetrinitrosamine*, $C_3H_6N_6O_3$, is obtained when an ice-cold solution of hexamethyleneamine (1 part) in water (40 parts) is mixed with ice-cold, dilute ($1\frac{1}{2}$ per cent.) hydrochloric acid, and a solution of sodium nitrite ($2\frac{1}{2}$ parts) in a small quantity of water immediately added. After about 15 minutes, the yellowish, crystalline substance which separates at the surface is thrown on to a filter, washed with cold water, and dried on porous plates. The yield is 50 to 60 per cent., or more, of the amine employed. It crystallises from boiling alcohol, in which it is moderately soluble, in small, yellowish, silky needles or prisms, melts at 105—106°, and is readily soluble in cold acetone, but only moderately so in warm benzene, chloroform, and ether, and insoluble in light petroleum. It dissolves unchanged in cold glacial acetic acid, and the molecular weight determined by Raoult's method was found to be 196. On exposure to moist air, the crystals lose their silky appearance, and when treated with cold water, a slight evolution of nitrogen occurs. It melts under boiling water to a yellowish oil which gradually dissolves with evolution of nitrogen, and the solution contains formaldehyde. The same decomposition takes place, but much more quickly, when it is warmed with glacial acetic acid or dilute acids, but the decomposition into formaldehyde and nitrogen is not quite quantitative, as traces of ammonia are formed at the same time. When heated in a capillary tube, or when treated with concentrated acids, it is immediately decomposed with evolution of nitrous fumes, and when heated on platinum foil it explodes. It gives Liebermann's reaction. The filtrate obtained in the preparation of this compound contains unchanged hexamethyleneamine; if, however, the mixture is kept for a long time before separating the nitrosoamine, the latter is decomposed into formaldehyde and nitrogen, and some of the hexamethyleneamine is converted into formaldehyde and ammonia.

Dinitrosopentamethylenetetramine was obtained by gradually adding dilute hydrochloric acid to a solution of hexamethyleneamine and sodium nitrite (compare Griess and Harrow, Abstr., 1888, 1268). It melts at 202—203°, and gives Liebermann's nitroso-reaction.

F. S. K.

Identity of Putresine and Tetramethylenediamine. By L. v. UDRÁNSZKY and E. BAUMANN (*Ber.*, 21, 2938—2941).—A direct comparison of the dibenzoyl-derivatives of putresine (Brieger), tetramethylenediamine, and the compound obtained by the authors from the urine of a patient suffering from cystinuria (compare Abstr., 1888, 1296), proved that these bases are identical.

Concentrated solutions of guanidine, creatine, creatinine, and similar compounds give a precipitate with soda and benzoic chloride, whereas no separation occurs in solutions containing less than 0·5 gram of the bases; it is therefore necessary that when benzoic chloride is used as a reagent for diamines (*loc. cit.*) only very dilute solutions of the latter should be employed. F. S. K.

Decomposition of Acetone with Bleaching Powder. By W. R. ORNDORFF and H. JESSEL (*Amer. Chem. J.*, **10**, 363—367).—Liebig stated that acetone could advantageously be substituted for alcohol in the preparation of chloroform; this statement has been contradicted by Siemerling, yet chloroform is now largely made from acetone. In a number of trials, the yield was 166 to 173 per cent. of the weight of the acetone used, and the residual liquors contained considerable quantities of calcium acetate. The reaction is represented by $2CO(CH_3)_2 + 6CaOCl_2 = 2CHCl_3 + 2Ca(OH)_2 + 3CaCl_2 + Ca(CH_3{\cdot}COO)_2$. Liebig states that calcium carbonate is precipitated during the reaction, but the precipitate is calcium hydroxide. Acetophenone similarly treated with bleaching powder, yields chloroform, calcium hydrate, and calcium benzoate. H. B.

Dinitrosoacetone. By H. v. PECHMANN and K. WEHSARG (*Ber.*, **21**, 2989—2993).—When dinitrosoacetone (compare Abstr., 1887, 28) is boiled with water or acids, it is decomposed into carbonic anhydride, hydrogen cyanide, water, and ammonium hydrogen oxalate; but when it is heated with glacial acetic acid, oxamic acid, melting at 210°, and hydrogen cyanide are formed.

Trinitrosopropane, $NOH{:}CH{\cdot}C(NOH){\cdot}CH{:}NOH$, prepared by heating a mixture of dinitrosoacetone (1 mol.), hydroxylamine hydrochloride (1 mol.), sodium acetate (1 mol.), and water at 50—60° for 1 to 2 hours, separates from hot water in the form of a colourless, crystalline powder melting at 171° with sudden decomposition. It is only sparingly soluble in ether, but readily soluble in alcohol, from which it crystallises in needles, and it dissolves slowly, but in considerable quantities, in hot water. It behaves like dinitrosoacetone when heated with dilute acids, but its aqueous solution can be boiled for a short time without decomposition taking place. Ferric chloride gives a brownish-red coloration with a dilute aqueous solution; ferrous sulphate produces a wine-red colour, and the solution then gives a violet precipitate with soda.

Dinitrosoacetonehydrazone, $NOH{:}CH{\cdot}C(N_2HPh){\cdot}CH{:}NOH$, prepared by treating dinitrosoacetone (1 mol.) with phenylhydrazine (1 mol.) in hot, alcoholic solution, crystallises in yellow needles, melts at 145° with decomposition, and is readily soluble in alcohol and ether, more sparingly in benzene and light petroleum, and insoluble in water. It dissolves in alkalis with a yellow, and in concentrated sulphuric acid with an orange-yellow coloration. The *acetyl*-derivative, $C_9H_9N_4O_2Ac$, a light yellow, crystalline compound, melts at 133°, and is soluble in dilute alcohol. It dissolves in alkalis with a yellowish coloration, but the solution becomes colourless on boiling, and on adding acids, a compound, $C_9H_8N_4O$, is precipitated in shining, colourless needles. This substance is also formed when the acetyl-derivative is boiled with water. A compound, $C_{15}H_{12}N_4$, is obtained when dinitrosoacetone is heated with excess of phenylhydrazine acetate. It crystallises from hot alcohol or benzene in shining, yellow plates melting at 122°. It is not acted on when boiled with ferric chloride, and its solution in concentrated sulphuric acid does not give a coloration with this reagent. F. S. K.

Sulphoisovaleric Acid. By G. de Varda (*Chem. Centr.*, 1888, 887—888, from *Rend. Acad. dei Lincei* [4], **4**, 1).—100 parts of isovaleric acid are mixed with 100 parts of chlorosulphonic acid, and, after the spontaneous reaction has ended, the mass is heated to 150°; it is then diluted with several volumes of water, and distilled from the oil-bath until the distillate no longer has an acid reaction. The distillate is then heated with plumbic carbonate for some time, filtered while hot, and the lead precipitated from the solution by hydrogen sulphide, the solution of the free acid being concentrated in a vacuum.

Sulphoisovaleric acid so obtained forms deliquescent crystals. The aqueous solution partly decomposes when heated on the water-bath. The lead salt, $C_5H_8SO_5Pb.2H_2O$, crystallises from water in colourless, odourless, small plates, which taste sweet; they are slightly soluble in water, and insoluble in alcohol, ether, and chloroform. The barium salt, containing 1 mol. H_2O, forms small, tabular crystals, without smell or colour, and taste bitter. It is soluble in water, insoluble in alcohol, ether, and chloroform. J. W. L.

Constituents of Cocoa Fat. By P. Graf (*Arch. Pharm.* [3], **26**, 830—846; comp. Kingzett, Trans., 1878, 38).—The melting point of various samples of commercial cocoa butter from widely different sources was determined both in open and closed glass tubes. In the open tube, the results varied from 29° to 33·4°, whilst in the closed tube 11 samples gave 34·3° and one 33·5°. The whole of the samples were mixed together for the further investigation. The fat was found to contain hardly any free acid. Two determinations of glycerol averaged 9·59 per cent. A little cholesterin and small quantities of formic, acetic, and butyric acids were detected. After the separation of oleic acid, the solid fatty acids were isolated by fractional crystallisation, followed by Heintz's method of fractional precipitation by means of magnesium and barium acetates. No acid with a higher molecular weight than arachidic acid was found; this confirms Traub's statement that he was unable to find theobromic acid asserted to be present by Kingzett. The presence of oleic, stearic, and palmitic acids was confirmed; and either lauric acid or one of its isomerides was isolated: there was not sufficient material at hand to settle this point. J. T.

Action of Hydrogen Phosphide on Aldehydes and Ketone Acids. By J. Messinger and C. Engels (*Ber.*, **21**, 2919—2928).—The compound obtained by passing hydrogen phosphide and hydrogen chloride into an ethereal solution of pyruvic acid has the constitution $P(CMe<{}^{O}_{CO}>)_3$, and is named by the authors *phosphorus-trianhydropyruvic acid* (compare Abstr., 1888, 441). It is insoluble in cold acids, and on heating, decomposition takes place. It dissolves in warm, glacial acetic acid, and separates unchanged on cooling. It is not acted on by bromine even at 150°, but when boiled with water it is decomposed into pyruvic acid and hydrogen phosphide.

Phosphorus-trihydropyruvic acid hydrazide,

$$P[CMe(OH)\cdot C(OH):N_2HPh]_3,$$

is formed when the preceding compound is warmed with phenylhydrazine in alcoholic solution; it is a colourless, crystalline compound, melts at 132°, and is moderately soluble in alcoholic ether, but only sparingly in cold alcohol, and almost insoluble in ether.

Hydrazonepyruvic acid hydrazide, $C_{15}H_{16}N_4O$, is formed, together with hydrogen phosphide, when phosphorustrianhydropyruvic acid is heated with excess of phenylhydrazine, in which it is readily soluble. It crystallises from hot alcohol in colourless, shining plates, melts at 162°, and is only sparingly soluble in cold alcohol and ether.

Phosphorus-trihydropyruvic acid dianilide,

$$CONHPh\cdot CMe(OH)\cdot P<{}^{CMe(OH)\cdot CO}_{CMe(OH)\cdot CO}>NPh,$$

is obtained when aniline is gradually added to an alcoholic solution of phosphorus-trianhydropyruvic acid. It separates from warm alcohol in colourless crystals, melts at 158°, is very sparingly soluble in cold alcohol and insoluble in water or ether. It is completely decomposed, with separation of phosphorus, when treated with hydrogen chloride in alcoholic or ethereal solution.

Dihydrazonepyruvic acid hydrazide, $NPh(CO\cdot CMe:N_2HPh)_2$, is formed when the preceding compound is treated with phenylhydrazide. It crystallises from alcohol in small needles melting at 169°.

Phosphorus-trianhydropyruvic acid and toluylenediamine yield a crystalline compound, $C_9H_9O_6P + 2C_6H_3Me(NH_2)_2$, which melts at 178° with decomposition.

Hydrogen phosphide, in presence of hydrogen chloride, has no action on ethyl acetoacetate or benzoylcarboxylic acid, but tribromopyruvic acid absorbs the gas in considerable quantities with evolution of hydrogen bromide and the ultimate formation of phosphorus-trianhydropyruvic acid. F. S. K.

Action of Heat on Tartaric Acid in Aqueous Solution. By E. M. WEDARD (*Chem. Centr.*, 1888, 889, from *Atti. R. Acad. Sci. Torino*, **6**, 65—67).—The author noticed that when tartaric acid had been heated for several days in sealed tubes with ferrous sulphate, several of the tubes exploded violently, and in the others a considerable quantity of carbonic anhydride was found. As the ferrous salt had not become oxidised at all, the reaction had not been a simple reduction of the tartaric acid. Tartaric acid heated with water alone at 150° in sealed tubes also suffered a considerable loss of carbonic anhydride. In one experiment, the author opened the tube after heating, allowed the carbonic anhydride to escape, then sealed it again, and submitted the contents to a further heating, and repeated the operation until no further evolution of carbonic anhydride took place, after which the resulting liquid was found to contain pyrotartaric acid along with undecomposed tartaric acid. J. W. L.

Freezing Points of Solutions of Aluminium Alkyls. By E. Louise and L. Roux (*Compt. rend.*, **107**, 600—603).—Pure ethylene bromide was used as a solvent, the molecular reduction, T, with this liquid being 118. The number obtained with mercury propyl was 124·8; mercury isobutyl, 122·7; mercury isoamyl, 123·6; mercury phenyl, 120·4.

Aluminium ethyl gave a molecular reduction of 115·6, which agrees with the formula Al_2Et_6.

Aluminium propyl, obtained by the action of aluminium on mercury propyl, is a colourless, mobile liquid, which boils at 250° and takes fire in contact with the air. *Aluminium isoamyl*, obtained in a similar way, is a somewhat viscous, colourless liquid, with an odour of amyl compounds; it boils at 250° under a pressure of 80—100 mm., and does not readily take fire in contact with the air. The molecular reduction with aluminium propyl is 92·8, and with aluminium isoamyl 84·5. These values agree more closely with the formula Al_2R_6 than with AlR_3, and hence confirm the conclusions deduced from vapour-density determinations (Abstracts, 1888, 583).

C. H. B.

Substituted Pyromucic Acids. By H. B. Hill and A. W. Palmer (*Amer. Chem. J.*, **10**, 373—391).—With the exception of a sulphopyromucic acid briefly described by Schwanert, no furfuran-derivatives containing the sulphonic group are described; yet the general behaviour of pyromucic acid is similar to that of benzoic acid.

δ-Sulphopyromucic acid is readily formed by treating pyromucic acid with fuming sulphuric acid. The acid itself is extremely soluble in water, but may be obtained in large, deliquescent crystals. The following salts are described: $BaC_5H_2SO_6 + 4H_2O$; $Ba(C_5H_3SO_6)_2 + 4H_2O$, and also with $6H_2O$; $CaC_5H_2SO_6 + 3H_2O$; $PbC_5H_2SO_6 + 2H_2O$, all readily soluble in hot water; $Ag_2C_5H_2SO_6$ is sparingly soluble in water; $K_2C_5H_2SO_6 + 4H_2O$; $KC_5H_3SO_6$; $Na_2C_5H_2SO_6 + 5H_2O$, and $NaC_5H_3SO_6 + H_2O$, all very soluble. All these salts crystallise readily. By treating the dry sodium salt with phosphorus pentachloride, and the resulting viscous oil with ammonia, the crystalline *δ-sulphopyromucamide*, $C_5H_2SO_4(NH_2)_2$, is obtained; it is readily soluble in hot water, and melts at 213°. The dry acid is only decomposed by bromine at 100°, dibromosuccinic acid and other products being formed; in aqueous solution the acid is mainly converted into fumaric acid. Dilute nitric acid oxidises it slowly, and also produces fumaric acid and some oxalic acid; concentrated nitric acid at 100° readily converts it into Klinkhardt's δ-nitropyromucic acid, and at the same time a neutral substance, in all probability αα-dinitrofurfuran, is formed.

Although bromine-derivatives of δ-sulphopyromucic acid cannot be obtained by the action of bromine, they may be obtained by sulphonating the corresponding bromopyromucic acids: *β-Bromo-δ-sulphopyromucic acid* is extremely soluble in cold water, and forms deliquescent crystals. The salts—

$$BaC_5HBrSO_6 + 4H_2O;\ CaC_5HBrSO_6 + 6H_2O;\ PbC_5HBrSO_6 + 4H_2O;$$
$$K_2C_5HBrSO_6 + 1\tfrac{1}{2}H_2O\ (?)$$

are described; they are all crystalline and soluble in water. That the acid is really a derivative of δ-sulphopyromucic acid is proved by obtaining this acid by treatment of the bromo-acid with zinc and ammonia. Bromine in aqueous solution readily converts the bromo-acid into monobromofumaric acid. Concentrated nitric acid readily yields *β-bromo-δ-nitropyromucic acid*, soluble in water, alcohol, &c., and melting at 159—160°.

β-γ-Dibromo-δ-sulphopyromucic acid is prepared by dissolving β-γ-dibromopyromucic acid in fuming sulphuric acid, but it is more advantageous to use the mixture of β-γ- and β-δ-dibromopyromucic acids resulting from the decomposition of the tetrabromo-acid, as the β-δ-dibromo-acid is but little acted on by the sulphuric acid. The acid in question is very soluble in water, and is crystalline; the following salts are described: $BaC_5Br_2SO_6 + 5H_2O$ and also with $3H_2O$; $PbC_5Br_2SO_6 + 4H_2O$; $Ag_2C_5Br_2SO_6 + H_2O$; $K_2C_5Br_2SO_6 + H_2O$. That the sulphonic acid occupies the δ-position, the only possible one, is proved by treatment of the above barium salt with zinc-dust and ammonia, when the δ-sulphopyromucic acid first described is obtained. Bromine in aqueous solution readily oxidises the barium salt, giving barium sulphate and dibromomaleic acid. Dilute nitric acid oxidises it to dibromosuccinic acid. Concentrated nitric acid yields a mixture of β-γ-dibromo-δ-nitropyromucic acid, crystallising from water in sparingly soluble, slender, yellow needles, that melt at 204—205°, and ββ-dibromo-αα-dinitrofurfuran, a substance melting at 150—151° and crystallising from benzene, as the compound $C_4Br_2(NO_2)_2O,C_6H_6$, which readily gives off this benzene of crystallisation. H. B.

Metadiethylbenzene. By A. Voswinkel (*Ber.*, **21**, 2829—2831). *Metadiethylbenzene*, $C_6H_4Et_2$, is obtained, together with the para-compound, by the action of ethyl bromide and aluminium chloride on benzene; the two compounds are separated from each other by means of the barium sulphonates. It boils at 181—182°, and does not solidify at −20°, but becomes thicker. Sp. gr. = 0·8602 at 20° compared with water at 4°. When boiled with dilute nitric acid, ethylbenzoic and isophthalic acids are formed. The *barium sulphonate* (with 3 mols. H_2O) crystallises in hemispherical groups of prisms, rather sparingly soluble in cold water. The *copper salt* (with 4 mols. H_2O) forms bright-blue plates of a satiny lustre; the *potassium salt* (with 1 mol. H_2O) crystallises in quadratic plates. The *sulphonamide* separates from the dilute alcoholic solution in long, flat needles, melting at 101—102°. The *bromine-derivative*, $C_6H_3Et_2Br$, boils at about 238°. The *tetrabromo-compound*, $C_6Et_2Br_4$, crystallises from alcohol in small, colourless prisms melting at 74°. *Nitrometadiethylbenzene*, $C_6H_3Et_2{\cdot}NO_2$, is a pale yellow liquid, which boils at

280—285°, with decomposition. The *trinitro-compound*, $C_6HEt_2(NO_2)_3$, crystallises from light petroleum in prisms melting at 62°. *Amidometadiethylbenzene*, $C_6H_3Et_2·NH_2$, prepared by reducing the nitro-derivative, is a colourless liquid which distils readily with steam; the *hydrochloride* crystallises in groups of very long needles; the *acetyl-derivative* forms stellate groups of needles melting at 104°. *Metadiethylphenol*, $C_6H_3Et_2·OH$, is obtained by fusing the sulphonic acid with potash; it boils at 225°, and dissolves sparingly in water; the solution gives a blue-violet colour (which changes to green on adding alcohol) with ferric chloride. *Meta-ethylbenzoic acid*, $C_6H_4Et·COOH$, crystallises in long needles, melts at 47°, and is almost insoluble in water. The *calcium salt* (with 4 mols. H_2O) forms lustrous needles, readily soluble in water and alcohol. N. H. M.

Synthesis of Consecutive Tetramethylbenzene. By O. JACOBSEN (*Ber.*, **21**, 2821—2828).—*Dinitrobromopseudocumene*,

$$[(NO_2)_2 : Br : Me_3 = 5 : 6 : 2 : 1 : 3 : 4],$$

obtained by the action of nitric and sulphuric acids on bromopseudocumene [$Br : Me_3 = 2 : 1 : 3 : 4$], crystallises from hot alcohol in small, yellowish-white, lustrous prisms, melts at 182°, and dissolves readily in hot benzene, sparingly in hot alcohol.

Bromopseudocumene, [$Br : Me_3 = 2 : 1 : 3 : 4$], has the same boiling point as the 5, 1, 3, 4 compound: 237—238° (not 226—229°). The sulphonamide melts at 185° (not 187—188°; compare Kelbe and Pathe, *Ber.*, **19**, 1546).

1, 2, 3, 4-Tetramethylbenzene is prepared by heating pure bromopseudocumene (25 grams), methyl iodide (40 grams), and sodium (14 grams), in presence of sufficient absolute ether to cover the latter. After two or three days, it is distilled. The yield of tetramethylbenzene is 38 per cent. of the weight of the bromopseudocumene.

Dibromometaxylene, [$Me_2 : Br_2 = 1 : 3 : 2 : 4$], is obtained in the preparation of symmetrical dibromometaxylene by brominating the hydrocarbon; it is an oily liquid which, when cooled, solidifies to a hard crystalline mass melting at −8°, and boils at 269° under 760 mm. pressure. The *dinitro-derivative* forms almost colourless, microscopic crystals, melts at 191°, and dissolves readily in toluene, very sparingly in alcohol. When exposed to light it becomes yellow. The *sodium sulphonate*, $C_6HMe_2Br_2·SO_3Na + H_2O$ [$= 1 : 3 : 2 : 4 : 6$], crystallises in groups of needles; the *potassium salt* with 1 mol. H_2O forms lustrous plates, sparingly soluble in cold water; the *barium salt* crystallises in small prisms. The *amide* separates from alcohol in small prisms, which melt with decomposition above 300°. When the sodium salt is treated with zinc-dust and ammonia, the salt of ordinary unsymmetrical metaxylenesulphonic acid is formed.

Orthodiamidometaxylene, [$Me_2 : (NH_2)_2 = 1 : 3 : 5 : 6$], is obtained by very prolonged action of tin and hydrochloric acid on the dinitrodibromo-compound, and is liberated from its hydrochloride by dry distillation with sodium carbonate in a stream of hydrogen. It crystallises from water in rhombic plates, melts at 78·5°, and dissolves readily in alcohol, ether, and hot water. When exposed to moist air, it becomes grey-violet. The constitution of this compound as given is proved by the synthesis of 1, 2, 3, 4-tetramethylbenzene from the liquid dibromometaxylene by the action of methyl iodide and sodium, using ether as a diluent.

When symmetrical dibromometaxylene is heated with sulphuric acid (3 parts) at 240°, it is converted into the liquid isomeride.

N. H. M.

Tetrethylbenzene. By O. JACOBSEN (*Ber.*, **21**, 2819—2821).—*Symmetrical tetrethylbenzene*, $C_6H_2Et_4$ [$Et_4 = 1 : 2 : 4 : 5$], is obtained, together with a smaller amount of the isomeride [$Et_4 = 1 : 2 : 3 : 4$], by the action of ethyl bromide on benzene in presence of aluminium chloride, at a temperature not above the boiling point of the bromide; the product is sulphonated in the cold and the sodium sulphonate heated at 170° with hydrochloric acid. It melts at 13°, and boils at 250°. When boiled with dilute nitric acid, and the product further oxidised with permanganate, pyromellitic acid is formed.

Dibromotetrethylbenzene, $C_6Br_2Et_4$ [$Et_4 = 1 : 2 : 4 : 5$], crystallises from hot alcohol in long, thin prisms melting at 112·5°.

Sodium tetrethylbenzenesulphonate, $C_6H\ Et_4\cdot SO_3Na + 4H_2O$, crystallises from water in very large, lustrous plates, sparingly soluble in cold water, much more readily in alcohol, almost insoluble in cold dilute aqueous soda. The *barium salt* (with 9 mols. H_2O) is sparingly soluble in hot water. The *sulphonamide*, $C_{14}H_{21}\cdot SO_2\cdot NH_2$, crystallises from hot dilute alcohol in rhombic plates, melting at 122°.

N. H. M.

Pentethylbenzene and its Decomposition by Sulphuric Acid. By O. JACOBSEN (*Ber.*, **21**, 2814—2819; compare Abstr., 1887, 660; 1888, 137).—*Pentethylbenzene*, C_6HEt_5, is prepared by the action of ethyl bromide on benzene in presence of aluminium chloride, and purified in a manner similar to the pentamethyl-compound (*loc. cit.*). It forms a thick oil, which boils at 277°, and does not solidify at −20°. Sp. gr. = 0·8985 at 19°.

Bromopentethylbenzene, C_6BrEt_5, obtained by brominating the hydrocarbon dissolved in glacial acetic acid, crystallises from alcohol in long needles, melts at 47·5°, and boils at about 315°. It is readily soluble in hot alcohol.

The *sulphone*, $SO_2(C_6Et_5)_2$, crystallises from light petroleum containing some alcohol in large, transparent, hexagonal prisms of a glassy lustre, melts at 76°, and is very readily soluble in alcohol, much less in light petroleum, and insoluble in water.

Sodium pentethylbenzenesulphonate, $C_{16}H_{25}\cdot SO_3Na + 4H_2O$, crystallises from water in thin, lustrous plates, moderately soluble in hot water, much more soluble in alcohol. The anhydrous salt crystallises from 90 per cent. alcohol in groups of hair-like needles. The *potassium salt* (with 2 mols. H_2O) crystallises in thin plates, rather readily soluble in hot water, much more soluble in alcohol. The *ammonium* (with 1 mol. H_2O) and *barium* (with 9 mols. H_2O) *salts* crystallise respectively in large, thin plates and small scales. When pentethylbenzene is treated with an equal volume of sulphuric acid so much fuming sulphuric acid added to the cooled mixture that a clear, brownish-yellow solution is obtained, and the whole kept for 4—5 days at the ordinary temperature, hexethylbenzene and tetrethylbenzene [Et_4 = 1 : 2 : 3 : 4] are formed.

Hexethylbenzene melts at 129° and boils at 298°.

Tetrethylbenzene [Et_4 = 1 : 2 : 3 : 4] boils at 254°, and does not solidify at −20°. It is probably identical with Galle's compound (Abstr., 1883, 1091). The *dibromo-derivative*, $C_6Br_2Et_4$, crystallises in prisms of a glassy lustre, melts at 77°, and is sparingly soluble in boiling alcohol.

Barium tetrethylbenzenesulphonate, $(C_{14}H_{21}\cdot SO_3)_2Ba + 6H_2O$, crystallises from water in flat prisms of a glassy lustre; the *sodium salt* (with 5 mols. H_2O) forms readily soluble. rhombic plates. The *amide* separates from its solution in water and alcohol in well-formed crystals of a glassy lustre, and melts at 107°. N. H. M.

Synthesis of Aromatic Selenium Compounds. By C. CHABRIÉ (*Bull. Soc. Chim.*, **50**, 133—137).—*Phenyl selenide*, $SePh_2$, is obtained by adding aluminium chloride to selenium tetrachloride (1 part) and benzene (3 parts), contained in a reflux apparatus, until no more hydrogen chloride is evolved. The temperature in the flask varies from 22° to 27°, and the operation is finished in about 60 hours. It boils at 227° under a few cm. pressure. Phenyl chloride and an oil boiling at 250° under a pressure of a few cm. are also formed.

Selenium oxychloride in presence of aluminium chloride and selenious anhydride, also react with benzene. N. H. M.

Consecutive Metaxylenol. By O. JACOBSEN (*Ber.*, **21**, 2828—2829).—The author previously (Abstr., 1878, 412) ascribed to consecutive metaxylenol the melting point 74·5°. Nölting isolated the compound from commercial xylidine, and found the melting point 49°. This melting point is now confirmed by preparing metaxylenol by heating pure parahydroxymesitylic acid; the product melted at 47—48°. The xylenol previously obtained (*loc. cit.*) was paraxylenol. N. H. M.

Nitronitrosoresorcinol. By C. DE LA HARPE and F. REVERDIN (*Bull. Soc. Chim.*, **49**, 760—763).—*Nitronitrosoresorcinol*,

$$[OH : NO_2 : O : NOH = 1 : 2 : 3 : 4],$$

is obtained when a cooled mixture of nitroresorcinol (1 mol.), melting at 85°, with a solution of soda (1 mol.) in 10 parts of water and an aqueous solution of sodium nitrite (1 or 2 mols.) is gradually added to excess of dilute and well-cooled sulphuric acid. The yellow, flocculent precipitate is washed with water, dried over sulphuric acid, and extracted with ether to remove traces of nitrosoresorcinol. It crystallises from alcohol in brownish needles, and is readily soluble in water, acids, and alkalis, but only moderately soluble in alcohol, and insoluble in ether, benzene, and chloroform. It is not changed when heated to about 200°, but at higher temperatures it deflagrates violently. It yields diamidoresorcinol (compare Fitz, *Ber.*, **8**, 631) when reduced with tin and hydrochloric acid. The aqueous solution gives an intense green coloration with ferrous sulphate or with iron filings, and a slightly acid solution of the colouring matter, which can-be precipitated from the aqueous solution by adding sodium chloride, dyes wool green (compare Fèvre, Abstr., 1883, 733). Concentrated sulphuric acid added to a mixture of resorcinol and nitronitrosoresorcinol, produces a green colour, which changes to blue and then to a dirty violet; from this solution water precipitates brown flocks, which dissolve in alkalis with a greenish-brown coloration.

Nitroresorcinol, $[(OH)_2 : NO_2 = 1 : 3 : 4]$, melting at 115°, does not form a nitroso-derivative when treated as described above.

F. S. K.

Condensation-product of Quinone and Ethyl Acetoacetate. By H. v. PECHMANN (*Ber.*, 21, 3005—3006).—A condensation-product, $C_{16}H_{16}O_6$, is formed when quinone (1 gram) is heated at 100° with ethyl acetoacetate (2·5 grams) and a 50 per cent. solution of zinc chloride (6 grams) in absolute alcohol. It melts at 184°, and is soluble in boiling alcohol or glacial acetic acid, but insoluble in water. The solution in concentrated sulphuric acid turns deep blue when heated. It yields crystalline derivatives when treated with bromine, but it is not acted on by phenylhydrazine, benzoic chloride, sodium ethoxide and alkyl iodides, or by boiling hydriodic acid. A crystalline bibasic acid, $C_{14}H_{12}O_6$, is precipitated when the preceding compound is hydrolysed with alcoholic potash and the solution acidified with acetic acid. It sublimes without melting, and is insoluble in all ordinary solvents. The *potassium* salt, $C_{14}H_{10}K_2O_6 + 2H_2O$, is a colourless, crystalline, sparingly soluble compound, and loses its water at 125°.

F. S. K.

Derivatives of Paramidoisobutylbenzene. By C. GELZER (*Ber.*, 21, 2941—2949, and 2949—2961).—*Paracetamidobromisobutylbenzene*, $C_4H_9·C_6H_3Br·NHAc$, prepared by brominating acetamidoisobutylbenzene, crystallises from hot dilute alcohol or benzene in large, shining scales or plates, and melts at 153°. It is readily soluble in alcohol, hot benzene, ether, carbon bisulphide, and chloroform, but only very sparingly soluble in boiling water.

Amidobromisobutylbenzene, $C_4H_9·C_6H_3Br·NH_2$, is a heavy, yellowish, aromatic-smelling oil, boiling at 264—265° (710 mm.) with decomposition, and volatile with steam; it is readily soluble in alcohol, ether, and benzene, but insoluble in water. The *hydrochloride*, $C_{10}H_{14}NBr,HCl$, crystallises from benzene in moss-like needles, and is readily soluble in water, alcohol, and warm benzene, but almost insoluble in ether. The *platinochloride*, $(C_{10}H_{14}NBr)_2,H_2PtCl_6$, obtained by precipitating a cold alcoholic solution of the base with a hydrochloric acid solution of platinic chloride, crystallises in slender, yellow needles, and is readily soluble in alcohol, but only sparingly in cold water, and insoluble in ether; it is decomposed when boiled with water. A light yellow, crystalline substance, $(C_{10}H_{14}NBr)_2PtCl_8$, is obtained when a cold alcoholic solution of the base is precipitated with a neutral solution of platinic chloride; it is sparingly soluble in cold alcohol, and is decomposed when the solution is heated. The *picrate*, $C_{10}H_{14}NBr,C_6H_3N_3O_7$, separates from a mixture of warm benzene and light petroleum in slender, yellow, spear-shaped crystals, and is readily soluble in cold alcohol, ether, or hot water, but only sparingly in cold water or cold benzene, and moderately soluble in hot benzene.

Bromisobutylbenzene, $C_4H_9{\cdot}C_6H_4Br$, obtained by treating the amido-derivative with nitrous acid and distilling the product, is a heavy, slightly yellow, aromatic-smelling oil, boiling at 231—232° (710 mm.), and only slightly volatile with steam. It is readily soluble in alcohol, ether, and benzene, but insoluble in water. It yields metanitrobenzoic acid when heated at 235—240° with nitric acid of sp. gr. 1·15.

Metanitroisobutylbenzene, $C_4H_9{\cdot}C_6H_4{\cdot}NO_2$, obtained by treating the amido-derivative with nitrous acid, and fractionating the product in a partial vacuum, is a bright yellowish-red, aromatic-smelling oil, boiling at 250—252° (740 mm.). It yields metanitrobenzoic acid when heated at 200° with nitric acid of sp. gr. 1·12.

Nitroisobutylphenol, $[C_4H_9 : NO_2 : OH = 1 : 3 : 4]$, prepared by boiling amidonitroisobutylbenzene with dilute potash and distilling the product, separates from alcohol in yellowish-red, deliquescent crystals, melts at 95°, and boils at 289—290° (711 mm.) with only slight decomposition. It is readily soluble in alcohol, ether, benzene, light petroleum, alkalis, and hot water.

Metamidoisobutylbenzene, $C_4H_9{\cdot}C_6H_4{\cdot}NH_2$, prepared by reducing the nitro-derivative with stannous chloride and hydrochloric acid, is a yellowish oil, boiling at 229° (708 mm.), and moderately volatile with steam. It is readily soluble in alcohol, ether, and benzene, but only sparingly in water. It dissolves in a solution of bleaching powder with a bright violet colour, and with potassium dichromate and sulphuric acid yields a reddish-violet coloration, which quickly changes to brown. The *hydrochloride*, $C_{10}H_{15}N,HCl$, crystallises from hot benzene in colourless plates, and is readily soluble in water and hot alcohol, but only sparingly soluble in benzene. The *platinochloride*, $(C_{10}H_{15}N)_2,H_2PtCl_6$, crystallises in bright yellow plates, and is readily soluble in boiling water and hot alcohol, but only sparingly in benzene and ether. The *oxalate*, $C_{10}H_{15}N,C_2H_2O_4$, crystallises from hot water or dilute alcohol, in which it is readily soluble, in large white plates. The *acetyl*-derivative, $C_4H_9{\cdot}C_6H_4{\cdot}NHAc$, crystallises from boiling water in colourless, shining plates, melts at 101°, and is readily soluble in alcohol, ether, and benzene.

Metacetamidonitroisobutylbenzene, $[C_4H_9 : NO_2 : NHAc = 1 : 2 : 3]$, obtained by nitrating the acetamido-derivative, crystallises from hot dilute alcohol in small, yellow needles, melts at 105·5°, and is readily soluble in alcohol, benzene, and ether, but very sparingly in boiling water.

Amidonitroisobutylbenzene, $C_4H_9{\cdot}C_6H_3(NO_2){\cdot}NH_2$, separates from dilute alcohol in bright yellow crystals, melts at 124°, and is readily soluble in alcohol, ether, benzene, and boiling water, but sparingly soluble in cold water. It is only a feeble base, and the salts are readily soluble.

Diamidoisobutylbenzene, $[C_4H_9 : (NH_2)_2 = 1 : 2 : 3]$, prepared by reducing the preceding compound with stannous chloride and hydrochloric acid, crystallises from alcohol in colourless plates, melts at 109°, is readily soluble in water, alcohol, ether, and benzene, and blackens on exposure to the air. The *oxalate*, $(C_{10}H_{16}N_2)_2,C_2H_2O_4$, crystallises in flat needles, and is readily soluble in boiling water, but only sparingly in cold, absolute alcohol, and almost insoluble in ether.

Phenanthroisobutylphenazine,  $C_4H_9{\cdot}C_6H_3\left<\begin{matrix}N{\cdot}C{\cdot}C_6H_4\\ N{\cdot}C{\cdot}C_6H_4\end{matrix}\right>$, separates when an alcoholic solution of the diamine is mixed with a glacial acetic acid solution of phenanthraquinone. It separates from hot dilute alcohol in yellow nodular crystals, melts at 144° with previous softening, and is readily soluble in warm alcohol, ether, and benzene, but only sparingly in boiling water. It dissolves in concentrated nitric acid with a brownish-red, in concentrated sulphuric acid with a scarlet coloration, and is precipitated unchanged from both solutions on adding water.

Benzilisobutylphenazine,  $C_4H_9{\cdot}C_6H_3\left<\begin{matrix}N{\cdot}CPh\\ N{\cdot}CPh\end{matrix}\right>$, prepared in like manner from the diamine and benzil, crystallises in small, light-yellow prisms, melts at 96°, and is only sparingly soluble in cold alcohol, but readily in ether, benzene, and hot alcohol. It dissolves in concentrated nitric acid or concentrated sulphuric acid, but is precipitated unchanged on adding water.

Acetamidobromonitroisobutylbenzene, $C_4H_9{\cdot}C_6H_2Br(NO_2){\cdot}NHAc$, prepared by nitrating acetamidobromisobutylbenzene, crystallises from a mixture of ether and light petroleum in small, rhombic plates, melts at 144°, and is readily soluble in hot alcohol, ether, or benzene, but only very sparingly soluble in boiling water.

Amidobromonitroisobutylbenzene, $C_4H_9{\cdot}C_6H_2Br(NO_2){\cdot}NH_2$, crystallises in long needles, melts at 69·5°, boils at 278—280° with partial decomposition, and is volatile with steam. It is very sparingly soluble in boiling water, but readily in alcohol, ether, and benzene.

Diamidobromisobutylbenzene, $C_4H_9{\cdot}C_6H_2Br(NH_2)_2$, obtained by reducing the preceding compound with stannous chloride and hydrochloric acid, crystallises from ether in slender, colourless needles, melts at 85·5°, and turns brown on exposure to the air. It sublimes with considerable decomposition, forming colourless needles which are stable in the air. It is readily soluble in alcohol, ether, and benzene, but only very sparingly in hot water. Ferric chloride produces a brownish-red coloration; bleaching powder precipitates oily drops, and platinic chloride gives a brownish-black coloration in a hydrochloric acid solution of the base. The *oxalate*,

$$C_{10}H_{15}BrN_2,C_2H_2O_4,$$

crystallises in small needles, and is moderately soluble in boiling alcohol, but only sparingly in ether, benzene, and warm water. The *picrate*, $C_{10}H_{15}BrN_2{\cdot}2,C_6H_3N_3O_7$, crystallises from hot water in yellow needles, and is readily soluble in alcohol and ether.

Phenanthrobromisobutylphenazine,  $C_4H_9{\cdot}C_6H_2Br\left<\begin{matrix}N{\cdot}C{\cdot}C_6H_4\\ N{\cdot}C{\cdot}C_6H_4\end{matrix}\right>$, crystallises from boiling alcohol in slender, yellow needles, melts at 153·5°, and is readily soluble in benzene, ether, and boiling alcohol, but only sparingly in cold alcohol. It dissolves in concentrated mineral acids, forming red solutions, from which it is precipitated unchanged on adding water.

Benzilbromisobutylphenazine, $C_4H_9{\cdot}C_6H_2Br\left\langle\begin{array}{l}N{\cdot}C{\cdot}Ph\\ \;|\quad\|\\ N{\cdot}C{\cdot}Ph\end{array}\right.$, crystallises from hot alcohol in colourless needles, melts at 172°, and behaves towards solvents similarly to the preceding compound; it dissolves in concentrated acids with a yellowish-red coloration.

Dibromisobutylbenzene, $[C_4H_9 : Br_2 = 1 : 3 : 5]$, obtained by heating metabromisobutylbenzene with bromine in presence of iodine, and distilling the product with steam, is a light yellow oil, boils at 276—277° (718 mm.), and is readily soluble in all ordinary solvents except water. When heated at about 250° with nitric acid, sp. gr. 1·20, it is converted into symmetrical dibromobenzoic acid.

F. S. K.

Decomposition of some Diazo-compounds by Formic and Acetic Acids. By W. R. ORNDORFF (*Amer. Chem. J.*, **10**, 368—372).—The decomposition of diazo-compounds by formic acid might be expected to furnish an easier means of displacing the amido-group by hydrogen than the decomposition with alcohol. But the reaction proceeds otherwise and could not be followed out, as the phenyl formate that was probably formed could not be isolated. Substituting acetic acid for formic acid, it is shown that phenyl acetate is produced; the yield is, however, small, as much tar is also formed; the reaction is analogous to the production of phenetoïl by the action of alcohol. The boiling point of phenyl acetate has been variously stated; it has been redetermined as 195° at 733 mm. pressure. Similarly, paradiazotoluene sulphate, when boiled with acetic acid, yields paracresyl acetate, boiling at 213°, and identical with that prepared from paracresol. Paradiazobenzenesulphonic acid appears to undergo a similar change, and the reaction therefore seems to be general.

H. B.

Chrysoïdincarbamide. Amidophenylenecarbamide. By A. JENTZSCH (*J. pr. Chem.* [2], **38**, 121—139).—When carbonyl chloride is passed into a moderately strong solution of chrysoïdin in dry chloroform, it is rapidly absorbed with development of heat, and red-brown flocks separate which become of a darker brown as the action proceeds. The brown matter is collected, dried, powdered, heated with dilute hydrochloric acid, and filtered hot; brilliant golden-yellow laminæ crystallise out on cooling, together with octohedral crystals of diamidoazobenzene hydrochloride. By dissolving the mixed crystals in alcohol and adding ammonia, golden-yellow needles of the corresponding bases are obtained, which may be separated by digestion with chloroform, the diamidoazobenzene being dissolved. The residue, consisting of the new base, is purified by dissolving in alcohol and passing hydrogen chloride through the solution to obtain the hydrochloride which is then decomposed by ammonia.

Chrysoïdincarbamide, $NPh\!:\!NC_6H_3\!:\!(NH)_2\!:\!CO$, thus obtained, crystallises in brilliant, golden-yellow laminæ, sparingly soluble in alcohol, nearly insoluble in water, ether, and chloroform. It does not melt at 300°. If the chloroform solution of diamidoazobenzene be saturated with carbonyl chloride and allowed to stand for some days, only carbamide hydrochloride and unaltered chrysoïdin hydrochloride will be found on evaporating the chloroform. The *hydrochloride* crystallises in golden-yellow laminæ, sparingly soluble in water, more so in alcohol, insoluble in ether. The *platinochloride*, $(C_{13}H_{11}N_4OCl)_2PtCl_4$, forms red-brown laminæ. The *nitrate* crystallises in brilliant, golden-yellow scales, very sparingly soluble in water, sparingly soluble in alcohol, and insoluble in ether; they decompose with slight explosion at above 200°. The *sulphate* forms a yellowish-red powder; it is very sparingly soluble in water, more so in alcohol.

When heated with moderately strong hydrochloric acid in a sealed tube at 200° for eight hours, chrysoïdincarbamide is decomposed, with the formation of carbonic anhydride and a dark-brown mass. The same dark-brown substance is obtained when chrysoïdin is treated in the same way. It yields phenol when distilled with steam, and a reddish-brown residue which has not been identified.

Inasmuch as chrysoïdin splits up into aniline and triamidobenzene when reduced by hydrochloric acid and tin, it seemed probable that its carbamide would yield aniline and a new substance,

$$NH_2{\cdot}C_6H_3{:}(NH)_2{:}CO,$$

by the same treatment, thus showing that both NH-groups are attached to the same benzene nucleus. 100 grams of the carbamide were heated with 50 grams of tin and 250 grams of hydrochloric acid (sp. gr. 1·2) in a flask. The solution became colourless at first, and subsequently brown, through oxidation; after the action had ceased, the hydrochloric acid was evaporated, the residue dissolved in hot water, and hydrogen sulphide passed through the solution; the filtrate from the tin sulphide was evaporated in a current of hydrogen sulphide, the crystalline residue dissolved in water, and made alkaline with barium hydroxide. This precipitated aniline, which was distilled off; the excess of barium hydroxide was precipitated from the liquid remaining in the retort by sulphuric acid, and the excess of the latter by barium chloride. From the filtrate, the hydrochloride of the new base did not crystallise well, so the solution was digested with ammonium oxalate and filtered hot. On cooling, *amidophenylenecarbamide oxalate* crystallised out in nearly white minute needles, collected in spheres, freely soluble in hot, sparingly in cold water, nearly insoluble in alcohol.

Amidophenylenecarbamide, $NH_2{\cdot}C_6H_3{:}(NH)_2{:}CO$, obtained from the oxalate by adding sodium carbonate to a hot solution of it in hydrochloric acid, forms brilliant and nearly colourless, pointed laminæ, sparingly soluble in cold, easily in hot water, freely soluble in hot alcohol, and decomposing at 220°. The *hydrochloride* crystallises in minute needles, freely soluble in water, very sparingly so in alcohol. The *sulphate* also forms minute needles, having the same solubility. The *triacetyl-derivative*, $NHAc{\cdot}C_6H_3{:}(NAc)_2{:}CO$, forms fine, white, silky needles, insoluble in water, fairly soluble in alcohol, and melting at 248°.

Dicarbonyltriamidobenzene,  $C_6H_3{<}^{NH{\cdot}CO}_{NH{\cdot}CO}{>}N$, was obtained by heating amidophenylene carbamide with liquid carbonyl chloride in a sealed tube for eight hours at 120°. The excess of carbonyl chloride was evaporated and the residue heated with water, which extracted the hydrochloride of the carbamide formed during the reaction, and left the carbonyl compound as a crystalline residue, insoluble in alcohol, ether, benzene, toluene, aniline, and acids, but very soluble in alkaline solutions, from which it is precipitated by acids.

By passing nitrous acid through a cooled, acidified aqueous solution of the sulphate of amidophenylenecarbamide, yellowish-green crystals, giving the reactions of a diazo-compound of the carbamide, were obtained, but they were not pure. By dissolving them in hydrobromic acid and adding a few drops of bromine, yellowish-red needles of the perbromide of the diazo-compound crystallised out; these lost bromine as they dried, and by digesting them with warm alcohol they were converted into yellow crystalline laminæ of the *diazobromide* of amidophenylenecarbamide. A. G. B.

Hydrazoximes. By H. v. PECHMANN and K. WEHSARG (*Ber.*, 21, 2994 — 3004).—*Nitrosoacetonehydrazone* (*methylglyoxal-αω-hydrazoxime*) $N_2HPh{:}CMe{\cdot}CH{:}NOH$, prepared by mixing nitrosoacetone (1 mol.) with phenylhydrazine (1 mol.) in alcoholic or ethereal solution, crystallises from alcohol in yellowish prisms or needles, melts at 134°, and is soluble in ether and benzene, but insoluble in hot water. It dissolves in concentrated sulphuric acid with a reddish-yellow colour which becomes deep blue on adding ferric chloride.

Methylglyoxalosazone hydrochloride is obtained when the preceding compound is warmed with concentrated hydrochloric acid in alcoholic solution. It crystallises from boiling methyl alcohol, melts at 197°, and yields the free base (compare Abstr., 1888, 1287) when treated with ammonia.

Diacetylhydrazoxime (*methylnitrosoacetonehydrazone*),

$$CMe(N_2HPh){\cdot}CMe{:}NOH,$$

prepared in like manner from nitrosomethylacetone, crystallises from dilute alcohol in large, colourless needles, melts at 158°, and resembles nitrosoacetonehydrazone in its behaviour towards solvents. It dissolves in concentrated sulphuric acid with a yellow coloration which changes to a bluish-violet on adding ferric chloride, and when heated with concentrated hydrochloric acid in alcoholic solution, yields a mixture of diacetylosazone melting at 241—242°, and diacetylhydrazone melting at 133°.

Glyoxylcyanide-α-hydrazone, $CHO{\cdot}C(N_2HPh){\cdot}CN$, is formed, together with hydroxylamine, when dinitrosoacetonehydrazone (compare this vol., p. 34) is warmed with alcohol and hydrochloric acid. It crystallises from boiling alcohol in pale-yellow needles, melts at 161° with decomposition, and is dissolved on warming in most solvents except water. It is soluble in dilute alkalis, and dissolves in concentrated sulphuric acid with a yellow colour which is not changed by ferric chloride. When boiled with hydriodic acid, it yields the theoretical quantity of aniline.

Glyoxylcyanideosazone, $N_2HPh{:}CH{\cdot}C(N_2HPh){\cdot}CN$, prepared by mixing a hot, alcoholic solution of the preceding compound with phenylhydrazine, crystallises from alcohol in orange-red needles, melts at 161° with decomposition, and is soluble in alcohol and glacial acetic acid, but only sparingly in most other solvents. The concentrated sulphuric acid solution is yellowish-red, and its colour is not changed by ferric chloride.

Glyoxylcyanideosotetrazone,  $\left\langle\begin{matrix}\mathrm{CH{:}N{\cdot}NPh}\text{——}\\ \mathrm{C(CN){:}N{\cdot}NPh}\end{matrix}\right\rangle$, is formed when the preceding compound is warmed with ferric chloride or with a solution of potassium dichromate and dilute acetic acid. It crystallises from acetone or alcohol in brownish-red, moss-like needles melting at 137° with decomposition. When heated with hydrochloric acid, a colourless, crystalline product, probably an osotriazone (*loc. cit.*) volatilises.

This compound, $C_9H_6N_3O{:}N_2Ph$, is formed by the combination of glyoxylcyanidehydrazone with diazobenzene chloride; it crystallises from alcohol in brownish plates, melts at 162—163°, and is insoluble in alkalis.

Glyoxylcyanide-αω-hydrazoxime, $NOH{:}CH{\cdot}C(N_2HPh){\cdot}CN$, prepared by boiling an alcoholic solution of the hydrazone (1 mol.) with hydroxylamine hydrochloride (1 mol.) and a few drops of hydrochloric acid, crystallises from alcohol in citron-yellow, sparingly soluble needles melting at 240° with decomposition. It dissolves in alkalis with a yellow coloration, but the yellow, concentrated sulphuric acid solution is not changed on adding ferric chloride.

A compound, $C_9H_7N_4$, is obtained when glyoxylcyanidehydrazoxime is dissolved in phosphorus oxychloride, heated with phosphoric chloride, the solution poured on to ice, the precipitated product extracted with ether, dissolved in dilute alkali, and fractionally precipitated with hydrochloric acid. It crystallises from a mixture of ether and light petroleum in yellowish needles, melts at 135° with decomposition, and is soluble in hot water, alkalis, and most of the ordinary solvents. It dissolves in concentrated sulphuric acid with a blood-red coloration which is not changed on adding ferric chloride. When warmed with concentrated hydrochloric acid or when boiled with alcoholic potash, it is converted into a compound, $C_9H_9N_4O$, which crystallises in small, yellow needles melting at 244—245°.

A compound, $C_{15}H_{13}N_5$, is formed in the preparation of glyoxylcyanidehydrazone, and can also be obtained by heating the hydrazoxime with alcohol (3 parts) and concentrated hydrochloric acid (10 parts). It crystallises from benzene in shining, orange-yellow plates melting at 165°, and does not give the osazone reaction (*loc. cit.*).

Methylglyoxal-αω-methylphenylhydrazoxime, $N_2MePh{:}CMe{\cdot}CH{:}NOH$, prepared by mixing an aqueous solution of nitrosoacetone with a solution of methylphenylhydrazine sulphate and sodium acetate, crystallises from dilute alcohol in orange-yellow prisms melting at 118°. Alkaline solutions are dark yellow, and the yellow, concentrated sulphuric acid solution changes to violet on adding ferric chloride.

Mesoxalaldehyde-αωω-methylphenylhydrazonedioxime (*dinitrosoacetonemethylphenylhydrazone*), $NOH{:}CH{\cdot}C(N_2MePh){\cdot}CH{:}NOH$, prepared in like manner, crystallises from dilute alcohol in orange-yellow needles or plates, melts at 137°, and is soluble in alkalis and most of the ordinary solvents. It dissolves in concentrated sulphuric acid, forming a brownish-red solution in which ferric chloride produces a light violet coloration. When heated with hydrochloric acid, it yields decomposition products the nature of which varies according to the conditions of the experiment.

Glyoxylcyanide-α-methylphenylhydrazone, $CHO\cdot C(N_2MePh)\cdot CN$, is obtained by dissolving the preceding compound in acetone (7 parts), adding concentrated hydrochloric acid (7 parts) and, after the first energetic reaction is at an end, heating the mixture for about a minute and adding water to the cold solution. It crystallises from benzene, alcohol, or light petroleum in yellow, feathery needles, or thick, spear-shaped crystals, melts at 113·5°, and is insoluble in alkalis. When mixed with phenylhydrazine, it yields a compound, probably $N_2HPh:CH\cdot C(N_2MePh)\cdot CN$, which crystallises from absolute alcohol in golden-yellow plates melting at 181°. The *anil*, $NPh:CH\cdot C(N_2MePh)\cdot CN$, prepared by mixing the hydrazone with aniline in acetic acid solution, crystallises from alcohol in slender, yellow needles, melts at 150—151°, and is reconverted into the hydrazone when warmed with dilute hydrochloric acid. The *hydrazoxime*, $NOH:CH\cdot C(N_2MePh)\cdot CN$, obtained by treating the hydrazone with hydroxylamine, crystallises in small, yellow needles melting at 178°. The *acetyl*-derivative, $NOAc:CH\cdot C(N_2MePh)\cdot CN$, of the hydrazoxime crystallises from alcohol in yellow needles, melts at 121·5°, and is reconverted into the hydrazoxime when boiled with soda. F. S. K.

Ethyl Phenylhydrazineacetylacrylate. By H. Decker (*Ber.*, **21**, 2937—2938).—The compound obtained by Bender (Abstr., 1888, 1188) by hydrolysing ethyl phenylhydrazineacetylacrylate, has already been fully described by L. Wolff (Abstr., 1887, 464). F. S. K.

Theory of Dyeing. By E. Knecht (*Ber.*, **21**, 2804—2805; compare Abstr., 1888, 832).—When wool is boiled with a mixture of sulphuric acid (2 parts) and water (3 parts) for two hours, it dissolves almost entirely; when filtered, a clear, light-brown solution is obtained. If this is mixed with aqueous solutions of acid coal-tar dyes, intensely coloured precipitates are formed, which dissolve readily in alkalis, but not in water or dilute acids.

A solution of silk in moderately dilute sulphuric acid behaves in like manner. Animal fibres, therefore, yield a substance which forms insoluble bases with acid coal-tar dyes; it has not yet been determined whether this substance already exists in the fibres, or whether it is gradually formed by the action of the acid bath. N. H. M.

Product of the Action of Nitric Acid on Acetophenone. By A. F. Hollemann (*Ber.*, **21**, 2835—2840; compare Abstr., 1888, 275).—The molecular weight of the compound $C_{16}H_{10}N_2O_4$, obtained by the action of nitric acid on acetophenone (*loc cit.*), was confirmed by a determination by Raoult's method (*Ber.*, **21**, 861). When the alcoholic solution is reduced with stannous chloride, benzoic and hydrocyanic acids are formed. By prolonged boiling with strong hydrochloric acid, it is decomposed into benzoic and oxalic acids; ammonia and hydroxylamine are also formed. These reactions make it probable that the compound has the constitution  $<\begin{matrix}\mathrm{CBz{:}N{\cdot}O}\\\mathrm{CBz{:}N{\cdot}O}\end{matrix}>$, which is further supported by the fact that the substance, which is named *diphenyldinitrosacyl*, can be prepared by oxidising nitrosoacetophenone.

Diphenyldinitrosacyl reacts with aniline with formation of benzanilide and a compound crystallising in lustrous, brown needles. When this is heated at 100° for some time, it gives an odour somewhat like that of carbylamine: when crystallised from dilute alcohol, it is nearly white, and melts at 205°.

When diphenyldinitrosacyl is heated with acetic anhydride at 110—120° for six hours, the compound $C_{16}H_{10}N_2O_4 + OAc_2$ is formed. This crystallises in stellate groups of needles melting at 149°.

The sparingly soluble compound melting at 177—179°, which is also obtained by the action of nitric acid on acetophenone (*loc. cit.*), has the same empirical composition as diphenyldinitrosacyl; it is, however, much more stable than the latter. Boiling aqueous potash and hot sulphuric acid decompose it, yielding benzoic acid; with potash, ammonia is evolved. N. H. M.

Consecutive Duryl Methyl Ketone. By A. CLAUS and E. FÖHLISCH (*J. pr. Chem.* [2], **38**, 230—235; compare Abstr., 1888, 275).—The boiling point of consecutive durene is 199—200° (uncorr.) and its melting point is −4°.

Consecutive duryl methyl ketone, $C_6HMe_4{\cdot}COMe$ [Me_4 : COMe = 2 : 3 : 4 : 5 : 1], is prepared in the manner previously described, by which 80—90 per cent. of the durene used is converted into the ketone; it is a brown, strongly refractive oil, of agreeable aromatic odour, boiling at 258—260° (uncorr.), and easily soluble in the usual solvents, except water. The *phenylhydrazine* compound forms colourless laminæ melting at 129° (uncorr.).

2 : 3 : 4 : 5-*Tetramethylphenylglyoxylic acid*, $C_6HMe_4{\cdot}CO{\cdot}COOH$, is formed when the above ketone is oxidised with potassium permanganate in the cold. It is a bright yellow syrupy oil, very little soluble in cold, more so in hot water, very soluble in alcohol, ether, carbon bisulphide, and chloroform; it solidifies on prolonged cooling and decomposes when heated. The *barium* and *calcium salts* (with 4 mols. H_2O), the *copper* (with 3 mols. H_2O), and the *silver salts* are described.

2 : 3 : 4 : 5-*Tetramethylmandelic acid*, $C_6HMe_4{\cdot}CH(OH){\cdot}COOH$, is obtained by reducing the foregoing acid with sodium amalgam. It crystallises from alcohol in colourless hexahedra, sparingly soluble in cold, readily in hot water and in alcohol, ether, and chloroform, and melts at 160° (uncorr.). The *potassium* (with 4 mols. H_2O), *barium* (with 3 mols. H_2O), *calcium* (with $2\frac{1}{2}$ mols. H_2O), and *silver* salts are described.

2 : 3 : 4 : 5-*Tetramethylphenylacetic acid*, $C_6HMe_4{\cdot}CH_2{\cdot}COOH$, is formed when either of the above described acids is reduced with

hydriodic acid. It crystallises from hot water in slender, colourless needles, melting at 125° (uncorr.), and easily soluble in alcohol, ether, and chloroform. The *calcium salt* forms colourless, silky needles containing 3 mols. H_2O.

By oxidising consecutive duryl methyl ketone or the foregoing derivatives, with the calculated quantity of potassium permanganate, at a gentle heat, 2 : 3 : 4 : 5- tetramethylbenzoic acid is obtained as a thick, colourless oil, sparingly soluble in water, freely so in other solvents. When heated, it decomposes at 270°, and an oil distils over, which solidifies and melts at 150°; this contains 73·8 per cent. of carbon and 7·9 per cent. of hydrogen. The *sodium* (with 3 mols. H_2O), *calcium* (with 3 mols. H_2O), *barium* (with 6 mols. H_2O), *silver* and *copper salts* are described. A. G. B.

Stilbene. By L. ARONSTEIN and A. F. HOLLEMANN (*Ber.*, **21**, 2831—2834).—The experiments described were made with a view to obtain a geometrical isomeride of stilbene which should exist according to Wislicenus' theory. No definite results were obtained, but the investigation is being continued. N. H. M.

Action of Heat on Benzildihydrazone. By K. AUWERS and V. MEYER (*Ber.*, **21**, 2806—2807).—*Triphenylosotriazone*,  $<\begin{matrix}CPh{:}N\\CPh{:}N\end{matrix}>NPh$, formed when benzilhydrazone is heated with alcohol at 200—210°, crystallises in white, lustrous plates, melts at 122°, and boils without decomposition. N. H. M.

Thio-derivatives of β-Dinaphthylamine. By O. KYM (*Ber.*, **21**, 2807—2813).—When sulphur chloride dissolved in benzene is added to β-dinaphthylamine, also dissolved in benzene, hydrogen chloride is evolved and two isomeric *dithiodinaphthylamines*, $C_{20}H_{13}NS_2$, are obtained. The one forms lustrous, brass-coloured plates melting at 205°, whilst the other crystallises in reddish-yellow prisms melting at 220°. Both compounds are sparingly soluble. When the dithio-compounds are boiled with cumene or with aniline, they are both converted with evolution of carbon bisulphide into Ris's thio-β-dinaphthylamine (Abstr., 1886, 1036). A small quantity of the latter compound is formed in the reaction between dinaphthylamine and sulphur chloride. *Acetylthio-β-dinaphthylamine*, $C_{22}H_{15}NOS$, is obtained by the action of acetic anhydride on the dithio-compound (m. p. 205°) or on the monothio-compound. It crystallises in slender, lustrous, almost white needles, melts at 211°, and is readily soluble in hot alcohol or benzene. When the dithio-compound (m. p. 205°) is treated with an ammoniacal alcoholic silver solution, a compound free from sulphur is obtained, which melts at 240°, and sublimes in slender, lemon-yellow needles.

Sulphur dichloride acts on β-dinaphthylamine, yielding as chief product thio-β-dinaphthylamine, and a sparingly soluble isomeride which melts at 303°. Sometimes a small amount of a compound, probably *thiotetranaphthylamine*, $S(C_{10}H_6{\cdot}NH{\cdot}C_{10}H_7)_2$, is obtained. This forms dark-yellow crystals melting at 307°. N. H. M.

Naphthoic Acids. By Å. G. Ekstrand (*J. pr. Chem.* [2], **38**, 139—185).—This paper is a summary of the author's work on the subject; much of it has already appeared. The following new compounds are described:—

Chloro-α-naphthoic amide is obtained by heating chloro-α-naphthonitrile (Abstr., 1884, 1361) with an alcoholic solution of potassium hydroxide; it forms crystalline laminæ, soluble in alcohol and melting at 239°.

The chloro-α-naphthoic acid which melts at 245° (Abstr., 1884, 1361) has the constitution [COOH : Cl = 1 : 4′], as it is obtained by treating 1 : 4′ amido-α-naphthoic acid by Sandmeyer's method (Abstr., 1884, 1311).

Chloro-α-naphthoic acid (1 : 1′) is obtained when 1 : 1′ amido-α-naphthoic acid (Abstr., 1885, 549) is dissolved in the calculated quantity of sodium hydroxide and potassium nitrite (1 mol. to 1 mol. of the amido-acid) added; the mixture is cooled to 0° and treated with excess of hydrochloric acid. The hydrochloride of the diazonaphthoic acid thus obtained is added to a boiling solution of cuprous chloride in hydrochloric acid; colourless crystals of the chloro-acid are formed; they melt at 167° and sublime as plates. The *calcium salt* crystallises with 2 mols. H_2O in long tabular needles, soluble in 42 parts of water at the ordinary temperature. The *ethyl salt* forms long needles melting at 50°.

Dichlor-α-naphthoic acid is obtained when the foregoing acid is dissolved in glacial acetic acid, some iodine added, and chlorine passed to saturation; crystalline scales separate, melting at 186—187°. The *calcium salt* crystallises with 2 mols. H_2O in long, colourless needles; the *ethyl salt* forms fine needles melting at 61°.

It is possible to obtain this acid from chlornitro-α-naphthoic acid [COOH : NO_2 : Cl = 1 : 1′ : 4′] (Abstr., 1886, 156), consequently its constitution is [COOH : Cl : Cl = 1 : 1′ : 4′].

Trichloro-α-naphthoic acid, the mother-liquor from the preparation of chloro-α-naphthoic acid (1 : 4′) by the action of chlorine on α-naphthoic acid in acetic acid solution, is saturated with chlorine at the boiling point; dilution with water then throws down a crystalline precipitate, which is heated with calcium carbonate, filtered, and the filtrate precipitated with acid; when crystallised from alcohol and water, this precipitate forms small, colourless needles, melting at 163—164° and subliming in fine needles.

The *ethyl salt* of monobromo-α-naphthoic acid, 1 : 4′ (Abstr., 1886, 715), forms colourless tables melting at 48—49°.

Mononitro-α-naphthoic acid of melting point 215° (Abstr., 1885, 548) is soluble in 21·5 parts of commercial alcohol, and in 2590 parts of water at the ordinary temperature. During its formation a small quantity of *α-mononitronaphthalene* (melting point 60°) is obtained.

The *calcium salt* of amido-α-naphthoic acid (Abstr., 1885, 549) crystallises with 9·5 mols. H_2O in fine needles, soluble in water. The *hydrochloride*, $COOH{\cdot}C_{10}H_6{\cdot}NH_2,HCl$, is precipitated in fine needles on adding hydrochloric acid to a solution of the sodium salt.

Naphthostyril, $C_{10}H_6{<}\genfrac{}{}{0pt}{}{NH}{CO}{>}$ (Abstr., 1886, 715), crystallises from an alcoholic solution of the amido-α-naphthoic acid; it is also formed when the acid is heated with water; it melts at 180—181°.

The *benzoyl-derivative* forms slender needles melting at 170°; the *hydrochloride* melts at 178°.

α-Naphthoylnaphthostyril.—When α-naphthoyl chloride and naphthostyril are heated together, a green product is formed, which is dissolved in alcohol and decolorised by animal charcoal. A mixture of granular crystals (melting at 110°) and needles (melting at 152°) is obtained; by recrystallising these, partly from alcohol and partly from glacial acetic acid, a mixture of the same crystals is obtained, melting at 150°.

β-Naphthoylnaphthostyril, is obtained in the same way as the above, only at a lower temperature, in slender colourless needles, melting at 197—198°.

The *calcium salt* of chlornitro-α-naphthoic acid, of melting point 225° (Abstr., 1886, 156), forms slender colourless needles, crystallising with 3 mols. H_2O, and the *ethyl salt* tabular crystals melting at 121°, and very soluble in alcohol. The question whether this acid has the constitution [COOH : NO_2 : Cl = 1 : 1′ : 4′ or 1 : 4 : 4′] is settled in favour of the former, as *chloronaphthostyril* (with Cl in position 4′) is obtained in yellow needles melting at 270°, by reducing the acid with ferrous sulphate in an ammoniacal solution.

Nitronaphthostyril (1 : 4′) is formed when nitric acid (sp. gr. 1·42) is added to a solution of naphthostyril in glacial acetic acid, and the mixture heated on the water-bath; the crystalline mass thus obtained is partially soluble in alcohol, from which yellow needles, melting about 235°, are obtained; the greater part recrystallises from glacial acetic acid in orange-yellow needles melting at 300°. Both are nitronaphthostyrils.

Amidonaphthostyril is formed when nitronaphthostyril is reduced with tin and hydrochloric acid, and the hydrochloride thus produced decomposed with ammonia; it crystallises in red needles melting at 239—240°, and freely soluble in alcohol and hot water. The *hydrochloride* crystallises in yellow needles melting above 290°.

Dinitronaphthostyril is obtained when the nitronaphthostyril is heated with nitric acid (1·43 sp. gr.); it forms yellow needles, or, when prepared by the action of nitric acid on naphthostyril, rhombic tables, melting above 290°. The *acetyl*-derivative melts above 290°.

Naphthostyrilquinone, $C_{10}H_4O_2<\substack{NH \\ CO}>$, is obtained when a solution of naphthostyril in glacial acetic acid is mixed with chromic acid and then with water; fine red needles are precipitated, which, after recrystallisation from glacial acetic acid, melt near 278°. When it is dissolved in warm glacial acetic acid and an acetic acid solution of toluylenediamine added, a yellow, crystalline powder, consisting of *naphthostyriltoluquinoxaline*, $C_{11}H_5N_3O,C_6H_3CH_3$, is obtained; it melts above 290°.

Nitronaphthostyrilquinone forms orange-red needles or tables, melting near 285°, soluble in alcohol and sparingly so in glacial acetic acid.

A. G. B.

β-Chloronaphthalenesulphonic Acid. By S. FORSLING (*Ber.*, **21**, 2802—2804).—When β-amidonaphthalenesulphonic acid (Abstr., 1887, 962) is converted into the diazo-compound, and this is boiled with strong hydrochloric acid and neutralised with potassium carbonate, potassium β-chloronaphthalenesulphonate separates.

β-Chloronaphthalenesulphonic chloride, $C_{10}H_6Cl{\cdot}SO_2Cl$ (Arnell, Abstr., 1886, 555), is prepared by mixing the well-dried potassium salt with phosphorus pentachloride and heating; it crystallises from chloroform in broad needles melting at 129°.

The *bromide*, $C_{10}H_6Cl{\cdot}SO_2Br$, prepared by the action of phosphorus bromide on the potassium salt, crystallises from chloroform in small needles melting at 139°.

The *amide*, $C_{10}H_6Cl{\cdot}SO_2{\cdot}NH_2$, is obtained by boiling the chloride with a mixture of equal parts of ammonia and alcohol, and crystallising the product from dilute alcohol, in which it is sparingly soluble; it melts at 235°.

β-Chloronaphthalenesulphonic acid has the constitution [Cl : SO_3H = 2 : 4 or 2 : 1]. N. H. M.

Filicic Acid. By G. DACCOMO (*Ber.*, **21**, 2962—2970).—Filicic acid, prepared by the method already described (Daccomo, Abstr., 1888, 521), has the composition $C_{14}H_{16}O_5$. It is a yellowish, odourless, crystalline powder, melts at 179—180° (uncorr.), and is insoluble in water, almost insoluble in absolute alcohol, moderately soluble in glacial acetic acid, ether, amyl alcohol, and toluene, and readily in chloroform, carbon bisulphide, and benzene. The *benzoyl*-derivative, $C_{21}H_{20}O_6$, separates from dilute alcohol in colourless crystals, melts at 123°, and is very readily soluble in ether, but insoluble in water. The *ethyl* salt, $C_{16}H_{20}O_5$, prepared by treating the acid with alcoholic potash and ethyl iodide, separates from dilute alcohol in reddish crystals, melts at 142°, and is very readily soluble in ether and benzene, but insoluble in water. The *propyl* salt melting at 158°, and the *ethylene* salt melting at 165°, resemble the ethyl salt in appearance and solubility.

Bromofilicic acid, $C_{14}H_{15}BrO_5$, prepared by treating the acid with bromine in glacial acetic acid solution, crystallises from alcohol in red prisms, melts at 122°, and is very readily soluble in absolute alcohol and ether, but insoluble in water.

Anilidofilicic acid, $C_{14}H_{15}O_4{\cdot}NHPh$, obtained by boiling a glacial acetic acid solution of the acid with aniline, separates from alcohol in reddish-violet crystals, melts at 140°, and is soluble in alcohol and benzene, but insoluble in water.

The *hydrazide*, $C_{14}H_{16}O{\cdot}(N_2HPh)_4$, prepared by boiling an ethereal solution of the acid with phenylhydrazine, crystallises from ether in red needles, melts at 198°, and is readily soluble in alcohol, but insoluble in water. When the acid (100 parts) is heated above its melting point (compare Luck, *Annalen*, **54**, 119), or heated with water at 170—190°, it is decomposed into isobutyric acid (32·5 parts) and a compound, the composition of which is $C_{20}H_{18}O_7$. Hydrochloric acid produces the same decomposition at 150—160°.

Filicic acid is completely oxidised when treated with chromic acid in glacial acetic acid solution, but when a solution of the potassium salt is oxidised in the cold with a 2 per cent. solution of potassium permanganate, isobutyric acid and oxalic acid are obtained. The same products are formed when nitric acid of sp. gr. 1·48 is employed. When the acid is treated with zinc-dust in alkaline solution, it is converted into an acid, the composition of which is probably $C_{14}H_{22}O_{11}$, and at the same time a small quantity of isobutyric acid is formed. When treated with sodium in amyl alcohol solution, it yields butyric acid and resinous products.

The compound $C_{20}H_{18}O_7$, referred to above, separates from ether or amyl alcohol as an amorphous, red powder, and has no well-defined melting point. It is soluble in most ordinary solvents, has an acid reaction, decomposes carbonates, and dissolves in alkalis, forming red solutions from which it is precipitated in red flocks on adding acids. It yields phthalic acid and small quantities of oxalic acid when oxidised with nitric acid of sp. gr. 1·40 in the cold. When reduced with zinc-dust in alkaline solution, it gives a colourless substance which rapidly oxidises, and is probably reconverted into the original compound.

From the above results, it follows that filicic acid is probably an isobutyric acid derivative of hydroxynaphthaquinone. F. S. K.

Quillajic Acid. By R. KOBERT (*Chem. Centr.*, 1888, 927—928, from *Arch. expt. Path. Pharm.*, **23**, 233).—The saponin of commerce, as all other specimens of saponin, is an almost inactive, non-poisonous modification of quillajic acid. The author precipitated the acid from the aqueous extract of the bark of *Quillaja saponaria* with neutral lead acetate; the precipitate was freed from lead, the solution of the acid evaporated almost to dryness, and then taken up with hot absolute alcohol. The colouring matter was precipitated with chloroform; the quillajic acid eventually crystallised out in pure white flakes. It is insoluble in ether, soluble in water and alcohol. On treatment with concentrated sulphuric acid, it becomes dark red. By boiling with dilute mineral acids, it is split up into an unfermentable glucose and sapoginin; this solution reduces Fehling's solution. Quillajic acid has the formula $C_{19}H_{30}O_{10}$. The sodium salt acts as a very severe caustic on the tongue and throat, and the smallest particles coming in contact with the nose or throat cause violent sneezing and coughing. Brought on to the eye, it causes severe pain, flow of tears, and swelling of the lids. Injected into the blood, the sodium salt proves fatal, causing cramp and paralysis of the respiratory organs and brain. On the other hand, it may be imbibed into the stomach without injury to the extent of 500 times the quantity which proves fatal when injected into the blood. J. W. L.

Brazilin. By C. SCHALL and G. DRALLE (*Ber.*, **21**, 3009—3017, compare Abstr., 1888, 295).—Tetramethylbrazilin is best prepared as follows:—A solution of brazilin (100 grams) in warm 98 per cent. alcohol is mixed with sodium ethoxide (30·26 grams sodium) and methyl iodide (206 grams), the mixture kept at 60—70° for 40 to 50 hours, cooled and poured into cold water. The precipitate is collected, washed with water, dissolved in ether, the solution shaken with soda (1—2 per cent.), washed with water, the ether evaporated, and the residue crystallised from alcohol with addition of animal charcoal. The yield is 58·5 per cent. of the theoretical quantity.

Trimethylbrazilin, $C_{16}H_{11}O_5Me_3 + \frac{3}{4}H_2O$, is obtained by neutralising the alkaline washings from the tetramethyl-derivative, extracting with ether, washing the extract first with sodium hydrgen carbonate, then with sodium carbonate, and evaporating the ether at the ordinary temperature. The residue is mixed with concentrated soda, the precipitated sodium-derivative collected, washed with alcoholic ether, dissolved in water, and precipitated from the filtered solution by treatment with carbonic anhydride. If the product is pure, it is obtained in the crystalline condition containing about 1 mol. H_2O, but the impure compound does not crystallise well even after keeping for months. It dissolves in dilute alcohol, and the solution gives a brown precipitate with ferric chloride; the solution in soda is colourless, and does not alter on keeping. The *acetyl*-derivative, $C_{16}H_{10}O_5Me_3Ac$, is crystalline, and melts at 95—97° with previous softening.

Bromotetramethylbrazilin, $C_{16}H_9BrMe_4O_5$, obtained by treating the tetramethyl-derivative (1 mol.) with bromine (1 mol.) in glacial acetic acid solution, crystallises from dilute alcohol in long, colourless prisms melting at 180—181°.

A crystalline tetrabromo-derivative, $C_{16}H_8Br_4Me_4O_5$, is formed when a larger quantity of bromine (2—3 mols.) is employed; this substance loses bromine (about 26 per cent.) when treated with dilute ammonia or soda, and appears to be dibromotetramethylbrazilin dibromide. It is probable that other bromo-derivatives exist, and a crystalline iodo-additive product was also obtained.

Tribromobrazilin dibromide, $C_{16}H_{11}Br_3O_5,Br_2 + 2H_2O$, is obtained in reddish-brown needles when bromine (4—6 mols.) is added gradually to a boiling glacial acetic acid solution of brazilin.

A compound, $C_{20}H_{14}O_9$, is obtained when brazilin (2·7 grams) is dissolved in water (150 c.c.) and soda of sp. gr. 1·37 (10 c.c.), and a stream of air passed through the solution for about 36 hours. It crystallises from alcohol in light brown, flat, microscopic needles, melts at 271°, and is readily soluble in dilute soda, sparingly soluble in ether or sodium carbonate, and insoluble in sodium bicarbonate. The aqueous alcoholic solution gives a slight violet coloration with ferric chloride, and a citron-yellow coloration with concentrated nitric acid. When heated above its melting point, shining scales sublime, but considerable decomposition takes place. F. S. K.

Nomenclature of Compounds containing Nitrogenous Nuclei. By O. Widman (*J. pr. Chem.* [2], **38**, 185—201).—A new system of nomenclature for the quinoxalines and compounds of allied structure. (Compare Mason, Proc., 1888, 109.)

Metapyrazolones. By E. Grimaux (*Bull. Soc. Chim.*, **49**, 739—740).—The compounds described by Pinner and Lifschütz, and named by them metapyrazolone-derivatives, are derivatives of glycolylcarbamide or hydantoïn, and the isomeric substances which Pinner and Lifschütz name metapyrazole-derivatives are simple ureïdes.

F. S. K.

Action of Phenylhydrazine and Hydroxylamine on Acetylacetone. By A. Combes (*Bull. Soc. Chim.*, **50**, 145—146; compare *ibid.*, **48**, 471).—*Dimethylphenylpyrazole*,  $\mathrm{CMe}\lessdot\begin{matrix}\mathrm{CH}\text{——}\\ \mathrm{NPh\cdot N}\end{matrix}\gtrdot\mathrm{CMe}$, is formed by the action of phenylhydrazine on acetylacetone: it boils at 270·5°. (Compare Claisen, Abstr., 1888, 692; and Zedel, 1051.)

N. H. M.

Derivatives of Methylpyrroline. By G. de Varda (*Ber.*, **21**, 2871—2874).—*Methyltetrabromopyrroline*, C_4NBr_4Me, obtained by digesting tetrabromopyrroline with caustic alkali and methyl iodide dissolved in methyl alcohol, crystallises from light petroleum in long, colourless needles, which melt at 154—155° to an intensely blue liquid.

Dibromomaleïnmethylimide, $C_4Br_2O_2NMe$, is prepared by slowly adding the above tetrabromide to fuming nitric acid (3 parts), cooled to 0°, and pouring the product into water (10 parts). It crystallises from boiling water in long, light-yellow needles melting at 121°. It distils readily with steam; the vapour has an irritating odour.

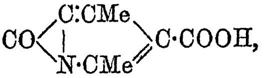
Methylpyrrylglyoxylic acid, $C_4NH_3Me{\cdot}CO{\cdot}COOH$, is obtained by treating a boiling solution of methylacetylpyrroline (5 grams) in alkaline water (500 c.c.) with a solution of potassium permanganate (15·5 grams) in water (500 c.c.). The whole is boiled, steam-distilled, and filtered; it is then evaporated down, acidified, and extracted with ether. The acid is crystallised from benzene, from which it separates in light-yellow needles which melt at 141—142·5° with decomposition; it is sparingly soluble. The *silver salt* was prepared. The *dibromo-derivative*, $C_4NHMeBr_2{\cdot}CO{\cdot}COOH$, prepared by brominating the acid dissolved in acetic acid, crystallises from benzene in small, sulphur-coloured prisms melting at 160°. When the dibromo-acid is slowly added to fuming nitric acid (10 parts), dibromomaleïnmethylimide is formed. The bromine-atoms and the $—CO{\cdot}COOH$ group have, therefore, the positions 3, 4, and 5 respectively.

N. H. M.

Derivatives of Unsymmetrical Dimethylpyrroline. By G. Magnanini (*Ber.*, **21**, 2864—2868, 2874—2879).—*Ethyl dimethylacetylpyrrolinecarboxylate*, $C_4NHMe_2Ac{\cdot}COOEt$ [2 : 4 : 5 : 3], prepared by heating ethyl hydrogen dimethylpyrrolinedicarboxylate (Knorr, *Annalen*, **236**, 318) with acetic anhydride at 200°, crystallises in needles, melts at 142—143°, dissolves very readily in alcohol, ether, acetic acid, and benzene, &c., sparingly in light petroleum. The *free acid* obtained by boiling the ethyl salt with aqueous potash, melts at about 152—158° with formation of *dimethylacetylpyrroline* and evolution of carbonic anhydride, is almost insoluble in boiling water, very sparingly soluble in ether, chloroform, and benzene, and readily soluble in hot acetic acid, from which it separates in long, lustrous needles. It gives a green coloration when heated with isatin and sulphuric acid.

Dimethylacetylpyrroline, $C_4NH_2Me_2Ac$ [= 2 : 4 : 5], is prepared by distilling dimethylacetylcarbopyrrolic acid in a retort heated in a metal-bath at 200°. It is first crystallised from water containing a little sodium carbonate, then from dilute alcohol, and lastly from light petroleum. It melts at 122—123°, sublimes at 100°, and is readily soluble in the usual organic solvents.

Dimethylpyrrolinedicarboxylic acid imineanhydride,



$$CO\left\langle\begin{matrix}C{:}CMe\\ |\\ N{\cdot}CMe\end{matrix}\right\rangle C{\cdot}COOH,$$

is obtained by boiling Knorr's unsymmetrical dicarboxylic acid (Abstr., 1887, 275) with acetic anhydride (10 parts) in a reflux apparatus for three to four hours. The acetic anhydride is distilled off under diminished pressure, the residue washed with alcohol, dissolved in aqueous sodium carbonate, filtered, and precipitated with acetic acid. It is almost insoluble in the usual solvents, becomes slightly brown at 300°, and decomposes at a higher temperature into dimethylpyrroline and dimethylpyrocoll. It resists the action of mineral acids, but seems to be partially decomposed by aqueous ammonia. The *silver salt* is a yellowish, amorphous substance; the *magnesium salt* forms lustrous needles. The *ethyl salt* crystallises in thread-like needles, melts at 270°, and is sparingly soluble.

2, 4-*Dimethylpyrocoll*, C_7H_7NO, obtained by distilling the copper or silver salt of the above acid in a stream of carbonic anhydride, is light yellow, melts at 272—272·5°, dissolves very readily in chloroform, readily in acetic acid, but only sparingly in ether, light petroleum, and cold alcohol; it is insoluble in water. The crystals are rhombic; $a : b : c = 0{\cdot}78834 : 1 : 0{\cdot}94602$. The compound is hardly attacked by aqueous potash. N. H. M.

Derivatives of Pyrrolinephthalide. By F. Anderlini (*Ber.*, **21**, 2869—2870).—*Dibromopyrrolinephthalide*, $C_{12}H_5Br_2NO_2$, prepared by treating a warm solution of pyrrolinephthalide (2 grams) in glacial acetic acid (15 grams) with bromine (8 grams), crystallises in small, yellow, lustrous needles, melts at 199°, is insoluble in water, sparingly soluble in boiling alcohol and ether.

Nitropyrrolinephthalide, $C_{12}H_6N_2O_4$, is formed when the phthalide is dissolved in strong nitric acid; it crystallises from alcohol in needles. When pyrrolinephthalide is treated with bromine in alkaline solution, tetrabromopyrroline and phthalic acid are formed. On similarly treating the dibromo- and nitro-derivatives, both compounds yield phthalic acid; the substituted radicles are therefore in the pyrroline nucleus.

When potassium pyrrolinephenylcarbinolorthocarboxylate,

$$C_4NH_3{:}C(OH){\cdot}C_6H_4{\cdot}COOK,$$

is distilled with potassium carbonate, it is decomposed into pyrroline and benzene. N. H. M.

Action of Methyl Iodide on some Pyrroline-derivatives. By G. Ciamician and F. Anderlini (*Ber.*, **21**, 2855—2864).—*Dihydrotetramethylpyridine*, $C_9H_{15}N$, is obtained, together with other bases, when sodium carbopyrrolate (5 grams), methyl iodide (10 grams), and methyl alcohol (7 grams) are heated at 120° for 12 hours. It boils at about 160°. The *aurochloride*, $C_9H_{15}N,HAuCl_4$, crystallises from very dilute solutions in long, flat, monoclinic needles; $a : b : c = 5\frac{1}{3} : 10 : 5\frac{1}{4}$; $\beta = 85\frac{4}{5}$. When the base is reduced with sodium and alcohol, the compound $C_9H_{19}N$ is formed. This boils at 150—152°. The *aurochloride* separates from its solution as an oil, which crystallises after some days in yellow needles melting at 117—119°. When the base $C_9H_{19}N$ is boiled with methyl iodide in a reflux apparatus, and the product, freed from the excess of methyl iodide, is dissolved in alcohol and precipitated with ether, the compound $C_{19}H_{18}NMe_2I$ is obtained in colourless prisms which melt at 262°. It is very readily soluble in water, insoluble in ether. The mother-liquor from the dimethyl compound contains a small amount of a *base*, $C_9H_{18}NMe$, which forms an oil.

Methyldihydropyrroline, $C_{10}H_{17}N$, is prepared by heating methylpyrroline (3 grams), methyl iodide (7 grams), potassium carbonate (3 grams), and methyl alcohol (5 grams), for 10 hours at 140°. The oily product is heated with strong hydrochloric acid at 125—130°, and distilled with potash. The *aurochloride*, $C_{17}H_{17}N,HAuCl_4$, crystallises from dilute hydrochloric acid in flat, yellow needles, which melt at 100°. N. H. M.

Dipiperidyl and Dipicolyl. By F. B. Ahrens (*Ber.*, **21**, 2929—2932).—*Dipiperidyl* is obtained when γ-dipyridyl is reduced with sodium and alcohol and the product purified by means of the nitroso-derivative. It crystallises in colourless needles, melts at 120—122° with previous softening, and is readily soluble in alcohol and ether, but insoluble in water. It absorbs carbonic anhydride when exposed to the air, and is only slightly volatile with steam. The *platinochloride*, $C_{10}H_{20}N_2,H_2PtCl_6$, forms microscopic crystals, is only sparingly soluble in water, and blackens when heated at 195°. The *aurochloride*, $C_{10}H_{20}N_2,HAuCl_4$, crystallises in small, yellow needles, is readily soluble in hot, dilute hydrochloric acid, and is gradually decomposed when heated at about 160°. The *picrate* crystallises from hot water in needles; it blackens when heated, and is completely decomposed at about 257°. Mercuric chloride, phosphomolybdic acid, and potassium ferrocyanide produce precipitates in a solution of the hydrochloride.

Dipicolyl, $C_{12}H_{12}N_2$, is obtained when picoline, boiling at 128—134°, is treated with sodium at 80—90°. After washing the product with water, it is dissolved in ether, the solution filtered, and the base extracted with dilute hydrochloric acid. The extract is mixed with excess of soda, the treatment with ether and hydrochloric acid repeated several times, and finally the ethereal solution is dried over potash and evaporated. The residual yellow oil is then distilled, and the portion passing at 270—300° collected; this distillate solidifies to a mass of yellowish, very deliquescent needles. The *platinochloride*, $C_{12}H_{12}N_2,H_2PtCl_6$, crystallises in small plates, and is very sparingly soluble in water, but readily in hydrochloric acid; it is only partially decomposed when heated at 275°. The *aurochloride*,

$C_{12}H_{12}N_2,HAuCl_4$, separates from warm, concentrated hydrochloric acid, in which it is readily soluble, in nodular crystals mixed with metallic gold; it is completely decomposed when heated at 200—201°. The *picrate* forms yellow, moss-like crystals, and is readily soluble in hot water. An aqueous solution of the hydrochloride gives precipitates with mercuric chloride, phosphomolybdic acid, potassium iodide, and potassium ferrocyanide. F. S. K.

Action of Chlorine on Hydroxyquinoline. By H. HEBEBRAND (*Ber.*, **21**, 2977—2989).—*Chlorhydroxyquinoline*, C_9NH_6OCl, is formed in small quantities when chlorine is passed into a well-cooled solution of 1-hydroxyquinoline (5 grams) in glacial acetic acid. Dichlorhydroxyquinoline (see below) separates at first, and is further converted into the hydrochloride whilst a further portion of the hydroxyquinoline is oxidised to the monochloro-derivative. As soon as the whole of the hydroxyquinoline is changed, the solution is filtered and the residue treated with absolute alcohol to dissolve the dichlorhydroxy-salt. The residue is dissolved in hot, dilute hydrochloric acid, the solution mixed with excess of sodium carbonate, and the precipitated monochlorhydroxy-compound recrystallised from methyl alcohol and light petroleum. It is thus obtained in colourless needles melting at 129—130°. The *hydrochloride* crystallises in small, yellow needles, melts at 253°, and is moderately soluble in alcohol and hot, dilute hydrochloric acid; it is very stable and sublimes in compact crystals. The *platinochloride*, $(C_9NH_6OCl)_2,H_2PtCl_6 + 2H_2O$, crystallises in yellow needles, and is readily soluble in hot but only sparingly in cold, dilute hydrochloric acid.

Dichlorhydroxyquinoline, $C_9NH_4Cl_2{\cdot}OH$ [$OH : Cl_2 = 1 : 2 : 4$], is prepared by passing chlorine into a 10 per cent. glacial acetic acid solution of hydroxyquinoline until the colour changes to yellow, pouring the solution into water, and recrystallising the precipitated product from alcohol. It is also obtained when trichloroketoquinoline (see below) is treated with hydrogen sodium sulphite or boiled with alcohol or dilute acids. It crystallises in long, slender needles, melts at 179—180°, and is readily soluble in warm alcohol or glacial acetic acid, but only moderately in hot benzene and light petroleum. It dissolves readily in alkalis and acids, forming yellow solutions, but the salts are unstable and cannot be recrystallised, and acid solutions are precipitated by water. When treated with chlorine in chloroform solution, it is converted into trichloroketoquinoline. The *hydrochloride* crystallises in long, yellow needles, and in aqueous solution gives a black precipitate with ferric chloride. The *platinochloride*, $(C_9NH_5OCl_2)_2,H_2PtCl_6 + 2H_2O$, crystallises in long, orange needles, and loses its water at 120°. The *acetyl*-derivative, $C_9NH_4OCl_2Ac$, separates from light petroleum in small, colourless crystals melting at 97—98°; it is very unstable, and is decomposed by water or when boiled for a long time with glacial acetic acid.

Trichlorhydroxyquinoline, [$OH : Cl_3 = 1 : 2 : 3 : 4$], is formed when the mother-liquor from trichloroketoquinoline is boiled or when the hydrochloric acid solution of pentachloroketoquinoline is treated with hydrogen sodium sulphite or with water. It crystallises from glacial acetic acid in long, colourless, moss-like needles, melts at 213—214°, and is readily soluble in hot alcohol or glacial acetic acid, but only sparingly in the cold solvents and in dilute acids; it is readily soluble in concentrated acids, but is reprecipitated on adding water. When treated with chlorine in chloroform solution, it yields a yellow powder, probably tetrachloroketoquinoline, which melts at 175° with decomposition, and is reconverted into trichlorhydroxyquinoline when boiled with alcohol. When heated with sodium carbonate, it yields a *sodium*-derivative melting at 270°. The *potassium*-derivative is crystalline. The *hydrochloride* crystallises in small, yellow needles. The *platinochloride*, $(C_9NH_4Cl_3O)_2,H_2PtCl_6 + 2H_2O$, crystallises from dilute hydrochloric acid in long, orange needles and loses its water at 140—150°. The *acetyl*-derivative separates from a mixture of glacial acetic acid and acetic anhydride in thin, transparent, forked, efflorescent crystals, melts at 172—173°, and is readily decomposed.

Trichloroketoquinoline hydrochloride, $C_9NH_4OCl_3,HCl + 2H_2O$, prepared by saturating a well-cooled glacial acetic acid solution of hydroxyquinoline with chlorine and washing the product with glacial acetic acid, is very unstable, hygroscopic, and sensitive to light. When simply dried between blotting paper, it melts at 93—95° to a yellow liquid which decomposes at 100—120° with evolution of gas and then solidifies, melting again at 170—180° with decomposition. When dried over sulphuric acid under reduced pressure, it does not begin to decompose until heated at 160° and melts at 180°. It is readily soluble in moderately dilute hydrochloric acid, but when the solution is evaporated under reduced pressure dichlorhydroxyquinoline separates. It is decomposed when warmed with solvents, generally with formation of the dichlorhydroxy-derivative, and this substance is formed very readily when the keto-derivative is reduced with hydrogen sodium sulphite. The *platinochloride* is very readily soluble, and when the solution is boiled or evaporated under reduced pressure, a mixture of platinochlorides is obtained. The free *base*,  $C_5NH_4{<}\begin{matrix}CO\cdot CCl_2\\ CCl{:}CH\end{matrix}{>}$, obtained by decomposing the hydrochloride with water and extracting the precipitated oil with ether, crystallises in long, thin, yellow prisms or needles, melts at 98°, turns brown at 130°, and is completely decomposed at 170°. It is readily soluble in benzene, alcohol, and glacial acetic acid, and does not decompose when kept.

Ethoxydichlorhydroxyquinoline, $OEt\cdot C_9NH_3Cl_2\cdot OH$ [$OH : Cl_2 : OEt = 1 : 2 : 4 : 1'$], is formed, together with dichlorhydroxyquinoline and a small quantity of the trichloro-derivative, when an alcoholic solution of freshly prepared trichloroketoquinoline is boiled for 1—2 hours. It crystallises from alcohol or benzene in long, thin, colourless needles, melts at 150—151°, and dissolves sparingly in most ordinary solvents in the cold but readily on warming. It is soluble in acids, forming colourless solutions, from which it is reprecipitated by water, and when warmed with alcoholic soda, it yields a solution from which a spongy sodium-derivative separates on cooling.

Dihydroxydichloroquinoline, [$(OH)_2 : Cl_2 = 1 : 1' : 2 : 4$], is obtained, together with ethyl chloride, when the preceding compound is heated at 110—120° with concentrated hydrochloric acid; it is also formed when trichloroketoquinoline is boiled with methyl alcohol. It crystallises from alcohol in needles, melts at 278°, and is more sparingly soluble than the chloro-derivatives of hydroxyquinoline. It crystallises from methyl alcohol in efflorescent needles containing alcohol.

Anilidoquinolinequinoneanilide,  $C_5NH_3<\begin{matrix}CO{\cdot}C(NPh)—\\C(NHPh){:}CH\end{matrix}>$, is obtained by treating an alcoholic solution of the ketochloro-derivative with excess of aniline. It crystallises in small, golden plates or long needles, melts at 222°, and shows all the properties of a feeble base. It is moderately soluble in glacial acetic acid, sparingly in alcohol, insoluble in water, and dissolves in dilute acids with a bluish-violet coloration. It is not changed by boiling with alcohol or concentrated potash, but is readily decomposed when heated with acids, yielding a yellow, crystalline substance which was not obtained in the pure state. The *hydrochloride* crystallises from acidified alcohol in small, dark-golden needles and is unstable. The *picrate* crystallises from alcohol in dark, copper-red needles. The *acetate* crystallises in needles, melts at 199°, and is decomposed by water.

Pentachloroketoquinoline platinochloride, $(C_9NH_3Cl_5O)_2,H_2PtCl_6$, is formed when trichloroketoquinoline hydrochloride (5 grams) is heated at 140—150° for six hours with manganese dioxide (35 grams) and concentrated hydrochloric acid (18 grams), the resulting solution filtered and mixed with platinic chloride. It is a yellow, crystalline compound, and when recrystallised or dried, it seems to lose hydrogen chloride and be converted into the salt of tetrachloroketoquinoline. A solution of pentachloroketoquinoline hydrochloride yields trichlorhydroxyquinoline when mixed with water or hydrogen sodium sulphite.

F. S. K.

Alkaloïds from Papaveraceæ. By E. SCHMIDT (*Arch. Pharm.* [3], **26**, 622—623).—The following abstract is the first of a series on these alkaloïds, giving the results of investigations undertaken at the instance of the author. Schiel's conclusion that chelerythrine and sanguinarine are identical is not confirmed. The former appears to have the formula $C_{19}H_{17}NO_4$, as deduced from the analysis of the small quantities obtained, whilst the latter, from the analysis of various compounds, has the formula, $C_{17}H_{15}NO_4$, thus confirming Naschold's result. Three more bases have recently been separated from *Chelidonium majus* which are now the subject of research.

J. T.

Chelidonine. By A. HENSCHKE (*Arch. Pharm.* [3], **26**, 624—644; compare Abstr., 1887, 854).—The alkaloïd was obtained partly by recrystallisation of the commercial base, and partly by direct extraction from the root of *Chelidonium majus*. Probst's method of extraction was employed, the stamped root being boiled in water acidified with sulphuric acid, ammonia in excess added, and the filtrate dried. This was purified by treatment with acidified alcohol, and again with ether, and finally was repeatedly crystallised from boiling alcohol. Chelidonine, $C_{20}H_{19}NO_5 + H_2O$, forms vitreous, tabular, colourless, monoclinic crystals of about 3 mm. diameter. The reactions of the base are given in detail. Solutions of the salts of this base have an acid reaction, and the hydrochloride has the formula $C_{20}H_{19}NO_5\cdot HCl$; the nitrate, $C_{20}H_{19}NO_5,HNO_3$; the sulphate, $C_{20}H_{19}NO_5,H_2SO_4 + 2H_2O$; the platinochloride, $(C_{20}H_{19}NO_5)_2,H_2PtCl_6 + 2H_2O$; this was not obtainable in a crystalline form; the aurochloride, $C_{20}H_{19}NO_5,HAuCl_4$, is easily obtained in crystals. Ethyl iodide combines with the base, and the compound is not acted on by potassium hydroxide; these and less positive results lead to the conclusion that chelidonine is a tertiary base. By oxidation with potassium permanganate in alkaline solution, chelidonine yields oxalic acid, methylamine and ammonia, the latter resulting from the decomposition of methylamine. In acid solution, the oxidation goes further, carbonic anhydride and methylamine resulting. J. T.

Alkaloïds from Cod-liver Oil. By A. GAUTIER and L. MOURGUES (*Compt. rend.*, **107**, 626—629; compare Abstr., 1888, 1315).—*Aselline*, $C_{25}H_{32}N_4$, is an amorphous, colourless solid which becomes green on exposure to light. It melts to a viscous, yellowish liquid with an aromatic odour recalling that of the ptomaïnes, is very slightly soluble in water, to which it imparts a bitter taste and an alkaline reaction, but dissolves in ether and still more readily in alcohol; sp. gr. about 1·05. The salts of aselline crystallise readily, but are partially decomposed by water. The mercurochloride crystallises from warm water; the aurochloride is very easily reduced; the platinochloride is orange-yellow, and dissolves in warm water, but is decomposed by boiling water. Aselline is feebly toxic, and produces fatigue and stupor; 3 mgrms. of the hydrochloride killed a greenfinch in 14 minutes.

Morrhuine, $C_{19}H_{27}N_3$, is separated from aselline by taking advantage of the greater solubility of its platinochloride. It is a thick, oily, amber-coloured liquid with an odour which recalls that of aselline, and is only slightly soluble in water, but more soluble in alcohol and ether. It is caustic and strongly alkaline, and absorbs carbonic anhydride from the air. The hydrochloride is very deliquescent; the aurochloride is yellow, and dissolves in warm water; the platinochloride is somewhat soluble and crystallises in needles.

Morrhuine constitutes one-third of the total bases in the oil, and an ordinary dose of one fluid ounce contains 2 milligrams. It excites the appetite and has remarkable diaphoretic and diuretic properties. In large doses it produces fatigue and stupor. C. H. B.

Physiological Chemistry.

The Nature of Fibrin Ferment. By W. D. HALLIBURTON (*J. Physiol.*, 9, 227—286).—This paper gives a full account of the researches of which a preliminary account has already been published (Abstr., 1888, 974). W. D. H.

The Glycogen in Muscle after Section of its Nerve and its Tendon. By E. KRAUSS (*Virchow's Archiv*, **113**, 315—332).—The first part of this paper is devoted to the histological changes that occur in muscle after neurotomy and tenotomy respectively.

For the glycogen estimations, the tendo Achillis was divided in 21 rabbits, and the sciatic nerve in 16 others. The animals were then fed for 1 to 3 days before death with 15—30 grams of sugar dissolved in water. The glycogen was determined by Külz' method (Abstr., 1886, 494). The animals were killed at different periods varying from 2 to 124 days after the operation.

The results of analysis, given in tabular form, show after neurotomy an increase of glycogen in 8, a normal amount in 3, and a decrease in 4 cases; after tenotomy an increase in 6, a normal amount in 8, and a decrease in 2 cases. The general result is therefore that in the pathological condition of muscle produced by section of its nerve or of its tendon, metabolism is altered in such a way that glycogen is not got rid of so easily as in healthy muscle. W. D. H.

Lactic Acid in the Blood. By G. SALOMON (*Virchow's Archiv*, **113**, 356—360).—Gaglio (*Arch. Anat. Physiol.*, *Phys. Abth.*, 1886, 400), and Berlinerblau (Abstr., 1888, 974) have described lactic acid as a constituent of blood. The author has for some years made similar observations in cases of disease. Thus in a specimen of leucæmic blood he found 0·05—0·06 per cent. of lactic acid; in pleural exudation from a case of carcinoma, there was a percentage of 0·007. In both cases, estimation of the water of crystallisation, and of the zinc in the zinc salt showed that sarcolactic acid was the particular form of lactic acid that was present.

More extended observations, however, have shown that lactic acid in the blood is not characteristic of the diseases mentioned, but can be obtained from the blood of patients who have died from nearly every variety of disease. Observations on the blood removed from the vessels during life show, however, that lactic acid is then as constantly absent as it is present in the blood examined after death.

If the blood is examined immediately it is drawn, lactic acid is found to be absent, but if the blood is allowed to stand a short time and then examined, the acid will then be found. Its formation is connected with the ferment actions that set in in shed blood, or in blood left in contact with dead tissues. If it is formed at all during life, it must be rapidly oxidised, and so cannot be discovered in living blood. W. D. H.

Micro-organisms and Proteolytic Digestion. By V. D. HARRIS and H. H. TOOTH (*J. Physiol.*, 9, 220—226).—The experiments of which this is a preliminary account gave the following results:—

(1.) The general belief that micro-organisms need take no part in gastric digestion, and are generally absent was confirmed.

(2.) Experiments to prove that micro-organisms are themselves competent to convert proteïds into peptone were very unsatisfactory; albumoses have been noticed, but never true peptone. Perhaps some special micro-organism is necessary.

(3.) As it was found exceedingly difficult to exclude micro-organisms in pancreatic digestions by employing strictly the principles of Listerian surgery in the removal of the pancreas, the organisms were killed by the addition of antiseptic reagents, of which mercuric chloride and phenol were found to be the most effective. It was found that the tryptic ferment is able to convert proteïds into peptone without the aid of micro-organisms, although that is no proof that the micro-organisms do not assist in the action in the intestine. Phenol, however, either prevents the pancreatic ferment from forming leucine and tyrosine, or else the formation of these substances depends in part at all events on bacteria.

(4.) With regard to the production of indole, it was found that the appearance of indole and its allies in alkaline pancreatic fluids is very capricious and can be easily prevented. In plugged flasks, it may not appear for a considerable time, no other precaution being taken than that of simply plugging the flasks, micro-organisms being present in large numbers. The smallest amount of mercuric chloride or phenol, even if not sufficient to render the liquid aseptic, also prevents the formation of these substances. Indole appears most readily in the digestion of uncoagulated (unboiled) proteïds. Whenever it is present, large numbers of all sorts of bacteria are there also, still it may be absent even if swarms of micro-organisms are present. It thus appears that there are special indole-forming organisms. Experiments with pure cultivations of the different forms of bacteria found are, however, at present incomplete. As a result of inoculation of solutions of pure peptone, and of solutions of leucine and tyrosine with a mixture of bacteria potent to cause the formation of indole, it was found that indole is formed from the peptone, not from leucine or tyrosine. It seems, therefore, likely that the formation of indole and its allies in the alimentary canal below the stomach is an alternative course for the excretion of nitrogen to that by the formation of leucine and tyrosine. W. D. H.

Glycogen in Diabetic Urine. By W. Leube (*Virchow's Archiv*, **113**, 391—393).—E. Reichardt (*Zeit. anal. Chem.*, 1875) has described "dextrin" as occurring in diabetic urine. Glycogen has, however, never been detected before. Two cases were examined in the present research. A large amount of urine (3—5 litres) was precipitated with alcohol, the precipitate collected and washed free from sugar. The precipitate was then dissolved in water, and the solution gave a brown colour with iodine; on boiling the solution with 10 per cent. of sulphuric acid, the carbohydrate (probably glycogen) was converted into dextrose. In one of the two cases, the amount of glycogen present was very small. It is considered probable that the sugar in the blood is partly converted into glycogen as it passes through the epithelium of the urinary tubules. W. D. H.

Aromatic Substances in Febrile Urine. By J. S. Haldane (*J. Physiol.*, **9**, 213—219).—Diseases and conditions of the body where putrefactive changes are greater than normal, cause the appearance of an increased quantity of certain aromatic substances, phenol, cresol, indole, scatole, &c., in the urine.

Brieger (*Zeit. klin. Med.*, 3, 465) classes, however, scarlet fever and diphtheria as putrefactive diseases with erysipelas and pyæmia in which putrefactive processes no doubt often go on. It seemed advisable therefore to repeat these observations with regard to scarlet fever and diphtheria, especially as Brieger's method, which consisted in weighing the phenol as tribromophenol, was found to be wanting in accuracy. It was found that the more concentrated the urine, the greater was the quantity of tribromophenol obtainable from it, on account of the solubility of the bromine-water precipitate. In fact, on comparing Brieger's results with control experiments performed with a urine concentrated to different extents, it was found that the increase in phenol as described by Brieger in scarlet fever and diphtheria, could be equally well explained by the rise of the specific gravity of the urine in those diseases. The method adopted was therefore that of estimating the proportion of sulphuric acid combined as ethereal hydrogen sulphates to that combined as ordinary sulphates. Taking the normal proportion as 1 to 10, it was found in 16 cases of scarlet fever in which the urine was passed during the fever to be 1 to 17, and in 13 cases in which the urine was passed during the first three days of convalescence to be 1 to 21: so far as the chemical composition of the urine goes, there is thus no ground for regarding scarlet fever as analogous to a putrefactive process.

The average of the ratio in five analyses made in cases of diphtheria was 1 to 13, hence in these cases also there was no increase in the elimination of aromatic substances. W. D. H.

Physiological Action of Para- and Meta-phenylenediamine. By R. Dubois and L. Vignon (*Compt. rend.*, **107**, 533—535).—Meta- and para-phenylenediamines are similar in constitution to the ptomaïnes and leucomaïnes, and their physiological action is therefore of considerable interest.

In doses of 0·1 gram per kilo. of body-weight, both compounds produce salivation, vomiting, diarrhœa, excessive emission of urine, and coma. Death follows in two to three hours in the case of the para-derivative and in 15 hours with the meta-derivative. The compounds remove oxygen from the blood and tissues in the same way as micro-organisms which are rapidly multiplying, and the brownish products thus formed impart a dark colour to the blood and tissues.

Metaphenylenediamine produces in the dog all the symptoms of aggravated influenza, with continual sneezing and a hoarse cough, which ends in coma and death. Paraphenylenediamine produces very remarkable exophthalmia, the tissues of the eye undergoing complete alteration. C. H. B.

Chemistry of Vegetable Physiology and Agriculture.

Action of Micro-organisms on certain Colouring Matters. By J. RAULIN (*Compt. rend.*, **107**, 445—447).—*Aspergillus niger* will grow in cultivation liquids containing ammonium nitrate, but not in similar liquids containing salts of aniline, rosaniline or indigocarmine.

Slightly acidified yeast solution, beer wort, and sugar solution tinted with indigocarmine, slowly decolorise in presence of air and in absence of all organisms, but this change is due to oxidation and does not take place in an atmosphere of carbonic anhydride. Certain aërobic organisms retard or prevent decolorisation by preventing the access of oxygen.

Active beer-yeast also decolorises indigocarmine in absence of oxygen, but decolorisation is due to reduction and the colour returns if the liquid is exposed to air. In this case, reduction is accompanied by the development of micro-organisms similar in appearance to the lactic ferment. The change takes place most rapidly if the yeast solution has been exposed to the air at 24° for several days; it then acquires a putrid odour and is full of bacteria. The rate of decolorisation increases with an increase in the number of organisms, and the addition of an antiseptic, or any other cause which destroys the organisms, prevents the changes. Reduction is due to changes connected with the vital processes of the organisms, and is not due to the liberation of hydrogen. It is not analogous to the reduction of indigocarmine by an alkaline solution of glucose, since in that case the presence of organisms is not essential.

Similar reducing actions were observed with logwood, orchil, cochineal, safranin, and several artificial colouring matters.

C. H. B,

Decolorisation of Tincture of Turnesole in closed Vessels. By R. DUBOIS (*Bull. Soc. Chem.*, **49**, 963—964).—The decolorisation of turnesole kept in a closed vessel is entirely due to the action of germs, as when the solution is sterilised the blue colour is permanent. The colourless solution contains only one species of living organisms; this is a very small, completely spherical micrococcus, which can be cultivated in slightly alkaline peptonised gelatin. The liquid decolorised by these micro-organisms at once regains its blue colour on exposure to the air. F. S. K.

Formation of Starch from Various Substances. By T. BOKORNY (*Chem. Centr.*, 1888, 858—859, from *Ber. deut. bot. Ges.*, **6**, 116—120).—Since earlier experiments had proved that algæ can be fed with methylal, the author has shown, by means of further experiments, that starch is formed from methylal. Spirogyra were used as the material for the investigation. Whilst in the absence of light, the formation of starch could not be observed, its formation could be readily detected after the spirogyra had lain in 1—0·1 per cent.

methylal in the sunlight. Spirogyra fed on solution of methyl alcohol of the same strength, namely, 1—0·1 per cent., showed at the end of 6 to 24 hours a very considerable new formation of starch. The author finds that glycol and glycerol, like mannitol, are also able to form starch. J. W. L.

Matter Excreted by Roots. By H. Molisch (*Ann. Agronom.*, **14**, 334—335).—It is known that roots excrete an acid juice capable of attacking minerals. The author finds that the liquid has much more extensive powers, namely, it has both reducing and oxidising properties; turns tincture of guaiacum blue; oxidises tannins and humic substances, and consequently promotes the decomposition of humus: transforms cane-sugar into reducing sugar, and acts feebly like diastase; corrodes a plate of ivory; and modifies the organic matter of soil. The root membranes are not simply permeated with this juice, it may sometimes be seen to exude in droplets.

J. M. H. M.

Occurrence of Solid Hydrocarbons in the Vegetable Kingdom. By H. Gutzeit (*Ber.*, **21**, 2881—2882. Compare Abbot and Trimble, Abstr., 1888, 1329).—The author points out that he has already described solid hydrocarbons which were obtained from the fruit of *Heracleum giganteum hort.*, *Heracleum spondylium*, L., and *Pastinaca sativa*, L. (*Beiträge zur Pflanzenchemie*, Jena, 1879), and that others have already proved the presence of such compounds in the vegetable kingdom. F. S. K.

Constituents of Bark of Rhamnus Frangula and R. Purshiana. By P. Schwabe (*Arch. Pharm.* [3], **26**, 569—594).—The coarsely powdered bark is freed from fat by means of ether, and extracted with 98 per cent. alcohol; the extract is mixed with several times its volume of water, and is shaken up by portions with ether. The first ethereal solutions are dark coloured, but on repeating the operation 10 or 12 times the ether remains colourless. The united ethereal solutions are distilled, when a light-yellow deposit forms in thin layers on the side of the vessel. The deeply coloured mother-liquor is filtered after remaining 24 hours. The residue on the filter is repeatedly washed with alcohol and ether, and finally crystallised several times from boiling alcohol, until the microscope shows distinct crystallisation, undoubtedly due to frangulin. The mother-liquor filtered from frangulin was brought to dryness, taken up with a little alcohol, mixed with several times its weight of water and again shaken up with ether, but only once or twice; in this way the beautifully crystalline body emodin (trihydroxymethylanthraquinone) was separated. On distilling off the ether, the residue is readily seen under a lens to be permeated with crystals. This is heated with glacial acetic acid, in which it readily dissolves, and on cooling emodin crystallises out. Recrystallisation yields emodin as a light red crystalline mass, which melts at 254°. The yield was frangulin 0·06 per cent., and emodin 0·10 per cent. Fresh bark gave no frangulin, thus confirming an observation previously made by Casselmann; whilst bark a year and a-half old gave frangulin 0·04 per cent., and emodin 0·10 per cent. as before. *Emodin*, $C_{15}H_{10}O_5 + H_2O$, gives red to brown-red amorphous precipitates with the alkaline earths and with lead, copper, and mercury salts. It dissolves in dilute alkalis to a splendid dark cherry-red colour, but gives no crystals on evaporation. A solution in alcoholic potash, heated at 100° in a sealed glass tube, showed fine needle-like aggregates after standing unopened for 24 hours. *Frangulin* melts at 228° to 230°, whilst Casselmann puts it at 249° and Faust at 226°, the differences being due to impurity in the last two cases. It is almost insoluble in water and ether, more easily in chloroform, benzene, and alcohol, and very soluble in hot acetic acid. When dry, it forms a beautiful, light-yellow, brittle mass, with somewhat silky lustre. Its composition is $C_{21}H_{20}O_9$. Four to five hours' boiling with 20 per cent. sulphuric acid converts it into emodin and glucose. If anywhere, frangulinic acid should make its appearance here, but the compound previously described under this name is identical with emodin.

The coarsely powdered root of *Rhamnus purshiana* (*Cascara sagrada*) was extracted with ether, and then with 98 per cent. alcohol. After the addition of water, the ether extract was shaken repeatedly with light petroleum until the oily extracts became almost colourless. On removing the petroleum, the dark-coloured mother-liquor gave an immediate brown-red, flocculo-crystalline precipitate. As in the case of *Rhamnus frangula* bark, the alcoholic extract shaken up with ether after the addition of water afforded a crystalline product. The petroleum product which proved to be identical with this, was found to be emodin. Frangulin was not present, although it may possibly occur in older bark. J. T.

Japanese Tobaccos. By M. Fesca and H. Imai (*Bied. Centr.*, 1888, 629—637).—The authors analysed the soils and the tobaccos produced in a locality in Oyamada, and also one other Japanese tobacco. Permeability and a certain amount of humus are far more important as regards the soil than the amount of plant food, as the latter can be supplied by manuring. The best tobacco soil exhibited only a moderate absorptive power for bases. The manures applied are human and animal excreta, wood and straw ashes, and bath-water. As regards analysis as a means of judging the quality of a tobacco, the authors came to the following conclusions:—(1.) Just as an alcoholic drink should contain a certain percentage of alcohol, so a tobacco should contain a certain percentage of nicotine; but that the quality of a tobacco depends on the percentage of the nicotine has not yet been proved. (2.) Nitric acid is not contained in well-fermented tobaccos. (3.) The ammonia in the older analyses was too high, as it included some that came from amides. The ammonia, which only comes to some tenths of a per cent., cannot account for lowered quality. (4.) The amount of albuminoïds, reckoned as it formerly was, without allowing for the amide-nitrogen present, affords no standard for judging tobacco. The worst tobacco analysed had the lowest total nitrogen, yet owing to the nicotine and amides being very low, it had the highest amount of albuminoïds. (5.) Amide nitrogen for the most part indicates the presence of compounds which do not injure and perhaps even enhance the quality of the tobacco. One of the most important duties of the fermentation is to change albuminoïds into amides. (6.) The determination of the amount of substances that ether extracts is of but little use. (7.) Carbohydrates, with the exception of cellulose, should not be present in well-fermented tobacco. A study of their decomposition, and of the formation and decomposition of organic acids and of amides should prove useful in determining the quality and guiding the culture and treatment of tobacco. (8.) Distinctions as to quality can only be drawn when the differences in the amounts of the substances estimated are considerable, and they can only be made safely when the whole composition proves quite satisfactory or quite the reverse; they can rarely be drawn from differences in the amounts of single substances. Inferiority can be more safely inferred than superiority. In very bad tobacco, the albuminoïds, the sulphuric acid, the chlorine and generally the mineral acids are high, whilst the amide nitrogen and the potash are low.

The remaining conclusions relate to the ash constituents. (9.) To indicate good quality and especially combustibility, there should be a medium amount of bases, especially of potash and lime. Within certain limits these bases appear capable of replacing one another. The percentage of one or the other must fall very low before it is to be regarded as a bad indication. Magnesia, if exceptionally high, appears to injure the combustibility. (10.) Mineral acids if high indicate bad combustibility; but they must be exceptionally high to surely indicate low value. Apart from silica, phosphoric acid appears to be the least injurious, chlorine considerably more, and sulphuric acid the most injurious to the quality and combustibility. (11.) The bases soluble in water and either free or existing as carbonates, appear to have no important influence, but the amount of carbonic anhydride up to a certain point indicates increased combustibility, and a large amount of carbonates in proportion to mineral salts indicates good value. (12.) A high proportion of bases in the ash, provided it is not caused by magnesia or iron, points especially to good combustibility.

H. H. R.

Formation of Nitrates in Soils of different Degrees of Fertility. By P. P. DEHÉRAIN (*Ann. Agronom.*, **14**, 289—320).—It appears probable, from the researches of Lawes and Gilbert, Warington, and others, that a soil exhausted by cropping contains only nitrogenous organic matter difficult to nitrify, and that the relative sterility which is produced by a number of successive crops without manure, is due not only to a decrease in the total amount of nitrogen, but also to the residual nitrogenous matter being less apt to nitrify than that in a fertile soil. To obtain confirmation of this, the author has studied the rate of nitrification in different soils, fertile and exhausted, manured and unmanured, under different conditions of humidity, temperature, division, &c. A few only of the results, most of which are provisional and require further elucidation, are given below. A saturated atmosphere is ultimately unfavourable to nitrification; probably because moulds are encouraged which destroy the nitrate. Soil very finely sifted, placed in a funnel, and submitted to frequent waterings, so as to alternate periods of comparative dryness and moisture, is very favourably circumstanced for nitrification; for example, in the 189 days from 17th May to 22nd November, there was formed per 1000 kilos. of soil, 880 grams nitric acid: reckoning the weight of the soil at 3600 tonnes per hectare, this would give 819·8 kilos. nitrogen per hectare nitrified in that space of time, a quantity infinitely superior to the requirements of the most exhausting crop. The waterings in this experiment were equivalent to five times the normal rainfall. The accumulation of nitrate in the soil, at any rate to the extent of 700 mgrms. per kilo., does not retard the rate of nitrification. The organic matter was more nitrifiable at the commencement of the experiment than afterwards, since much more nitrate was formed in the first 27 days than in any subsequent similar period, notwithstanding the lower temperature of this first month as compared with the two following. Again, in the December to January period more nitrogen was nitrified per diem than in the October to November period, in spite of the lower temperature; from this the author infers that the organic matter of the soil is subject from time to time to changes rendering it more or less easy of nitrification. Trituration of the soil and elevation of temperature were both found to greatly accelerate nitrification. The addition of sodium nitrate to the soil in quantities of 0·06 and 0·60 per cent. almost prevented nitrification for the first 40 days, and greatly retarded it during a subsequent like period, although eventually nitrification at something like the normal rate occurred; the addition of 1 : 1000 of common salt to the soil exercises little or no effect, 2·5 : 1000 is injurious, and 5 : 1000 prevents nitrification.

Three soils, long unmanured and poor in nitrogen, developed very little nitrate for some weeks after being placed in circumstances the most favourable for nitrification, but afterwards fairly rapid nitrification set in, which the author attributes to changes undergone by the organic matter under the new conditions. A fourth poor soil, unmanured and equally poor in nitrogen with the other three, proved, however, very nitrifiable, it developed from the first more nitrate than a fertile soil placed in the same conditions. J. M. H. M.

Loss and Gain of Nitrogen in Agriculture. By B. FRANK (*Bied. Centr.*, 1888, 610—617).—Among the sources of loss is the volatilisation of ammonia from the soil. In some experiments in which ammonium sulphate solution was added to samples of soil, the author found that the ammonia thus added soon disappeared, being to a small extent converted into nitrates whilst the greater part volatilised. A light and pure sandy soil does not expel the ammonia and has only a feeble nitrifying power, so that the ammonium salt is retained nearly undiminished for a long time. Of the individual constituents, quartz grains and clay are inactive, whilst calcium carbonate causes both slow nitrification and also partial liberation of ammonia. Another source of loss was mentioned by Boussingault, namely, that when nitrates were given to plants growing in the dark, there was a liberation of free nitrogen, which he attributed to the action of some organic substance excreted by the roots. The author experimented on the point, growing bean seeds in the dark in nutritive solutions, both with and without nitrogen compounds. As in every case there was a loss of nitrogen, it could not be due to reduction of nitrates, and he attributes it to the loss of nitrogen consequent on the decay of those parts of the seed not made use of by the germinating plant.

Next, treating of the gain of nitrogen, he combats Hellriegel's view that the root nodules of the Leguminosæ are concerned in rendering free nitrogen available to the plant. His own experiments lead him to the conclusion that the land gains in combined nitrogen in some way besides that caused by lightning discharges, which at present is the only one undisputed. He found that the presence of vegetation raised the amount of this gain, that this could not be accounted for by the ammonia of the air, and that it must be derived from the free nitrogen of the air. The gain rises with increased plant development, and both the kind of soil and the species of plant have an influence. Lupines are very effective as compared with non-leguminous plants; but the difference in the powers of increasing the combined nitrogen is one of degree, not one of kind; hence it cannot be ascribed to the nodules. Further, nodules did not occur in lupines grown in sterilised soil, yet the plants developed better than in a parallel experiment with unsterilised soil where the plants had nodules, and besides the nodules the legumes have no other organs to supply nitrogen which other plants do not also possess. The next question is how soil unoccupied by a crop gains in combined nitrogen. This gain takes the form chiefly or entirely of organic nitrogen compounds, thus agreeing with Berthelot's experiments, and is explained by the growth in the soil of the cryptogamic plants, algæ containing chlorophyll and allied forms which the author discovered there. He next discusses the question whether these plants avail themselves of free nitrogen or of nitrogen oxidised in the soil by an inorganic process. He asserts that under the influence of calcium or magnesium carbonates free nitrogen can be oxidised to nitric acid, the action being distinct at 100°, still apparent at 45—50°, and no longer apparent at 15—22°, but thinks that in the German climate this action can only very rarely occur. He concludes that it is not an inorganic process that makes the free nitrogen available, but that the combined nitrogen is due to a development of plant cells containing albuminoïds which is not to be connected with any process occurring in the soil. This power of assimilating free nitrogen is very different for different plants; the result is smallest in fallow land, where only the lower plant forms are at work; it is larger with higher plant forms, and among these the lupines and probably other Leguminosæ produce the greatest result.

H. H. R.

Action of Superphosphate on Nitrates. By A. DEVARDA (*Chem. Centr.*, 1888, 899—900).—Experiments by the author go to show that, at the ordinary temperature, the phosphoric acid, hydroflouric acid, and readily decomposable organic compounds, as well as ferrous salts present in superphosphates, cause no loss of nitrogen from nitrates which may have been mixed with them. In those cases, however, where the mixtures are exposed to a moderately high temperature, the loss of nitrogen is considerable, although in this

case the ferrous compounds take no part in the reaction. The author also found that in mixtures of superphosphate and nitrates the soluble phosphate becomes insoluble much more quickly than when the nitrate is omitted, and the mixing of nitrate with superphosphate for any length of time is therefore not to be recommended.
J. W. L.

Analytical Chemistry.

Preparation of Starch Solution for Use in Volumetric Analysis with Iodine. By G. Gastine (*Bull. Soc. Chim.*, **50**, 172—173).—Five grams of potato-starch is mixed with 0·01 gram of mercury iodide, stirred with a little water, and poured into boiling water (1 litre). It is allowed to settle, and the clear liquid poured off. A solution prepared in this manner has been kept for more than a year without deteriorating. N. H. M.

Use of Salicylic Acid for Preserving Standard Solutions. By H. Bornträger (*Zeit. anal. Chem.*, **27**, 641—642).—The addition of a pinch of salicylic acid to each litre of a thiosulphate solution greatly diminishes its tendency to decompose. The author's determinations show large variations, but not a progressive diminution in strength. M. J. S.

Applications of Spectrophotometry to Chemical Physiology. By E. Lambling (*Arch. de Physiol.*, 4th Series, **12**, 1—34).—This paper gives an historical account of the spectrophotometer, and of the principles upon which the spectrophotometric method depends. The practical application of the method for quantitative purposes involves:—(1) The choice of a region of the spectrum; (2) the determination of the coefficient of extinction of the coloured solution for that region; and (3) the determination of the amount of absorption of the colouring matter for the same region. When two colouring matters are mixed in a solution, they may also be estimated quantitatively, provided the absorptive power of each of the two pigments for two regions of the spectrum be previously known.

Finally, the application of such methods to animal pigments (of the blood, bile, urine, &c.), is pointed out. W. D. H.

Determination of Chlorine in Plant-ashes. By A. Jolles (*Chem. Centr.*, 1888, 863—864, from *Zeit. Nahrungsmittel u. Hygiene*, **2**, 81).—The method the author proposes as the best is as follows:—The plant (10 grams) is incinerated gently in a platinum dish, moistened with an alcoholic solution of sodium carbonate, the alcohol burned off, and the process repeated; after this, the whole of the carbon may be burnt off without any fear of chlorine being lost, and the ash may be extracted by means of water and the determination finished in the usual manner with silver nitrate. This deviation from the ordinary direct combustion of vegetable matter in the determination of chlorine obviates the chance of a loss of this element which might otherwise take place. J. W. L.

Method for the Determination of Bromine in Sea-water. By F. GUTZKOW (*Chem. News*, **58**, 190—193).—250 c.c. of sea-water is mixed with a drop or two of sulphuric acid and with 100 c.c. of a solution containing about 25 grams of copper sulphate. It is then treated with sodium sulphite solution until the precipitate redissolves with difficulty, and heated until the blue colour returns; more sodium sulphite is now added, about one-third that already used, and the whole again heated until blue, and then cooled. In this way, all the bromine is precipitated in a few minutes. After washing the precipitate, first with 100 c.c. of water containing 1 gram of sulphuric acid, then with a few drops of sodium carbonate solution, it is warmed with hydrochloric acid until all sulphurous anhydride is removed, and is finally treated with zinc. The filtrate and washings from the copper, which combined should not exceed 25 c.c., are titrated with sodium hypochlorite by a method of the author's which is described in detail in the original. The flask containing the liquid is fitted with a triple-bored cork; through one hole passes a tube closed by a piece of india-rubber tubing and a clip, through the other holes two thistle-headed funnels reaching nearly to the bottom of the flask, one is roughly graduated. By blowing into the tube, a quantity of liquid is forced up both funnels and is titrated in the graduated one, the other serving for comparing the colour; in this way an indication of the quantity of hypochlorite required by the whole liquid is obtained, and so the operation can be finished with greater rapidity than by the ordinary mode of procedure. D. A. L.

Determination of Fluorine in Substances Decomposable by Sulphuric Acid and especially in Natural Phosphates. By H. LASNE (*Bull. Soc. Chim.*, **50**, 167—170).—Sufficient substance to yield 0·2 gram of calcium fluoride is put into a flask containing strong sulphuric acid (50 c.c.) and pure sand (10 grams), and connected with two wash-bottles, the first of which contains 2·5 grams and the second 0·5 gram of soda dissolved respectively in 25 c.c. of water. Dry air is passed into the flask, which is heated for an hour at 180—200°; it is then allowed to cool, dry air being passed through. The soda solutions are united and boiled for ¼ hour; phenolphthaleïn is added, and carbonic anhydride passed through the solution until it is colourless; it is then heated for ½ hour at 50°, and treated with ammonium carbonate, when the silica is almost completely precipitated. The liquid is cooled quickly, diluted to 125 c.c., filtered through a large folded filter, and 100 c.c. collected. A few drops of tropæoline solution is added to the solution, which is carefully neutralised with dilute hydrochloric acid. It is then treated with pure sodium carbonate (equal to 0·5 gram of anhydrous carbonate), boiled until free from carbonic anhydride, and precipitated with a slight excess of calcium chloride. The precipitate is ignited, treated with acetic acid, evaporated to dryness, again treated with acetic acid, and the undissolved calcium fluoride, washed, ignited, and weighed. N. H. M.

General Method for the Separation and Volumetric Estimation of Acids: Application to Sulphuric Acid. By G. LINOSSIER (*Bull. Soc. Chim.*, **50**, 46—47).—The method is applicable to all acids which yield insoluble compounds when combined with metals which are precipitated by hydrogen sulphide in acid solution. The determination of sulphuric acid is carried out as follows:—The solution of the sulphate (containing 0·05 to 0·1 gram) contained in a dish is treated with alcohol (2 vols.), heated almost to boiling, and precipitated with a slight excess of lead acetate. When cold it is washed by decantation with a mixture of alcohol and water (0·5 to 1 vol.), passing the decanted liquid through a small filter. The trace of lead sulphate on the filter is washed with aqueous hydrogen sulphide into a flask; the rest of the lead sulphate is shaken with a saturated solution of hydrogen sulphide, the liquid poured on to a filter, and the precipitate treated with a fresh amount of hydrogen sulphide and filtered. It is then washed with aqueous hydrogen sulphide until the filtrate gives no reaction with Poirrier's orange. The whole of the sulphuric acid is then in the filtrate, and is titrated with decinormal soda solution. N. H. M.

Volumetric Estimation of Boric Acid, and of Ammonia in Ammonium Salts. By J. MCGLASHAN (*Chem. News*, **58**, 175—176).—By using Poirrier's oranges I and II, boric acid and ammonium borate can be titrated directly with normal soda, but borax must first be made neutral to methyl-orange with sulphuric acid; boracite must be heated with dilute sulphuric acid, made neutral to methyl-orange with soda, and any carbonic anhydride eliminated before titrating. Ammonia is objectionable in any form except as borate or hydroxide, the latter when dilute is neutral to both oranges. Therefore, with these indicators ammonia may be titrated with soda, in any ammonium salt, without distillation. With ammonium carbonate and with arsenates, the end reaction is not distinct, but with hydrogen sulphide it is sharp. D. A. L.

Resorcinol as a Test for Nitrates. By D. LINDO (*Chem. News*, **58**, 176—177).—For testing with resorcinol, 10 grams are dissolved in 100 c.c. of water, and one drop of this solution, one drop of 15 per cent. hydrochloric acid, and 2 c.c. of concentrated sulphuric acid are added to 0·5 c.c. of the nitrate solution (compare Abstr., 1888, 1337); one in 500,000 gives a definite permanent purple colour after some time, whilst with increasing strengths of nitrate solution the colour becomes more intense, until with one in 10,000 the vivid purple-red colour is so intense as only to be distinctly seen in the lower portion of the band. Resorcinol is valueless without hydrochloric acid, but with it, is a more delicate test for nitrates than ordinary phenol. Copper sulphate does not aid the reaction materially. The reagents alone gave a band which, however, cannot be mistaken for the nitrate band. With nitrites, it is more delicate than with nitrates; with chlorates it is no good, with dichromate (0·5 gram per litre) it gives a red to buff upper with a purplish lower band, the latter changing to pink or with hydrochloric acid to reddish-brown; the colours are slightly different if the acid is run in at once, or after some delay. Permanganate, N/10, with 4 vols. water, gives a dark-orange upper and yellowish lower band; with hydrochloric acid, these are respectively orange, red, and greenish. Hydrogen peroxide in dilute solution yields a green and brownish compound band. D. A. L.

Estimation of Phosphorus in Iron and Steel. By P. W. SHIMER (*Chem. News*, **58**, 165—166).—Dissolve 1 gram of iron in 20 c.c. of nitric acid, sp. gr. 1·20, and add to the boiling solution 10 c.c. of a solution of 20 grams of potassium permanganate in a litre of water, 2·5 c.c. at a time, and after a few minutes 5 c.c. of hydrochloric acid, sp. gr. 1·12. When the action has ceased, add a mixture of 5 c.c. of concentrated sulphuric acid and 5 c.c. of water, and evaporate until fumes of sulphuric acid begin to come off. When cool, add 5 c.c. of nitric acid, sp. gr. 1·20, and sufficient water; boil to dissolve iron salts, filter, and wash with water. The residue serves well for the estimation of silicon. Heat the filtrate to 80° and add 5 c.c. of ammonium molybdate (5 grams of MoO_3, 20 c.c. ammonia, sp. gr. 0·96, 30 c.c. nitric acid, sp. gr. 1·20), then keep at 60° until the liquid is clear, which occupies less than an hour when the solution is not too dilute. The yellow precipitate is washed with acid ammonium nitrate solution, dissolved in ammonia and precipitated by magnesia mixture. The method gives good results both for silicon and phosphorus.

A few experiments were made using sulphuric acid and ammonium sulphate instead of nitric acid and ammonium nitrate for the molybdate precipitation, with satisfactory results. D. A. L.

Influence of Sulphur on Eggertz's Carbon Colour-test. By T. W. HOGG (*Chem. News*, **58**, 175).—When ordinary steels containing say 0·05 per cent. of sulphur are dissolved in the usual manner, the sulphur separates out and produces a turbidity which interferes with the colour-test for carbon; a fact easily proved by dividing such a solution into two portions, filtering one, and then comparing the colour produced in the filtered and unfiltered solutions. Consequently, if a common steel is compared with a standard of pure steel, the colour intensity is sure to be over-estimated, and *vice versâ*.

D. A. L.

Quantitative Analysis by Electrolysis. By A. CLASSEN and R. SCHELLE (*Ber.*, **21**, 2892—2899).—The current from two of Farbaky and Schenek's accumulators, fully charged by a dynamo giving a current of 20—25 ampères, was employed in making 50 analyses in the course of six days. Four to eight analyses were made simultaneously, and the current was employed continuously day and night, except during the short intervals required for changing the platinum dishes. During this time the strength of the current decreased from 2·05 to 1·92 volt, so that one charge would be sufficient for 60 to 70 analyses. The condition of the accumulator can be ascertained from the specific gravity of the sulphuric acid, which is 1·240 when the accumulator is charged and 1·118 when it is not charged. The precipitated metal is in a more suitable condition than when a battery or dynamo is employed.

Experiments which were made with Neumann's (Abstr., 1888, 529) and Wolff's (*Zeit. ang. Chem.*, 1888, 296) voltameters, employing currents of various strengths, show the necessity of working under the same conditions when repeating electrolytic methods of analysis (compare Classen, *Quantitative Analyse durch Electrolyse*, 2nd ed., 43).

In the separation of antimony from tin in sodium sulphide solution, the solution, freed from antimony, is boiled with ammonium sulphate, and the tin precipitated by electrolysis (compare Abstr., 1884, 932). A simpler and more convenient method is to convert the stannic sulphide into hydrogen stannic oxalate and electrolyse the solution. For this purpose, the solution is acidified with dilute sulphuric acid, and the sulphide oxidised with ammoniacal hydrogen peroxide, or the hot alkaline solution is treated at once with hydrogen peroxide until it becomes colourless, acidified with sulphuric acid, neutralised with ammonia, and more hydrogen peroxide added. The solution is then boiled, filtered, and the residual stannic acid washed off the filter with and dissolved in a hot solution of oxalic acid. If there is a residue of sulphur, it is separated by filtration, washed with a cold saturated solution of hydrogen ammonium oxalate, and the washings added to the filtrate. The solution, which should contain at least 50 c.c. of the hydrogen ammonium oxalate solution, is electrolysed with a current giving 8—10 c.c. of explosive gas per minute.

The electrolytic deposition of copper from its salts, dissolved in a saturated solution of ammonium oxalate, is hastened very considerably if the solution is kept acid, especially towards the end of the operation, by adding excess of a cold, saturated solution of oxalic acid. The smaller the quantity of copper, the more oxalic acid solution may be added. A solution poor in copper can be mixed with the oxalic acid solution at the commencement of the process, but in concentrated solutions, the precipitation must be carried out in a solution as nearly neutral as possible to avoid the separation of copper oxalate. If the copper solution is kept at 40—50°, about two grams of copper are deposited in from 3 to 4 hours. A current giving 3—4 c.c. of explosive gas per minute was employed, and quantitative experiments showed that the whole of the copper is deposited.

F. S. K.

Separation of Calcium, Barium, and Strontium. By KUPFFERSCHLAEGER (*Bull. Soc. Chim.*, **49**, 854—856).—A quantitative analysis of a mixture of the carbonates of barium, strontium, and calcium can be carried out as follows:—The mixture is dissolved in a slight excess of very dilute nitric acid, the solution evaporated to dryness, the residue dissolved in distilled water, and the filtered solution again evaporated to complete dryness. The residue of mixed nitrates is agitated with a small quantity of a mixture of absolute alcohol and ether, and the solvent separated by filtration as soon as the solution becomes clear; this process is repeated three times, the proportion of ether being gradually increased until the mixture contains equal volumes of the constituents. The residual mixture of the nitrates of barium and strontium is dried, dissolved in water, and treated with a cold saturated solution of potassium dichromate. The precipitated barium dichromate is washed with cold, very dilute alcohol, and converted into sulphate by heating with sulphuric acid. The strontium in the filtrate is converted into sulphate by warming the solution with dilute sulphuric acid. A solution of strontium chloride is not precipitated by potassium dichromate. F. S. K.

Volumetric Estimation of Mercuric Chloride. By G. KASSNER (*Arch. Pharm.* [3], **26**, 595—604).—The method promises well for pharmaceutical practice. 50 grams of the organic compound containing mercuric chloride is placed in a porcelain dish without previous division, 500 c.c. of water is added, and the mass is well kneaded with a pestle. 500 c.c. of a solution of 0·4 gram of potassium antimonious tartrate and 1 gram of sodium phosphate, or in place of the latter 1 to 2 grams of sodium acetate, is now added and the kneading continued. A very intimate mixture is thus obtained, and a milky liquid results from the decomposition of the mercuric chloride. About 500 c.c. is now filtered off, and titrated with decinormal iodine solution after the addition of freshly prepared starch solution, and a sufficient quantity of sodium hydrogen carbonate. The iodine employed corresponds to the amount of unchanged tartrate remaining in the filtrate. The reaction is as follows:—$4HgCl_2 + Sb_2O_3 + 2H_2O = 4HCl + Sb_2O_5 + 4HgCl$. The presence of phosphoric and organic acids is admissible, but not of free hydrochloric acid. J. T.

Microchemical Reactions. By A. STRENG (*Jahrb. f. Min.*, 1888, ii, Mem., 142—152; continuation of Abstr., 1886, 487).—For detecting *tin* under the microscope, the author avails himself of the brown colour produced on adding hydrochloric acid and platinum chloride. When the solution is effected, a drop of the liquid is transferred to an object-glass, and a grain of potassium chloride added, and the solution slightly evaporated. In this way, rhombic crystals of potassium stannous chloride ($2KCl + SnCl_2 + H_2O$) are formed. They are mostly combinations of the forms ∞P, $\infty\bar{P}\infty$, $\infty\breve{P}\infty$, $\bar{P}\infty$, $\breve{P}\infty$. When the stannous chloride has been thus detected, a drop of nitric acid is added, and the solution heated. The stannous chloride is converted into stannic chloride, and the imperfectly soluble salt, K_2SnCl_6 is formed. This crystallises in the regular system, and is perfectly isotropic. This reaction may be employed for detecting stannous and stannic oxides in compounds soluble in hydrochloric acid. Cæsium chloride may be used instead of the isomorphous potassium salt. The author also describes methods for detecting potassium, cæsium, and rubidium, sodium, and silicon. B. H. B.

Detection of small Quantities of Germanium. By K. HAUSHOFER (*Chem. Centr.*, 1888, 867, from *Sitzber. Akad. München*, 1887, 133).

—By heating in an atmosphere of hydrogen sulphide, the germanium in the mineral argyrodite is converted into the sulphide GeS, which is crystalline, and may be detected and recognised by means of the microscope. With concentrated sulphuric acid, it forms a white, non-crystalline substance, with concentrated nitric acid it is converted into the white, crystalline oxide, GeO_2, which is soluble in dilute nitric acid and water, and crystallises out of the solution again on evaporation. Heated in a tube, it sublimes similarly to antimony oxide, but differs from this by its solubility in water, and also by melting to clear colourless drops. It is necessary to apply the potassium iodide test also, as a means of distinguishing it from the mercuric sulphide, which has also been found present in argyrodite. J. W. L.

Characteristic Reaction of Bismuth. By E. Léger (*Bull. Soc. Chim.*, **50**, 91—93).—A solution of bismuth iodide and potassium iodide is sometimes used for detecting alkaloïds, with which it gives orange-yellow precipitates. It is suggested that the reaction should be employed for detecting bismuth. A solution is prepared by dissolving cinchonine (1 gram) and potassium iodide (2 grams) in water (100 c.c.). Other alkaloïds may be used instead of cinchonine, but this seems to give the most sensitive reaction. The reagent must be added in excess; the presence of too much nitric acid, and especially the presence of hydrochloric and sulphuric acids, is to be avoided. Bismuth may be detected in solutions containing only 1 part in 500,000 parts. Solutions which contain other metals besides bismuth are precipitated with hydrogen sulphide, the sulphides of copper, lead, cadmium, mercury, and bismuth converted into nitrates, then into carbonates, and the carbonates of bismuth and lead separated by means of potassium cyanide; these carbonates are converted into chlorides, and the lead chloride separated by means of alcohol. The alcoholic solution is evaporated to dryness, dissolved in a drop of nitric acid and some c.c. of water, and treated with the reagent. Solutions of the salts of mercury, cadmium, silver, copper, and lead also give precipitates of various colours with the cinchonine reagent.
N. H. M.

Determination of Oxygen dissolved in Water. By L. W. Winkler (*Ber.*, **21**, 2846—2854).—The method consists in oxidising an excess of manganese hydroxide in presence of alkali by the oxygen present in a weighed amount of the water; potassium iodide and hydrochloric acid are then added, and the iodine which separates (which is equivalent to the amount of dissolved oxygen) titrated with sodium thiosulphate. A solution of manganous chloride (free from iron) is made of such a strength that 100 c.c. contains 40 grams of the salt ($MnCl_2 + 4H_2O$). The soda must be free from nitrate, and the solution prepared of eight times the normal strength; potassium iodide (10 grams) is dissolved in 100 c.c. of the soda solution, the rest of which is kept. A strong flask of about $\frac{1}{4}$ litre capacity is filled with the water; 1 c.c. of the potassium iodide soda solution is added by means of a pipette reaching nearly to the bottom of the flask, then 1 c.c. of the manganous chloride solution. The flask is closed, care being taken that no bubble of air remains, and the contents mixed.

When the precipitate settles, fuming hydrochloric acid (3 c.c.) is added by means of a pipette similar to those previously used. The flask is again closed, the contents mixed, and the yellow liquid titrated in the usual manner with sodium thiosulphate, the most convenient strength of which is 1/100 normal, so that each c.c. corresponds with 0·055825 c.c. of oxygen (at 0° and 760 mm. pressure).

When the water to be analysed contains much carbonic anhydride, more of the reagent must be added, as manganous carbonate is not oxidised by the oxygen. In the case of waters containing nitrates, the process has to be modified: a soda solution containing no potassium iodide is first added, then hydrochloric acid (twice the amount otherwise used), and after three minutes a solution of potassium iodide. A manganic chloride solution is then prepared as follows:—500 c.c. of distilled water is treated with the pure soda solution (1 c.c.), 5 to 10 drops of the manganous chloride solution, and then sufficient hydrochloric acid is added to dissolve the precipitate. 100 c.c. of this solution is taken out and diluted with distilled water; to the rest, 100 c.c. of the water to be examined is added. After two to three minutes, both solutions are treated with potassium iodide and the iodine which separates determined as usual. From the difference in the amount of thiosulphate used, the correction for 100 c.c. of water is calculated.

Concordant results obtained by the new method are given.

N. H. M.

Ash Determination. By F. A. Flückiger (*Zeit. anal. Chem.*, **27**, 637—638).—The substance is heated in a roomy platinum capsule so gently that carbonisation takes place without combustion. It is then cooled, a copious amount of water is added, and the whole evaporated completely on the water-bath. On reheating the carbonaceous residue very gradually, it burns at a low temperature, and very quickly.

M. J. S.

Wet Methods of Organic Analysis. By J. Messinger (*Ber.*, **21**, 2910—2919).—Organic compounds, as Cross and Bevan have shown (Proc., 1888, 76, and Trans., 1888, 889), are completely oxidised when warmed with chromic acid and concentrated sulphuric acid. If nitrogen is present, it is evolved as such or as ammonia, whilst sulphur, phosphorus, and arsenic are converted into the corresponding acids. Halogens are evolved in the free state, and metals remain as sulphate or, with a large excess of chromic acid, as chromates.

To estimate the quantity of carbon, the substance (0·15—0·35 gram) is weighed in a small bulb or tube, and placed in the apparatus employed by Classen for the estimation of carbonic anhydride (*Quantitative Analyse*, 3rd ed., 239), together with chromic acid (5—6 grams) or powdered potassium dichromate. A gentle stream of air, free from carbonic anhydride, is passed through the apparatus to drive out the carbonic anhydride, the weighed potash bulbs and soda-lime tube are attached, and the latter connected with a calcium chloride tube to prevent absorption of moisture from the air. Concentrated sulphuric acid (30 c.c.) is then poured through the funnel, and the stream of air stopped. The flask is warmed very cautiously until the evolution of carbonic anhydride commences, and then the heating is immediately discontinued until the reaction is almost at an end. The process occupies about two hours. Pure air is passed through the apparatus for half an hour, and the tubes weighed. The results obtained are very satisfactory, except in the case of substances which sublime readily, but great care must be taken when heat is first applied. In analysing volatile substances, the bulb is broken by means of the funnel. If the substance contains halogens, a Dreschler's flask of about 100 c.c. capacity, containing 40 c.c. of concentrated potassium iodide solution, and a small U-tube filled with glass-wool, half of which is moistened with a solution of silver nitrate and half with concentrated sulphuric acid, are interposed between the condenser and the potash bulbs. Quantitative experiments with compounds of the most varied nature gave satisfactory results (compare Cross and Bevan, *loc. cit.*).

Sulphur can be estimated, except in the case of extremely volatile substances, as follows:—The substance (0·15—0·35 gram), together with potassium permanganate (1½—2 grams), and pure potash (0·5 gram) is placed in a flask of 500 c.c. capacity provided with a condenser, water (25—30 c.c.) poured down the condenser, and the mixture heated for 2—3 hours. Concentrated hydrochloric acid is then gradually poured down the condenser into the cold mixture, which should be of a reddish colour, and after the evolution of gas has ceased, the whole is heated until the liquid becomes clear. The sulphuric acid is then precipitated with barium chloride. Potassium dichromate (2—3 grams) and hydrochloric acid (20—25 c.c.: 2 parts concentrated acid, 1 part water) may be employed instead of potassium permanganate and potash. The operation is carried out in the manner described, but after heating for about two hours a few drops of alcohol are added to determine whether all the dichromate has been reduced; if the odour of aldehyde is perceptible, the mixture must be heated again and the test repeated. Both methods can also be employed for the detection of sulphur. Numerous quantitative experiments gave satisfactory results, but in the case of a few sulphones it was found that sulphur cannot be estimated by this method.

Phosphorus, arsenic, and antimony in organic compounds can be estimated by placing the substance (0·3—0·4 gram) with chromic acid (4—5 grams) in a flask provided with a condenser, pouring sulphuric acid (10 c.c., 2 parts concentrated acid, 1 part water) down the condenser, and heating gently. After an hour's time, sulphuric acid (10 c.c.) is added, and the heating continued for about an hour. The mixture must always be heated very carefully, and the cold solution should be perfectly clear. Some antimony compounds require only 1 gram of chromic acid and 10 c.c. of sulphuric acid.

In the estimation of phosphorus, the solution is warmed with ammonium nitrate (3—4 grams) and ammonium molybdate solution (50 c.c.) for 2—3 hours, filtered, the precipitate washed 6 to 8 times by decantation with ammonium nitrate solution (20 grams in 100 c.c. of water), thrown on to a filter, and dissolved in not more than 40—50 c.c. of warm dilute (2 per cent.) ammonia; a concentrated solution of citric acid (4—5 drops) is added to the filtrate, and the phosphoric acid precipitated with magnesia mixture.

In estimating arsenic, the solution is diluted to about 100 c.c., heated to about 70°, and the arsenic precipitated with hydrogen sulphide. The precipitate is washed with water containing hydrogen sulphide until free from chromium salts, and then converted into arsenic acid by means of ammoniacal hydrogen peroxide (compare Classen, Abstr., 1883, 934). After boiling for an hour, ammonia is added to the filtered solution, and the arsenic precipitated with magnesia mixture. Antimony is estimated by adding potash and excess of sodium sulphide, boiling for half an hour, and precipitating the metal electrolytically.

Metals are estimated by mixing the solution with excess of ammonium oxalate and precipitating electrolytically. Halogens can be detected by warming the substance (1—2 mgrms.) with chromic acid and sulphuric acid, and passing the gas evolved into a dilute solution of potassium iodide; quantitative experiments gave unsatisfactory results. F. S. K.

The Safety of Commercial Kerosene Oils. By S. B. Newbury and W. P. Cutter (*Amer. Chem. J.*, 356—362).—Although oils are regularly tested for their flashing points and conclusions drawn as to their being safe for burning in lamps, it is noteworthy that many modern lamps heat their reservoir of oil to temperatures above the legal flashing point, and that there are not sufficient experimental data to allow of the correct interpretation of the flashing point determinations into terms expressing the inability of such oils to form explosive mixtures of vapour with air. All hydrocarbons up to and including octane, form at ordinary temperatures mixtures that can be exploded; nonane mixtures (b. p. 148—150°) explode sharply at 79° F., and decane at 104° F.

The addition of small quantities of low-boiling oils materially lowers the flashing point of another sample. Thus a sample flashing at 212° F. was made to flash at 145° F. by the addition of 5 per cent. of heptane; at 110° F. by the addition of 5 per cent. pentane or hexane, or 10 per cent. heptane; at 96° F. by the addition of 15 per cent. heptane; and at ordinary temperatures by the addition of 10 per cent. pentane or hexane, or 20 per cent. heptane. The temperatures at which an oil may be kindled in an open vessel approaches the more nearly to the flashing point the more homogeneous the oil is. The flashing point of an ordinary oil may be materially raised, with but little diminution of weight, by passing a current of air through it for several hours. H. B.

Solubility and Estimation of Paraffin. By B. Pawlewski and J. Filemonowicz (*Ber.*, **21**, 2973—2976).—The following table gives the solubility at 20° of ozokerit paraffin of sp. gr. 0·9170 at 20°, melting at 64—65°, and solidifying at 61—63°:—

Solvent.	Paraffin (grams), dissolved by		Weight of solvent required to dissolve completely 1 part of paraffin.
	100 grams.	100 c.c.	
Carbon bisulphide	12·99	—	7·6
Light petroleum, up to 75° C., sp. gr. 0·7233	11·73	8·48	8·5
Turpentine oil, sp. gr. 0·857; b. p. 158—166°	6·06	5·21	16·1
Cumene (comm.), up to 160°, sp. gr. = 0·867	4·28	3·72	23·4
Cumene (frac.), 150—160°, sp. gr. = 0·847	3·99	3·39	25·0
Xylene (comm.), 135—143°, sp. gr. = 0·866	3·95	3·43	25·1
„ (frac.), 136—138°, sp. gr. = 0·864	4·39	3·77	22·7
Toluene (comm.), 108—110°, sp. gr. = 0·866	3·83	3·34	26·1
„ (frac.), 108·5—109·5°, sp. gr. = 0·866	3·92	3·41	25·5
Chloroform	2·42	3·61	41·3
Benzene	1·99	1·75	50·3
Ethyl ether	1·95	—	50·8
Isobutyl alcohol (comm.), sp. gr. = 0·804	0·285	0·228	352·9
Acetone, 55·5—56·5°, sp. gr. = 0·797	0·262	0·209	378·7
Ethyl acetate	0·238	—	419·0
Ethyl alcohol, 99·5° Tr.	0·219	—	453·6
Amyl alcohol, 127—129°, sp. gr. = 0·813	0·202	0·164	495·3
Propionic acid	0·165	—	595·3
Propyl alcohol	0·141	—	709·4
Methyl alcohol, 65·5 - 66·5°, sp. gr. = 0·798	0·071	0·056	1447·5
Methyl formate	0·060	—	1648·7
Glacial acetic acid	0·060	0·063	1668·6
Ethyl alcohol, 94·5° Tr.	0·046	—	2149·5
Acetic anhydride	0·025	—	3856·2
Formic acid (cryst.)	0·013	0·015	7689·2
Ethyl alcohol, 75° Tr.	0·0003	—	330000·0

The liquid constituents present in many products of the petroleum or ozokerit industry are soluble in glacial acetic acid, whereas vaselin, cerisin, ozokerit, and paraffin are almost insoluble. To estimate the quantity of solid paraffin in petroleum, lubricating oils, mineral oils, vaselin, &c., 5—20 c.c. of the mixture is well shaken with 100—200 c.c. of glacial acetic acid, the residual paraffin thrown on to a weighed filter, washed two or three times with glacial acetic acid, and then two or three times with alcohol of 75° Tr., dried and weighed, or the residual paraffin is washed, dissolved in benzene or ether, the solution evaporated, and the residue weighed. This method is quick and accurate, and can be carried out at the ordinary temperature. F. S. K.

Analysis of a Mixture of Silver Chloride, Cyanide, Thiocyanate, Ferricyanide, and Ferrocyanide. By J. Teissier (*Bull. Soc. Chim.*, **50**, 104—106).—The mixture occurs in the analysis of materials used in the purification of coal-gas. Sodium carbonate is heated in a crucible until anhydrous, the weighed substance and some potassium nitrate are added, and the whole is heated. The product is extracted with water, which leaves a residue of pure silver and ferric oxide. In the solution, sulphur is determined as barium sulphate and chlorine as silver chloride. The residue is dissolved in nitric acid, the silver determined as chloride, and the iron as sesquioxide. Equations are given by means of which the amount of each salt present in the mixture is calculated. N. H. M.

Estimation of Paranitrotoluene. By F. Reverdin and C. de la Harpe (*Bull. Soc. Chim.*, **50**, 44—46).—The method is based on the fact that paranitrotoluenesulphonic acid is readily converted by boiling with soda into dinitrosulphostilbene which yields a red colour when dissolved in alkali, whilst orthonitrotoluenesulphonic acid is not attacked by soda, and the alkaline solution is yellow. 2 c.c. of pure orthonitrotoluene is heated in a water-bath with 6 c.c. of sulphuric acid (containing 25 per cent. of anhydride) for three hours, the product cooled and diluted to 1 litre. In a similar manner a mixture of orthonitrotoluene (96 parts) and paranitrotoluene (4 parts) is sulphonated and the product diluted to 200 c.c. In determining the amount of paranitrotoluene, the substance and nitrotoluene (containing 4 per cent. of the para-compound) are sulphonated, the products diluted to 200 c.c., and the colours compared which are obtained by mixing 1 c.c. of each solution with 5 c.c. of aqueous soda. If the sample to be analysed gives a stronger colour, a measured quantity (20 to 50 c.c.) is progressively diluted with the solution of orthonitrotoluenesulphonic acid until 1 c.c. when heated with 5 c.c. of aqueous soda gives the same amount of colour as the solution containing 4 per cent. The percentage of paranitrotoluene can then be calculated. N. H. M.

Detection of Methyl Alcohol in Wood Spirit. By J. Habermann (*Zeit. anal. Chem.*, **27**, 663, from *Verhandl. nat. Ver. Brünn*, **26**).—Commercial methyl alcohol contains impurities which reduce permanganate energetically. Cazeneuve and Cotton shake 10 c.c. of the spirit to be tested with 1 c.c. of a 0·1 per cent. solution of permanganate at 20°. If wood spirit is present, decolorisation takes place immediately; with pure alcohol, 20 minutes is required. Ethereal oils, which may be present in spirit or brandy, and would cause a similar reduction, may be removed by shaking the spirit twice with half its volume of the purest olive oil and then filtering through a well wetted filter. If sugar is present, the spirit must be distilled.

M. J. S.

Composition of Natural Brandies and the Way of Distinguishing them. By X. Rocques (*Bull. Soc. Chim.*, **50**, 157—164).—500 c.c. of the brandy is distilled in a Le Bel-Henniger apparatus and nine fractions of 50 c.c. each collected, the temperatures being noted. Each fraction is subjected to the following tests:—(1) Rosaniline bisulphite, (2) aniline acetate, (3) sulphuric acid, (4) permanganate, (5) ammoniacal silver nitrate solution. The results of several analyses of brandies are given in tables.

N. H. M.

Estimation of Sugar in Presence of Carbohydrates. By R. W. BISHOP (*Chem. Centr.*, 1888, 952—953, from *Msc. Mon. Sci.*, **32**, 558).—The author has carried out a number of experiments with a view to determine the conditions under which inversion may be completed without at the same time damaging the accompanying carbohydrates. It was found that sulphuric acid has a greater power of inversion than hydrochloric acid, but it appears that hydrochloric acid is the best for the conversion of starch into dextrose. Prolonged heating of inverted sugar with the acid seems to act on the lævulose rather strongly, and the solution becomes less lævorotatory and eventually dextrorotatory. For the inversion of cane-sugar, 0·5 c.c. of hydrochloric acid is sufficient, and the heating is continued for 10 minutes at 95°. For the conversion of dextrin, the solution should not contain more than 1—3 grams of carbohydrates in 50 c.c. The inversion is performed by adding 2 c.c. of hydrochloric acid and heating for three hours at 95°. J. W. L.

Detection of Sugar in Urine. By C. SCHWARZ (*Arch. Pharm.* [3], **26**, 796, from *Pharm. Zeit.*, **33**, 465).—1 to 2 c.c. of lead acetate is added to 10 c.c. of urine and filtered; 5 c.c. of the filtrate is mixed with 5 c.c. of normal potash solution and one or two drops of phenylhydrazine, well shaken and vigorously boiled; in the presence of sugar, the liquid becomes lemon- to orange-yellow, and becomes opaque on adding an excess of acetic acid owing to the immediate formation of a finely divided yellow precipitate. In the absence of sugar, this precipitate never occurs with urine. J. T.

Detection of Chloral or Chloroform in Liquids. By C. SCHWARZ (*Zeit. anal. Chem.*, **27**, 668—669, from *Pharm. Zeit.*, **33**, 419).—Either of these substances when boiled with resorcinol and an excess of soda gives a red colour, which disappears on acidifying and is restored by alkalis. If, on the other hand, an excess of resorcinol and only a drop or two of soda solution is used, the product is a yellowish-red solution with intense yellowish-green fluorescence. 0·0001 gram of chloral hydrate in 1 c.c. gives this reaction very distinctly when vigorously boiled with 0·05 gram of resorcinol and five drops of soda solution. M. J. S.

Modification of the Reichert-Meissl Method of Butter Analysis. By M. MANSFELD (*Chem. Centr.*, 1888, 870—871, from *Milch Zeit.*, **17**, 281—283).—In order to obviate the possible error arising from the use of alcohol in the saponification of the butter-fat, the author has tried the use of alkali alone, the latter being added to the fat in a small flask and heated on the water-bath for two hours, at the end of which time the saponification is complete, and the process is finished as Wollny prescribes. J. W. L.

Densities and Refractive Indices of Certain Oils. By J. H. LONG (*Amer. Chem. J.*, **10**, 392—405).—The following values are obtained—the densities at 20° being compared with water at 4° as unity, and the substance weighed in a vacuum; the refractive indices are for sodium light at 20° :—

Olive oil	0·9130	Ref. index	1·4703
Cotton-seed oil	0·9191		1·4732
Sesame oil	0·9191		1·4740
Mustard oil........	0·9121		1·4742
Castor oil..........	0·9589		1·4791
Lard oil	0·9122		1·4686
Peanut oil	0·9173		1·4717

The densities and refractive indices are also given for other temperatures than 20°. In nearly all cases, the variations due to temperature are the same, namely, about —0·00068 in density and —0·0004 in refraction for each rise of 1°. The author believes such determinations may prove of value in the identification of other oils. H. B.

Bechi's Newest Method for the Detection of Cotton-seed Oil in Mixtures. By G. BIZIO (*Chem. Centr.*, 1888, 873, from *Atti Inst. Veneto* [6], 6).—The author finds that pure olive oil gives Bechi's new cotton-seed oil reaction with slightly acid silver nitrate, whilst, on the other hand, he finds that there are some cotton-seed oils which do not give the reaction at all. J. W. L.

Qualitative Test for Resin Oil in Vegetable and Mineral Oils. By HOLDE (*Chem. Centr.*, 1888, 952, from *Pharm. Zeit.*, **33**, 298).—Whereas Storch's reagent (concentrated sulphuric acid and anhydrous acetic acid) for the detection of resin oil is not always admissible, the author recommends sulphuric acid of sp. gr. 1·53, which produces a violet coloration with resin oil. If the oil under examination becomes so dark-coloured with sulphuric acid as to interfere with the reaction, the resin oil may first be extracted with alcohol, when the colour test is readily performed. J. W. L.

Test for "Saccharin." By D. LINDO (*Chem. News*, **58**, 155).—The author modifies his test for "saccharin" (Abstr., 1888, 1350). After evaporating to dryness with nitric acid on a water-bath, a few drops of alcoholic potash is added to the cold residue; when this is heated, a greater variety of colours is obtained than by following the original directions. D. A. L.

Recent Processes for Testing Quinine. By W. LENZ (*Zeit. anal. Chem.*, **27**, 549—631).—The foreign alkaloïds in commercial quinine consist chiefly of cinchonidine and hydro-bases. Four principal methods are in use for the determination of these. In all these methods, a product ("Nebenalkaloïde") is obtained, containing the greater part of the impurities together with a certain quantity of quinine. In this product, the cinchonidine is determined by the "tetrasulphate process." 1 gram of the mixture is dissolved in 9 grams of absolute alcohol and 3 grams of 50 per cent. sulphuric acid. The mixture is kept at 0° for 24 hours, the acid liquid is removed by suction, the crystals are washed with a little absolute alcohol, and then air-dried. They are then dissolved in water, and the base is precipitated by excess of sodium carbonate. It is dried first over sulphuric acid, and then at 115°. A correction (the amount of which depends on the percentage of cinchonidine found) must be applied. The author gives a curve for the purpose. The cinchonidine is very nearly pure. The hydro-bases are determined approximately by oxidising the quinine and cinchonidine in acid solution by a 1 per cent. solution of potassium permanganate, rendering alkaline, and shaking with ether, followed by chloroform. The residues from these solutions, although very impure, are regarded as hydroquinine.

For the "chromate process" of De Vrij see Abstr., 1887, 404; for the "oxalate test," see Schaefer (Abstr., 1887, 623). The amount of oxalate prescribed is insufficient for samples containing less than 15 per cent. of water, and the cooling at 20° should be prolonged to one hour. Schaefer's correction of 0·04 gram per 100 c.c. appears to be too large.

In Hesse's "bisulphate process" 5 grams of quinine sulphate is dissolved in 12 c.c. of normal sulphuric acid by warming, and the solution is allowed to crystallise in a narrow-necked funnel in a cold place. The mother-liquor is withdrawn by a filter-pump into a graduated cylinder, and the crystals washed with 3 c.c. of water. This solution is shaken with 16 c.c. of ether (0·721—0·728), then 3 c.c. of ammonia (0·96) added, again shaken, and left for 24 hours. The ether is removed by a pipette, the crystals are collected on a filter, washed with water saturated with ether, dried between filter-paper, washed again with ether, and dried.

In the "crystallisation process" of Paul and Hesse, 5 grams of quinine sulphate is dissolved in boiling water, and crystallised out four times, using in the first case 150 c.c., next 130 c.c., and then twice 120 c.c. The united mother-liquors are evaporated at a low temperature almost to dryness, the residue dissolved in the smallest possible quantity of dilute sulphuric acid, made up to 20 c.c., and shaken with ether and excess of ammonia. The crystals which form are treated as in the bisulphate test. The hydro-bases crystallise in part with the quinine, therefore the mother-liquor should not be used for their determination.

The chromate process gives very varying results, but on the average gives the highest yield of cinchonidine, especially with the purer samples. The oxalate test gives the lowest numbers, but they are more concordant than those of the chromate process. The composition of the bye-product is, however, variable. The bisulphate test gives results varying considerably. The alkaloïds in the ethereal solution ought to be submitted to the process a second and even a third time, but even with this improvement the whole of the cinchonidine is not obtained, and the results vary much, but the composition of the bye-product is more uniform than in the other processes. The crystallisation test has the same advantages as the bisulphate test if the crystallisation is repeated often enough, and is the process which is least influenced by the presence of hydro-bases. It is, however, tedious. The process of the German Pharmacopœia depends on the fact that the precipitate produced by ammonia in solutions of the alkaloïds is soluble in excess of ammonia, but that much more ammonia is required for quinine than for the other alkaloïds. The excess of ammonia required varies, however, very considerably with the temperature. M. J. S.

Method for Recognising the Adulteration of Pepper by the Addition of Ground Olive Stones. By GILLET (*Bull. Soc. Chim.*, **50**, 173—174).—When 1 gram of olive stones is treated with 1 c.c. of a 5 per cent. iodine tincture, it acquires, after a quarter of an hour, a yellowish colour, whilst pepper is coloured brown or maroon. A series of mixtures of pepper with 5, 10, 15, and 20 per cent. of olive stones are prepared and coloured with iodine tincture. It is then easy to determine the amount of olive stones in samples of pepper by comparing the colour obtained with these types. N. H. M.

A New Test for the Blood in Carbonic Oxide Poisoning. By K. KATAYAMA (*Virchow's Archiv*, **114**, 53—64).—When ammonium sulphide holding sulphur in solution and acetic acid are added to blood containing carbonic oxide, the result is a beautiful clear red or rose colour; whereas normal blood becomes greenish-grey, or reddish-green-grey on the addition of the same reagents. On examining these liquids spectroscopically, it is found that both in the case of normal and carbonic oxide blood the absorption-spectrum indicates that a mixture of two substances is present. In the case of normal blood, there is a band between C and D and another between D and E; this last becomes double on shaking up the mixture with air. In other words, there is a mixture of sulphur methæmoglobin (see Hoppe-Seyler, *Physiol. Chem.*, 386) and reduced hæmoglobin.

In the case of carbonic oxide there are three bands: one between C and D, due to sulphur methæmoglobin, and two between D and E, due to carbonic oxide hæmoglobin. That is to say, in spite of the presence of sulphur methæmoglobin, the liquid does not become greenish, but remains red, the colour of carbonic oxide hæmoglobin overpowering the olive-green of the sulphur methæmoglobin. This test is stated to be more delicate than Hoppe-Seyler's (Abstr., 1888, 540), and is obtained with a mixture which contains one part of carbonic oxide blood to five parts of normal blood. W. D. H.

Estimation of Albumin in Urine. By H. SCHAUMANN (*Zeit. anal. Chem.*, **27**, 635—636).—The estimation of albumin is much accelerated by collecting it, not on a paper filter, but in a filter-tube plugged with cotton-wool and connected with a filter-pump. When the washing with hot water is complete, a calcium chloride tube is connected, and dry air is drawn over the albumin whilst gradually raising its temperature to 110°. M. J. S.

General and Physical Chemistry.

Spectrum of Magnesium. By G. D. LIVEING and J. DEWAR (*Proc. Roy. Soc.*, **44**, 241—252).—When an electric arc is formed between magnesium electrodes, most of the lines produced by the spark discharge are observed. The larger number of lines with an arc discharge may be due not to lowness of temperature, but to the greater mass of incandescent matter, and to a wider range of temperature at different portions of the discharge, recombinations occurring at its edge. The electric discharge itself may also give rise to vibrations distinct from those due to heat. The seven bands in the green are due to the oxide, as they are only produced in the presence of oxygen or its compounds. If a piece of burnt magnesium wire be heated in the oxyhydrogen flame, the spectrum of magnesium is produced, the metallic lines appearing if the hydrogen is in excess. The triplet near M which is produced when magnesium is burnt, is found to be produced in the arc between magnesium electrodes and in many other cases when oxygen is present, but not in an atmosphere of nitrogen or hydrogen, hence it is due to the oxide. Vacuous tubes are found to be very untrustworthy for the ultra-violet spectra, as the water-spectrum and lines of nitrogen are nearly always present, and the spectra sometimes vary unaccountably. A pump is described in which rubber connections and free contact of the mercury with air are avoided. H. K. T.

Ultra-violet Spectra of Nickel and Cobalt. By G. D. LIVEING and J. DEWAR (*Proc. Roy. Soc.*, **43**, 430).—A comparison is made between a plane Rowland's grating with a goniometer and the concave grating (20 feet focal length) used by Bell. The results agree very closely, the concave grating gives more light, and is more suitable for complicated spectra, as the overlapping spectra of different orders are not all in focus at once.

Ultra-violet lines of cobalt and nickel are compared. The coincidences are not greater than the theory of chances would allow, and do not correspond with their chemical relationship. H. K. T.

Two-fluid Cells. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, **43**, 489—493).—Cells are set up consisting of platinum plates in acid and alkaline solutions, with the further addition either of oxidising agents to the acid solution or of reducing agents to the alkaline solution. Currents are produced, in the first case with evolution of oxygen from the alkaline solution, in the second with evolution of hydrogen from the acid solution. The quantity of gas evolved was equivalent to the current. The acid and alkali were sulphuric acid and potassium hydroxide respectively; the oxidising agents being potassium permanganate, dichromate, and ferricyanide, ferric chloride, and solutions of chlorine and bromine and the reducing agents sodium hyposulphite, pyrogallol, cuprous chloride, and ferrous sulphate and ammonium chloride in ammoniacal solution. Hydrogen was not evolved with sodium sulphite or hypophosphite, potassium ferrocyanide, or manganous hydroxide in ammoniacal ammonium chloride, nor was oxygen with barium dioxide and sulphuric acid, or with hydrochloric acid and iodine. On the other hand, an aëration plate of platinum sponge gave a current four times as great. Plates of oxidisable metals in alkaline solution could be substituted for the reducing substance, hydrogen being evolved in the acid solution; this was particularly the case when potassium cyanide was used. Gold, silver, and palladium in cyanide solution gave hydrogen, but platinum and iron were ineffective. When both oxidising and reducing agents are used, comparatively powerful currents are produced.

Effect of Chlorine on the Electromotive Force of a Voltaic Couple. By G. GORE (*Proc. Roy. Soc.*, **44**, 151—152).—If the electromotive force of a small magnesium-platinum couple in distilled water is balanced through a galvanometer and dilute chlorine-water is gradually added, the electromotive force does not alter at first, but after a certain point has been reached (1 in 17,000 millions) it begins to increase rapidly. In this way, the one ten-thousand-millionth of a grain of chlorine in 0·1 c.c. of water can be detected. Other electrolytes give the same reaction, but require a larger quantity of dissolved substance.

H. K. T.

Development of Voltaic Electricity by Atmospheric Oxidation. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, **44**, 182—200).—The electromotive force of cells in which aëration plates are used, falls off very rapidly if the current density exceeds a certain amount. When oxidisable liquids are used, it is difficult to determine, as it appears to vary with the nature of the aëration plate, and also with the incorrodible plate in the liquid to be oxidised. For determining these electromotive forces, an arrangement is used in which the aëration plate can be kept undisturbed, and in which the oxidisable substances are protected from alterations of temperature, impurities from the air, &c. After a few hours or days, the currents become constant. In these cells, variation of the aëration plate produces a difference in the electromotive force independent of the oxidisable plate used; similarly the effect of varying the metal is independent of the aëration plate. The nature and strength of the liquid affects the results to some extent. Tables of results are given. The electromotive force actually generated falls very considerably short of that corresponding with the chemical change, especially when the current density is large. With silver as the oxidisable plate, however, the electromotive force is higher than the theoretical, this being due to the high negative value of the thermovoltaic constant of silver in contact with sulphuric acid. When oxygen was substituted for air over the aëration plate, a slight rise in the electromotive force was observed. With aëration plates immersed in coal-gas or hydrogen, and opposed to a platinum plate in alkaline permanganate or in sulphuric acid and potassium dichromate, very weak and variable currents were observed. The same was the case with cells formed of aëration plates in hydrogen and air respectively. H. K. T.

Electrolytic Conductivity of Rock Crystal. By E. WARBURG and F. TEGETMEIER (*Ann. Phys. Chem.* [2], **35**, 455—467).—In a former paper (*ibid.* [2], **32**, 447), the authors showed that a slice of rock crystal cut perpendicularly to the principal axis, and having its ends covered with layers of gold or plumbago, when subjected at a temperature of about 230° to a long-continued E.M.F. of considerable intensity, had its conductivity permanently reduced to a small fraction of its original amount. In directions perpendicular to the axis, rock crystal, even at higher temperatures, has little or no conductivity.

As the result of their further investigations, the authors have arrived at the conclusions that—

(1.) The electrolytic conductivity of rock crystal in the direction of the principal axis is, at high temperatures, about the same as that of ordinary glass.

(2.) When a slice cut perpendicularly to the axis is electrolysed, sodium-amalgam being used as the anode, sodium migrates through the slice, its amount being in accordance with Faraday's law, and the weight of the slice remains unchanged.

(3.) Even at high temperatures, rock crystal acts as a good insulator with respect to an E.M.F. in a direction perpendicular to the principal axis.

When sodium-amalgam was used as the anode in an experiment lasting for three days, at a temperature of 250°, 88 milligrams of silver were deposited in a silver voltameter in the circuit, and the only substance which could be detected at the cathode was sodium.

When potassium was used in the place of sodium, it was found that after 40 hours the current had sunk to about the hundredth part of its original value, only 2 milligrams of silver were separated, and no potassium could be detected at the cathode, even by means of the spectroscope. The authors therefore conclude that the conductivity is due to the presence of sodium, in the form of Na_2SiO_3, which was shown, by an analysis specially made by Baumann, to be present in the crystal employed in the proportion of 1 part in 2300, so that the crystal might be regarded as a very dilute solution of this salt.

The electrolytic character of the conductivity was further confirmed by the fact that a cell giving an E.M.F. of from 1·3 to 2 volts could be formed of mercury, a slice of quartz at a temperature of 225°, cut perpendicularly to the axis, and sodium-amalgam.

According to Clausius's theory of electrolysis, the fact of electrolytic conduction only taking place in the direction of the principal axis would tend to the inference that in the case of rock crystal not traversed by an electric current, the interchange of atoms between the molecules can only take place, at any rate to a sensible extent, in the direction of the principal axis.

A confirmation of this inference is found in the fact first noted by Salm-Horstmar (*Ann. Phys. Chem.*, **120**, 334), that the action of hydrofluoric acid on rock crystal is much greater in the direction of the axis than perpendicular to this axis. The authors have themselves made experiments to test the truth of this statement, and the results are in agreement with those of Salm-Horstmar.

It would appear from the results obtained in the paper, that the silicate Na_2SiO_3 contained in the crystal must partake of its crystalline structure. G. W. T.

Effect of Occluded Gases on the Thermoelectric Properties of Compounds. By J. MONCKMAN (*Proc. Roy. Soc.*, **44**, 220—236). —When a portion of platinum or palladium wire is charged with hydrogen by electrolysis, and the wire afterwards heated, a current passes from the protected to the unprotected part. The same occurs with rods of carbon after charging and pressing together, the current passing from the hydrogen to the oxygen. The wires and rods are found to have an increased resistance, that of the oxygen rod being the greatest. The effect disappears after short circuiting. If the wires or rods be charged twice in opposite directions, the effect disappears, unless the second charging is of very short duration; in this case, a reversal takes place. With carbon rods at different temperatures in contact, reversal occurs at 250°; with a thermoelectric couple of carbon and platinum, the thermoelectric line rises below 250°, and falls above that temperature. The rate of decrease of resistance of carbon diminishes as the temperature rises to 250°, but increases afterwards. The rate of expansion increases as the temperature rises to 250°, but afterwards decreases. The specific heat increases fairly regularly up to 250°, but above that temperature falls to half. Experiments were also made with graphite rods. H. K. T.

Electrochemical Effects on Magnetising Iron. By T. ANDREWS (*Proc. Roy. Soc.*, **44**, 152—168).—A magnetised and an unmagnetised bar of iron or steel are immersed in different reagents, and the current produced noted. The amount varies considerably, but is large in the case of bromine, salts of copper, and nitric acid. The result is dependent both on the strength of the solution and the degree of magnetisation. With powerful oxidisers, the magnetised bar is generally electropositive, but becomes electronegative with sulphuric acid, dilute hydrochloric acid, and ferric chloride and chlorine. In the last-named instances, the effect may be due to the diamagnetic properties of the solutions, or of the gases evolved. With ferric chloride alone, the magnetised bar is electropositive, with chlorine electronegative, with the two together, electronegative until the chlorine is exhausted, when it becomes electropositive. In the same bar, local currents are produced from the more magnetised portions to the less. These may cause the magnetised bar to be acted on to a greater extent than the unmagnetised. In strong nitric acid, a current is produced from the magnetised to the unmagnetised bar. H. K. T.

Specific Heat of some Solid Organic Compounds. By H. HESS (*Ann. Phys. Chem.* [2], **35**, 410—429).—The author states that, with the exception of some investigations by De Heen (*Bull acad. roy. belg.*, **5**) and A. Battelli (*Atti R. Inst. Veneto* [6], **3**), he has not been able to find any account of investigations of the specific heats of solid organic compounds, and he therefore undertook the present investigation with a view especially of determining the manner in which the specific heats of solid organic substances depend on temperature.

The author gives a number of curves showing the relation between specific heat and temperature in the substances examined, temperatures being taken as ordinates, and the corresponding specific heats as abscissæ. The curves he finds to be sensibly straight lines intersecting the specific heat axis above the zero point, so that the specific heat

can be represented by a formula of the form $a + bt$. The results obtained are given in tabular form (p. 93), c representing the mean specific heat between the temperature limits indicated, and b the temperature coefficient.

The values obtained by assuming the true specific heat to be represented by a formula of the form $a + bt$ are given in the second table, under the head of "observed specific heat," the column headed "calculated specific heat" being calculated from Kopp's law, that the molecular heat of a body is equal to the sum of the atomic heats of its constituents. The atomic heats of carbon, hydrogen, and oxygen respectively are taken as 1·8, 2·3, and 4·0. The column headed t gives the temperature at which the observed and calculated specific heats are equal, and it will be seen that with the exception of oxalic and isosuccinic acids, the different substances obey Kopp's law for some temperature within the limits 35° and 50°.

Kopp's law might be generalised if we could assume the specific heats of carbon, hydrogen, and oxygen to be functions of the temperature, but this would not lead to correct general formulæ, for Regnault (*Compt. rend.*, **26**, 311) and E. Wiedemann (*Ann. Phys. Chem.* **157**, 1) have shown that the specific heats of hydrogen and oxygen are sensibly independent of the temperature, and although H. F. Weber has shown (*Ann. Phys. Chem.*, **147**, 362) that the specific heat of carbon increases considerably with the temperature, this increase would not be sufficient to account for the observed increase in the temperature coefficient.

Name of substance.	Specific heat.		t.
	Calculated.	Observed.	
Oxalic acid	0·2689	0·2941 + 0·00167t	−15·1°
Malonic acid	0·2942	0·2473 + 0·00144t	+32·6

Glutaric acid (liquid)	—	0·6580 + 0·00142t	—
Benzoic acid	—	0·3474 + 0·00262t	—

The author's results show that there are often considerable differences in the specific heats of different isomeric compounds.

G. W. T.

Evolution of Gases from Homogeneous Liquids. By V. H. Veley (*Proc. Roy. Soc.*, **44**, 239—240).—The addition of finely divided substances is found to increase the rate of evolution of gases from liquids in which they are formed. When the temperature remains the same, the rate of evolution rises slowly until a maximum is reached, which is maintained for some time. The rate then decreases proportionally to the diminution in mass. The phenomenon repeats itself when the temperature is lowered and then raised to its former point, and also when the pressure is suddenly increased. The reduction of the pressure to a fraction of an atmosphere produces no permanent effect. The rate of decomposition of formic acid into carbonic anhydride and water is also examined, and is found to agree with the equation $\log(\tau + t) + \log r = \log c$, where τ is the time from the commencement of the observations, t the interval of time from the moment of commencement up to the moment at which the time required for unit change is *nil*, r the mass at the end of each observation, and c a constant. The curve of rate of change conforms with the law $dr/d\tau = -r^2/c$, which expresses the rate at which equivalent masses react on one another. Hence it is presumable that equivalent masses react, and that the change is represented by the equations $HCO{\cdot}OH + HCO{\cdot}OH = HCO{\cdot}O{\cdot}CHO + H_2O$ and $HCO{\cdot}O{\cdot}CHO = 2CO + H_2O$, a reaction similar to the production of ethyl formate from formic acid and alcohol. H. K. T.

Properties of Matter in the Gaseous and Liquid State under Various Conditions of Temperature and Pressure. By the late T. ANDREWS (*Ann. Chim. Phys.* [6], **13**, 411—432).—Regnault (*Mem. Acad. Sci.*, **26**, 680—696) made a series of experiments to determine the tension of a mixture of a gas and a vapour, such as nitrogen or air, and the vapour of water or some more volatile liquid, and came to the conclusion that Dalton's law of partial pressures may be considered theoretically correct in the case of such mixtures, and that probably this law could be proved to be correct experimentally if the mixture of gas and vapour could be enclosed in a vessel the interior surface of which was composed of the volatile liquid. He also found that, under pressures varying from $\frac{2}{3}$ to 2 atmospheres, the compressibility of a mixture of ordinary gases, such as air and carbonic anhydride, hydrogen and sulphurous anhydride, was intermediate between that of each gas separately for the same variations of pressure (*ibid.*, 258).

The results of all experiments which had been carried out up to the time when the author's investigations were commenced, had been to show that, with one exception, Dalton's law is true in all cases for mixtures of gases or vapours, or at any rate in the case of gases and vapours which exert no chemical action on one another. A mixture of the vapours of two mutually soluble liquids, in presence of the two liquids mixed or dissolved, constitutes, however, an important exception to this law, because of the disturbing influence of the chemical affinity of the liquids. But as, up to this time, no experiments had been carried out to prove the truth of Dalton's law under pressures greater than 2 atmospheres, the author investigated the change in volume of a mixture of 3 vols. of pure carbonic anhydride and 4·05 vols. of nitrogen at temperatures above and below the critical temperature of carbonic anhydride, the pressure employed varying between about 40 and 300 atmospheres.

From the results, which are given in tabular form, curves are drawn showing the volume of the mixture at the various temperatures and pressures. These curves are all very similar, showing no difference in character for temperatures above or below 31°. If it be granted that Dalton's and Boyle's laws are true in the case of nitrogen under the pressures employed, the curves showing the change in volume of the carbonic anhydride in the mixture under the various conditions of temperature and pressure prove that below 31° this gas tends to occupy the volume corresponding with the liquid state, although the curves are quite different from those of carbonic anhydride alone. It follows, therefore, that Dalton's law is no longer applicable in this case, and is only strictly true of a perfect gas.

As no liquefaction took place in any of the above experiments, showing that the presence of nitrogen lowered the critical point of the carbonic anhydride, the author investigated this phenomenon more fully. A mixture of 6·2 vols. of carbonic anhydride and 1 vol. of nitrogen was placed under a pressure of 48·3 atmospheres; no condensation occurred until the temperature was lowered to 3·5°. As the pressure was increased the volume of the liquid augmented, and after each increase of pressure, the volume continued to augment slowly for some time; for example, under a pressure of 82 atmospheres the relative volumes of the gas and liquid were at first 8·5 and 5·8, but, the apparatus having been left for some time, the volume of the liquid slowly increased. The pressure having been then raised to 102 atmospheres, the volume of the gas which was at first 1·7 diminished gradually until only a small globule remained, which finally disappeared entirely, the nitrogen dissolving in the liquid carbonic anhydride. In a second experiment, with the same mixture at a higher and constant temperature, the liquid had at first its usual concave surface, and as the pressure was increased, the volume of the liquid also augmented without any noticeable change in the appearance of the concave surface; on further increasing the pressure, the surface of separation appeared in section as a fine line, but when the pressure was again increased, it disappeared entirely, the whole becoming homogeneous. The position in the tube, occupied by the surface of separation, depended on the temperature at which the observation was made; at 14° the liquid filled about two-thirds of the entire space at the very moment when the surface of separation was about to disappear.

The critical temperature of a mixture of 1 vol. of nitrogen and 3·43 vols. of carbonic anhydride was found to be 14°, and the corresponding pressure 98 atmospheres. Experiments with this mixture showed that at 6·3° no condensation took place until the pressure reached 68·7 atmospheres; the liquid then disappeared under increased pressure, but reappeared when the pressure reached 113·2 atmospheres. At 9·9°, the liquid first appeared when the pressure reached 77·6 atmospheres; after having disappeared it was again formed under a pressure of 107·8 atmospheres. At 13·2°, the liquid appeared under a pressure of 91·6 atmospheres, disappeared as the pressure was increased, and reappeared when it attained 103·2 atmospheres. If the mean of the two pressures for each of the above temperatures is taken, the critical pressure at 6·3°, 9·9°, 13·2°, and 14° is found to be 90·9, 92·7, 94·4, and 98 atmospheres respectively.

In the course of these experiments, the author found it convenient to employ a tube bent twice at right angles. When the gaseous mixture was compressed below the critical point, the liquid carbonic anhydride collected in the lower portion of the tube, although part of the liquid was first formed at the surface of the mercury; but the whole of the liquid soon collected at the bottom of the tube. In some experiments, the carbonic anhydride liquefied at temperatures above 20°, and sometimes no condensation took place even a few degrees below this temperature. This phenomenon was found to be owing to the fact that when liquefaction had taken place, if the pressure was diminished so that the mixture could become completely gaseous, the liquid separated into two portions, one rich, the other poor, in carbonic anhydride. The portions of the tube which had been previously occupied by the liquid then contained a large excess of carbonic anhydride, especially when the tube had been previously cooled to −10°, so that almost the whole of the carbonic anhydride had been liquefied. If the pressure was reduced so as to bring the whole of the liquid to the gaseous state, the temperature being at the same time raised to 26°, it was found that the carbonic anhydride could be liquefied by pressure alone (at 26°), provided that the experiment was performed without loss of time. When, however, the mixture was left for some time in the gaseous state, diffusion gradually took place, and the temperature at which liquefaction was possible decreased accordingly. Diffusion was not complete until after some hours, and then increased pressure caused no liquefaction until the temperature was reduced to 14°.

This method of separating the gases was employed to show the effect of diffusion as follows:—A mixture of carbonic anhydride and nitrogen was kept at 8·5° under a pressure of 46·4 atmospheres until diffusion was complete; the volume of the mixture was then 162·2. After liquefying the carbonic anhydride by employing great pressure and lowering the temperature to −12°, the temperature was again raised to 8·5°, and the pressure brought back to 46·4 atmospheres; the volume was then found to be 159·5, showing that a contraction of 2·7 vols. had taken place owing to the separation of the mixed gases. At the end of 1½ hours the volume had increased to 161·5 in consequence of partial diffusion.

In a second experiment at 16°, under a pressure of 47·9 atmospheres, the original volume of the mixture was 164·6, but, after liquefaction, only 161·9 when brought back to the initial temperature and pressure; after 1½ hours the volume had increased to 164·1. In a third experiment at 20°, under a pressure of 46·4 atmospheres, the volume decreased from 175·8 to 173·5 after the separation of the gases.

These results show that when the two gases diffuse into one another under great pressure, an increase in volume occurs, and when they are separated the volume is diminished. This change in volume undoubtedly occurs also under ordinary pressures, but the variation would probably be so small that it would be difficult to detect experimentally. F. S. K.

The Behaviour in Relation to Boyle's Law of certain Gases at Low Pressures. By F. Fuchs (*Ann. Phys. Chem.* [2], **35**, 430—450).—The author, from the results of a series of experiments on atmospheric air, carbonic and sulphurous anhydrides and hydrogen, arrives at the following conclusions:—

(1.) At ordinary temperatures, Boyle's law does not represent a limiting state towards which a gas approaches indefinitely with increasing rarefaction, but at pressures respectively above and below a certain amount, the deviations from Boyle's law are respectively positive and negative. The limits of pressure within which Boyle's law holds are indefinitely small, as any finite change in volume will alter the forces between the gaseous molecules.

(2.) In the case of atmospheric air at the temperature 0°, a change of sign of this kind takes place at a pressure very slightly below the ordinary atmospheric pressure. If any similar change of sign occurs with carbonic and sulphurous anhydrides, it must be at pressures less than any at which the author's observations were made.

(3.) The deviations from Boyle's law in the case of hydrogen at low pressures are so small that hydrogen under these circumstances may, without sensible error, be regarded as a perfect gas.

G. W. T.

Constitution of Solutions. By F. Rüdorff (*Ber.*, **21**, 3044—3050).—Salts of the composition $R_2SO_4 + R''SO_4 + 6H_2O$ and $R_2SO_4 + R_2'''(SO_4)_3 + 24H_2O$ are partially decomposed into their constituents when dissolved in water (compare Abstr., 1888, 342). Hydrogen potassium sulphate behaves similarly, but hydrogen ethyl sulphate diffuses unchanged. The following salts:—

$$3K_2C_2O_4,Fe_2(C_2O_4)_3 + 6H_2O;\ 3Na_2C_2O_4,Fe_2(C_2O_4)_3 + 6H_2O;$$
$$3K_2C_2O_4,Cr_2(C_2O_4)_3 + 6H_2O;\ 2(NH_4)HC_2O_4 + H_2O;$$
$$NaHC_4H_4O_6 + H_2O, \text{ and } 2K(SbO)C_4H_4O_6 + H_2O,$$

diffuse unchanged, but $(NH_4)HC_2O_4,C_2H_2O_4 + 2H_2O$ is partially decomposed into oxalic acid and hydrogen ammonium oxalate.

Solutions of potassium chromate, potassium dichromate, and sodium dichromate diffuse unchanged, but the salt

$$(NH_4)_2CrO_4,MgCrO_4 + 6H_2O$$

is partially decomposed when dissolved in water.

The following salts:—$2NaCl,PtCl_4 + 8H_2O$; $2KCl,PtCl_2$; $2NH_4Cl,HgCl_2$; $Ba(CN)_2,Pt(CN)_2 + 4H_2O$, and all double cyanides are true molecular compounds, but $KCl,Hg(CN)_2$ is partially resolved into its constituents when dissolved in water (*loc. cit.*). NaH_2PO_4 and Na_2HPO_4 diffuse unchanged: Na_3PO_4, on the contrary, is partially decomposed. The three sodium salts of citric acid are not decomposed in aqueous solution.

F. S. K.

Physical Properties of Colloïd Solutions. By C. Lüdeking (*Ann. Phys. Chem.* [2], **35**, 552—557).—In a paper with Wiedemann (Abstr., 1885, 1031) it was shown that the vapour-pressure of a

40 per cent. aqueous solution of gelatin was less at a temperature of 40° than that of pure water. According to Guthrie (this Journal, 1877, i, 36), a 40 per cent. solution of gum boiled at 98°, and a 45 per cent. solution of gelatin at 97·5°: results which were in contradiction to those above mentioned.

With a view of discovering the reason of the discrepancy, the author made experiments on solutions of gum arabic, gum tragacanth, dextrin, starch, and agar-agar.

He finds that a 40 per cent. solution of gum arabic boils at 100°, but carbonic anhydride begins to be given off at a temperature of about 90°, and at a somewhat higher temperature gives the appearance of boiling to the solution.

The other solutions also boiled at 100°, although in the case of gelatin boiling began with the thermometer at 98°, which, however, the author attributes to the liquid not rapidly assuming the same temperature throughout, owing to its viscidity preventing the formation of convection currents. This opinion was based on the fact that the thermometer did not remain at 98°, but gradually rose to 99·8°, where it remained constant.

The author found that the addition of the colloïd in every case slightly lowered the vapour-pressure, and, as he points out, the presence of a solid in solution could not possibly increase the vapour-pressure. For example, if the steam given off at 98° from a gelatin solution had a pressure of 760 mm., it would necessarily recondense to water and mix again with the solution.

When solutions of gum or gelatin are cooled considerably below zero, the author finds that they do not solidify as a whole, as stated by Guthrie, but ice crystals gradually separate out. He finds that gelatin has a strong condensing action on the water of solution.

G. W. T.

Precipitation of Colloïd Substances by Salts. By O. NASSE (*Pflüger's Archiv*, **41**, 504—514).—All proteïds except peptone can be precipitated by saturating a neutral solution with ammonium sulphate, some more easily than others, for instance, globulins more easily than albumins. Other salts have the same power, but none act so readily as ammonium sulphate. This property, however, is not characteristic of proteïds: soaps, gelatin, and certain soluble carbohydrates (glycogen, amidulin, inulin, &c.), are similarly precipitated; it in fact seems to be a property common to colloïd substances.

The question arises, on what does the difference in the concentration of the salt necessary to produce precipitation depend? Is the action of the salt simply due to a struggle of the molecule of proteïd, gelatin, &c., with that of the salt for water, and that the precipitation of the colloïd substance occurs as soon as its water-attracting power is exceeded by that of the salt?

In order to determine whether this is the case, one must ascertain the amount of two or more different salts necessary to precipitate the same amount of one colloïd substance, the necessary concentration of the salt solutions corresponding with $a : b : c$, &c. The same question is then investigated for another colloïd substance, and the ratio

$a' : b' : c'$, &c., found. If then we have only to deal with attraction for water, $a : b : c$, &c., will be found $= a' : b' : c'$, &c.

The following table illustrates the results obtained:—

	The solution contained in 100 c.c. the following amounts of salt when precipitation began.		
Colloïd substances.	*a.* Ammonium sulphate.	*b.* Magnesium sulphate.	*a* : *b*.
Gelatin	12·4	14·8	0·84
White of egg......	20·2	19·6	1·03
"	18·5	19·3	0·95
Serum proteïds	17·4	18·5	0·94
Albumose.........	12·7	13·6	0·93
"	14·9	17·6	0·85
Amidulin.........	20·9	10·5	1·99
Glycogen-dextrin ..	44·7	22·7	1·99

The differences of the numbers in the last column show that water-attracting power is not the only influence at work, but some other relation must exist between the colloïd and the salt. Still it is possible that it may explain some of the precipitations, especially that of gelatin. Gelatin loses many of its characteristic properties after the prolonged heating of its solutions; it, for instance, no longer gelatinises on cooling, and its water-holding power is greatly increased, yet the ratio $a : b = 0·84$ remains constant for the gelatin in all the different stages of this change.

With regard to the proteïds, in which such wide differences occur, it is thought probable that the explanation lies in the fact that loose compounds with the salts are formed.

The paper concludes with some remarks on the influence of temperature in determining precipitation by salts. W. D. H.

New Formula for Calculating the Molecular Volumes of Chemical Compounds at the Boiling Points. By J. A. GROSHANS (*Rec. Trav. Chim.*, 7, 220—225).—The molecular volume of a substance, $C_pH_qO_r$, at the boiling point may be represented by $v_s = a + 10(p + q) - 7·28\,B$ for a fatty compound, or by the same expression *minus* 15 for an aromatic compound, a being the number of c.c. equal to the molecular weight of the compound, and $B = p + q + r$. Both these formulæ obey Kopp's rules, that homologous compounds differing in their composition by CH_2 should differ in their molecular volumes by 22, and that a fatty compound should have approximately the same volume as an aromatic compound which differs in its formula by $C_2 - H_4$.

With hydrocarbons, since $r = 0$, the formula may also be written $(v_s - a)/B = 2·72$ for fatty compounds, or $(v_s - a + 15)/B = 2·72$ for aromatic, both of which are found to agree well with experiment. For halogen-derivatives, an addition of 15 must be made for each atom of halogen contained. H. C.

Molecular Lowering of the Freezing Point of Benzene by Phenols. By E. PATERNÒ (*Ber.*, **21**, 3178—3180).—The author made a number of experiments to ascertain whether the fact that certain substances containing the hydroxyl-group produce an abnormal lowering of the freezing point of benzene was true of all substances, and whether this abnormal behaviour was sufficient proof of the presence of the hydroxyl-group (compare Raoult, Abstr., 1884, 953). The results showed that although phenol behaves in an abnormal manner, the following compounds: ethylphenol, acetylphenol, two isomeric nitrophenols, tribromophenol, picric acid, paracresol, methyl salicylate, thymol, nitrothymol, nitrosothymol, α-naphthol, β-naphthol, and benzylphenol, all produce the normal lowering of the freezing point of benzene and of acetic acid, either in dilute or moderately concentrated solutions, the variations caused by change in concentration of course being taken into consideration.

The molecular weight of water determined by Raoult's method in acetic acid solution was found to be 18 (compare Raoult, *loc. cit.*), but the author points out that this result is not by any means conclusive, as, even if the molecules were originally more complex, they would be simplified by the act of solution.

Hentschel's experiments with acetic acid (*Zeit. phys. Chem.*, **2**, 308) seem to point to an opposite conclusion, but in this case the freezing point of the benzene solution was considerably below that of acetic acid. The fact that the molecular weight of water is found to be 36 when the freezing point of the solution lies below 0° shows that the temperature at which the mixture freezes is a most important factor in the case. F. S. K.

Inorganic Chemistry.

Preparation of Chemically Pure Hydrogen Peroxide. By MANN (*Chem. Zeit.*, **12**, 857).—Hydrogen peroxide of commerce contains many impurities; it is mixed with a ¼ per cent. of phosphoric acid and then, while stirring vigorously, barium hydroxide is added until the solution is exactly neutral to litmus. The clear solution is poured into a cold saturated solution of barium hydroxide, and the precipitate of barium peroxide is well washed and may be kept for the preparation of pure hydrogen peroxide. For this purpose, it is made into a thin magma and carefully decomposed by dropping steadily into dilute sulphuric acid containing 12 per cent. of concentrated acid; any excess of sulphuric acid being removed by hydroxide, and *vice versâ*. Excess of barium peroxide must be avoided as it decomposes hydrogen peroxide. D. A. L.

Compounds of Chlorine with Iodine. By W. STORTENBEKER (*Rec. Trav. Chim.*, 7, 152—205).—The only compounds of iodine with chlorine which are capable of existing in the solid state are ICl and ICl_3. Two modifications of the first exist which the author terms α and β. ICl is best prepared by passing dry chlorine over iodine and then distilling the product with a few grams of iodine. If the distillate is allowed to solidify at −25°, the α-modification is obtained in long, dark-red needles, melting at 27·2°. If the crystallisation take place between +5° and −10°, modification β is usually, but not invariably, obtained. When slowly formed, it crystallises in dark-red plates melting at 13·9°. It is unstable and readily converted into the α-modification, into which it is gradually changed. The most favourable temperatures for its existence are between 0° and −10°. If cooled below −12° it changes into the α-modification.

The trichloride ICl_3 is prepared by treating iodine, or the liquid ICl with excess of chlorine. It sublimes very readily and settles on the sides of the apparatus in slender, yellow needles. It melts at the ordinary pressure at temperatures varying between 20° and 60°, but under a pressure of 16 atmos. melts regularly at 101°. After fusion, it solidifies in brownish-red crystals.

The author further shows that every mixture of the two elements, chlorine and iodine, is possible in the liquid state above a certain temperature which depends on the proportion of the two elements. Below that temperature, one of the substances I_2, $ICl\alpha$, $ICl\beta$, ICl_3, or Cl_2 will separate in the solid state. If on a diagram representing pressures and temperatures the two points be taken at which chlorine and iodine melt, corresponding with the temperatures −102° and 114·3°, then between these points will lie the curve which is the locus of the points at which the various mixtures of chlorine and iodine exist in the liquid state. These two end points are triple points for the pure elements, and on the intermediate curve will be found three quadruple points, each corresponding to equilibrium between four phases (comp. Roozeboom, Abstr., 1888, 1151).

t.	*p.*	Phases present.
7·9°	11 mm.	I_2, $ICl\alpha$, $I \sim Cl_{0\cdot66}$, $I + Cl_{0\cdot02}$ (gas).
22·7	42 ,,	$Cl\alpha$, ICl_3, $I \sim Cl_{1\cdot19}$, $I + Cl_{1\cdot75}$ (gas).
−102·0	< 1 atmos.	ICl_3, Cl_2, $I \sim Cl_n$, $I + Cl_m$ (gas).

Complete solidification will only occur at the three distinct temperatures of the quadruple points, when separation of a mixture of the solids $I_2 + ICl$, $ICl + ICl_3$ or $ICl_3 + Cl_2$ will take place.

A study of the compounds of iodine and chlorine in the gaseous state shows that molecules ICl exist in that condition, and only suffer slight dissociation even at 80°, whereas ICl_3 cannot exist as gas, the molecules undergoing complete dissociation. H. C.

Theory of the Lead Chamber Process. By F. RASCHIG (*Annalen*, **248**, 123—140), and by G. LUNGE (*Ber.*, **21**, 3223—3240).—Controversial papers.

Compounds of Ammonia with Selenious Anhydride. By C. A. CAMERON and J. MACALLAN (*Proc. Roy. Soc.*, **44**, 112—115).—Dry ammonia passed into an alcoholic solution of selenious anhydride forms *ammonium selenosamate*, $NH_4{\cdot}SeO_2{\cdot}NH_2$, which crystallises in hexagonal prisms and pyramids. It loses ammonia very easily even on exposure to air or treatment with solvents and on heating. It is only partially converted into ammonium selenate by the action of water even after continued boiling. Potassium hydroxide at once liberates ammonia. Sulphuric acid reacts violently with it, and chlorine oxidises it to ammonium selenate. Sulphurous anhydride and stannous chloride reduce it with separation of selenium. The acid salt formed from the above by loss of ammonia has the composition $(NH_4)H(SeO_2{\cdot}NH_2)_2$, and is a deliquescent salt soluble in alcohol. It behaves like the normal salt, but is much more stable. When strongly heated, it is decomposed into ammonium selenite, ammonia, water, nitrogen and fused selenium. These compounds of selenious anhydride are more akin to the compounds of sulphuric anhydride with ammonia than to those of sulphurous anhydride. H. K. T.

Constitution of Phosphorous Acid. By V. WEDENSKY (*J. Russ. Chem. Soc.*, 1888, **20**, 29—32).—When phosphorous acid is dissolved in acetic anhydride, a colourless crystalline substance separates after a time. This is washed with ether and analysed; the results agree with the formula of a monacetyl-derivative of phosphorous acid, $(C_2H_3O)H_2PO_3$. When acetic anhydride acts on phosphorus trichloride, an analogous compound is obtained; this, however, seems to be a mixture, and cannot be obtained free from chlorine. A phosphorous triacetyl-derivative could not be obtained.

B. B.

Compounds of Arsenious Acid with Sodium Iodide and Bromide. By F. RÜDORFF (*Ber.*, **21**, 3051—3053).—The compound $NaBr,2As_2O_3$ is obtained when arsenious acid (20 grams) and sodium bromide (120 grams) are dissolved in boiling water (350 c.c.), and the filtered solution allowed to cool slowly (compare Abstr., 1887, 107). It crystallises in hexagonal plates and is decomposed when warmed with water.

The compound $NaI,2As_2O_3$, prepared by dissolving arsenious acid (22 grams) and sodium iodide (60 grams) in hot water (500 c.c.), crystallises in hexagonal plates and is decomposed by hot water.

F. S. K.

Preparation of Boron and Silicon by Electrolysis. By W. HAMPE (*Chem. Zeit.*, **12**, 841).—When fused borax is submitted to electrolysis in a gas-carbon crucible with a platinum positive and a gas-carbon negative electrode, oxygen is evolved from the platinum, whilst in the first instance sodium separates at the negative electrode, but this by a secondary reaction liberates boron. The negative electrode is from time to time withdrawn from the crucible, and when cool, the slag carrying the boron is carefully knocked off. This is treated with hydrochloric acid and water, leaving pure amorphous boron mixed with a small quantity of carbon and some isolated microscopic crystals of, at present, unknown composition. Fused boric anhydride does not conduct. But amorphous silicon may be prepared in a similar manner from fused sodium silicate.

D. A. L.

Beryllium Silicates. By P. HAUTEFEUILLE and A. PERREY (*Compt. rend.*, **107**, 786—789).—If the constituents of an aluminium or beryllium leucite are fused at 600—800° with excess of potassium vanadate, mineralisation takes place rapidly, but the composition of the product varies as the vanadate gives up more or less of its alkali, and it is rarely homogeneous. The product is washed with water and very dilute potash, and the crystalline constituents are separated by solutions of cadmium tungstoborate of varying specific gravity.

All the products crystallise in icositetrahedrons, a^2. In the aluminium compounds, the potassium and aluminium are always present in the proportion $Al_2O_3 : K_2O$, whilst in the beryllium compounds the ratio of beryllia to potash varies from 1·25 to 0·5. The silicate containing $Be_2O_3,2K_2O$ is obtained with a mixture which always contains an excess of alkali, whilst the silicate containing Be_2O_3,K_2O is obtained with a neutral mixture. In the aluminium compounds, the ratio of silica to potash varies from 4 to 5, whilst in the beryllium compounds the same ratio varies from 4·5 to 5·0. In the latter case, the product is always heterogeneous, and probably results from the simultaneous crystallisation of silicates containing $4SiO_2$ and $5SiO_2$. The silicate $4SiO_2,Be_2O_3,K_2O$ is obtained in icositetrahedrons by rapidly heating its constituents to a high temperature and cooling very gradually.

Products were also obtained containing both alumina and beryllia. They are all fusible, and are homogeneous with respect to sp. gr. The following ratios were observed:—$K_2O : SiO_2 :: 1 : 4·5—4·8$; $K_2O : R_2O_3 :: 1 : 0·75—1·0$; $Be_2O_3 : Al_2O_3 :: 1 : 0·5—1·75$. Silicates containing beryllia and ferric oxide are yellowish, crystallise in the same form, and are homogeneous with respect to specific gravity. The following ratios were observed:—$K_2O : SiO_2 :: 1 : 4·59—5·0$; $K_2O : R_2O_3 :: 1 : 0·6—1·3$; $Be_2O_3 : Fe_2O_3 :: 1 : 0·3—1·3$.

Alumina and silica in the proportion of 1 mol. of Al_2O_3 to 6 mols. of SiO_3, heated with potassium vanadate, yield orthoclase in macled, prismatic crystals; but with beryllia in place of alumina, the crystals are always icositetrahedrons. With a mixture of alumina and beryllia, however, non-macled, prismatic crystals, of the composition $6SiO_2,R_2O_3,K_2O$ are obtained, and are homogeneous with respect to specific gravity. The ratio $SiO_2 : K_2O$ remains constant, whilst the ratio $Al_2O_3 : Be_2O_2$ varies.

The silicates obtained with beryllium may be regarded as mixtures of the following compounds:—

$8SiO_2,Be_2O_3,2K_2O$ $10SiO_2,Be_2O_3,2K_2O$,
$4SiO_2,Be_2O_3,K_2O$ $5SiO_2,Be_2O_3,K_2O$.

The fact that the beryllia can be replaced by alumina and ferric oxide in these compounds, and can replace alumina in orthoclase, combined with the well-known relations of beryllium to magnesium, would seem to indicate that beryllia has sometimes the functions of a monoxide and sometimes those of a sesquioxide. C. H. B.

Occlusion of Gas by Electrolytic Copper. By A. SORET (*Compt. rend.*, **107**, 733—734).—With dilute copper solutions, unless the current is very weak, the precipitated metal is spongy, the nature of the deposit depending not only on the strength of the solution and the intensity of the current, but also on the proportion of free acid present. Lenz obtained 4·4 vols. of hydrogen from 1 vol. of deposited copper.

The author finds that electrolytic copper always contains hydrogen, which, however, is simply occluded. There is a connection between the volume of gas occluded and the temperature and acidity of the solution. These conditions also affect the malleability of the metallic deposit. The occluded hydrogen sometimes contains small quantities of carbonic anhydride and traces of carbonic oxide. C. H. B.

Mechanical Properties of Metals in Relation to the Periodic Law. By W. C. ROBERTS-AUSTEN (*Proc. Roy. Soc.*, **43**, 425—428). —Very pure gold was alloyed with 0·2 per cent. of various metals, and the tensile strength determined. The tenacity was found to be affected by the elements in the order of their atomic volumes, those elements which have a higher atomic volume than gold diminishing its tenacity very considerably, whilst silver, which has nearly the same atomic volume as gold, hardly affects either its tenacity or extensibility. Hence it appears that Carnelley's law—that "the properties of compounds of the elements are a periodic function of their atomic weights," may also be applied to alloys. Tenacity was chosen for examination, since those metals which are most tenacious have the highest melting points, and the melting point, according to Pictet, is intimately connected with the lengths of the molecular oscillations. H. K. T.

Dissolution of Iron in Aqueous Soda. By G. ZIRNITÉ (*Chem. Zeit.*, **12**, 355).—When a strong current of air is blown into a hot, concentrated solution of soda containing about 34 per cent. of hydroxide, standing in an iron vessel, or to which finely divided hydrated ferric oxide has been added, perceptible quantities of iron are dissolved without colouring the liquid. The solution remains clear and colourless for several days at the ordinary temperature, but ultimately becomes turbid, yellow, and finally red, owing to the separation of the hydrated ferric oxide; this colour, however, disappears again on heating. When the colourless solution is diluted, the ferric oxide is precipitated in about half an hour, but is redissolved by concentrating the diluted solution. Hydrogen sulphide at first produces a deep, cherry-red coloration in the colourless liquid, and on continuing the action a greenish-black precipitate is formed, leaving a clear solution free from iron, but slightly yellow from sodium sulphide. It is suggested that the iron exists in solution as sodium perferrate, $NaFeO_4$. D. A. L.

Ammonium Fluoroxymolybdates. By F. MAURO (*Chem. Centr.*, 1888, 1056—1057, from *Mem. R. Acad. dei Lincei* [4], 4, 481—488).—*Triammonium fluoroxymolybdate*, $MoO_2F_2,3NH_4F$, prepared by evaporating a solution of ammonium molybdate in excess of ammonium fluoride solution acidified with hydrogen fluoride, is obtained in clear and colourless rhombic prisms. The faces (100), (010), (110), and (011) were observed, and the angles (100) : (110) = 28° 36′, (011) : $(0\bar{1}1)$ = 82° 29′, and (011) : (110) = 71° 36′. Axial ratio, $a : b : c = 0{\cdot}5452 : 1 : 0{\cdot}8767$. It is soluble in water, producing an acid solution. On heating, white fumes are evolved and anhydrous molybdic acid remains. It contains no water of crystallisation.

Fluorammonium-molybdic anhydride, $MoO_3,2NH_4F$, prepared by adding ammonia to the solution of the last-named salt, and is thus obtained as a white, microscopic, crystalline precipitate. Larger crystals may be obtained by dissolving the compound in a hot solution of ammonium fluoride and ammonia, and allowing to evaporate spontaneously by exposure to the air or over sulphuric acid, when the salt crystallises out—at first as prisms, but later in octahedrons. If the precipitated salt is simply dissolved in ammonia and then allowed to evaporate, monoclinic crystals of hydrated ammonium molybdate separate first, then, later, the prisms and octahedrons of the new salt. The crystals appear usually in the form of twins, grown together in such a manner as to give the crystal the appearance of a hexagonal prism. They are shining, transparent, light-yellow, and belong to the rhombic system; $a : b : c = 0{\cdot}57464 : 1 : 0{\cdot}67705$. The faces (010), (001), (110), and (011) were observed. Twinning plane (110). The angles measured were: (110) : $(1\bar{1}0)$ = 59° 46′; (010) : (110) = 60° 7′; (010) : (011) = 55° 54′; and (110) : (011) = 73° 47′. This salt is decomposed by water. It is anhydrous, and is decomposed on heating above 100°, molybdic acid remaining.

Normal ammonium fluoroxymolybdate, $MoO_2F_2,2NH_4F$, is prepared from the last-named salt by spontaneous evaporation of the aqueous solution, rendered acid with hydrogen fluoride. It consists of brightly shining, transparent, colourless plates or prisms belonging to the rhombic system; $a : b : c = 0{\cdot}8413 : 1 : 1{\cdot}0164$. The faces (010), (001), (011), (201), and (221) were observed. The angles measured were: (001) : (201) = 67° 31′; (001) : (011) = 45° 28′; (001) : (221) = 72° 26′; (201) : (011) = 74° 27′; (011) : (221) = 49° 31′; and (201) : (221) = 37° 52′. This salt is sparingly soluble in water, and is decomposed by heating above 100°; ammonium fluoride and hydrogen fluoride are evolved, leaving molybdic acid.

Octahedric ammonium fluoroxymolybdate,

$$MoO_2F_2,4NH_4F,(NH_4)_2MoO_4,$$

a double salt of ammonium fluoroxymolybdate with ammonium molybdate, is prepared by allowing a solution of triammonium fluoroxymolybdate in ammonia to evaporate spontaneously in the air or over sulphuric acid. It forms small, colourless, transparent, lustrous octahedrons, which gradually disintegrate when exposed to the air. It is isomorphous with the corresponding double salt of tungsten. It is soluble in water, and does not again crystallise out of the solution. It suffers decomposition, like the other salts, when heated above 100°.

Ammonium dimolybdate, $2MoO_3,(NH_4)_2O + H_2O$, prepared by dissolving fluorammonium-molybdic anhydride in ammonia and allowing the solution to remain. It forms transparent, colourless, lustrous, monoclinic crystals—usually pyramidal;

$$a : b : c = 0{\cdot}99628 : 1 : 0{\cdot}94497 ; \beta = 72° 47' 41''.$$

The faces observed were: (100), (010), (011), $(10\bar{1})$, (111), and $(\bar{1}11)$; the angles: (001) : (100) = 72° 48'; (001) : $(\bar{1}01)$ = 52° 44'; (100) : $(10\bar{1})$ = 54° 28'. By heating above 100° this compound behaves exactly like the other members of the series, and leaves a residue of molybdic acid. J. W. L.

Tin. By L. VIGNON (*Compt. rend.*, **107**, 734—737).—When sheet zinc is immersed in a solution of a tin salt which contains no free acid, and the precipitated tin is washed with water and dried in contact with air, the product is infusible and burns like tinder when heated in presence of air. If heated to redness in a porcelain tube in a current of carbonic anhydride for two hours, it separates into small globules of fused tin and a grey powder. These are separated by levigation, and after the powder has been dried, it burns readily when heated in the air. The infusible tin occurs in slender, dendritic forms of sp. gr. 6·910 to 7·198 at —15°, and contains 96 to 97·3 per cent. of tin. It dissolves readily in hydrochloric acid with evolution of hydrogen. The alteration in the properties of the tin does not take place during precipitation, but when the tin is dried in contact with air it is partially converted into stannous oxide, the alteration taking place the more readily the less the proportion of free acid in the liquid from which the tin is precipitated. If much free acid is present, the tin does not oxidise when dried. The proportion of stannous oxide in the oxidised tin varies from 22·5 to 33·4 per cent., and when combustion takes place stannic oxide is formed.

C. H. B.

Fluorine-derivatives of Vanadium and its Analogues. By E. PETERSEN (*Ber.*, **21**, 3257—3259).—The following compounds were prepared by treating the oxides dissolved in hydrofluoric acid with a solution of the various fluorides.

(I.) *Compounds derived from the Sesquioxide.*—(1) $V_2F_6 + 6H_2O$, large, readily soluble, dark green rhombohedra; (2) $V_2F_6,4KF + 2H_2O$, bright green, sparingly soluble, crystalline powder; (3) $V_2F_6,6AmF$, small, grass-green, regular octahedra; (4) $Cr_2F_6,6AmF$ (Wagner, Abstr., 1886, 676), rather darker green octahedra; (5) $Ti_2F_6,6AmF$ (Piccini, *Compt. rend.*, **97**), small, red-violet octahedra; (6) $Al_2F_6,6AmF$, sparingly soluble, dazzling white, crystalline powder; (7) $V_2F_6,4AmF + 2H_2O$, emerald-green, rather large crystals, like octahedra, but polarising; (8) $V_2F_6,2AmF + 4H_2O$, darker green, lamellar aggregates; (9) $V_2F_6,5NaF + H_2O$, bright green, sparingly soluble, crystalline powder; (10) $V_2F_6,2CoF_2 + 14H_2O$, small, dark green, monoclinic prisms; (11) $Cr_2F_6,2CoF_2 + 14H_2O$, pure dark green, monoclinic prisms; (12) $V_2F_6,2NiF_2 + 14H_2O$, grass-green, monoclinic prisms;

(13) $Cr_2F_6,2NiF_2 + 14H_2O$, emerald-green, monoclinic prisms. The last four compounds are isomorphous.

(II.) *Compounds corresponding with Vanadium Dioxide.*—(14) $VOF_2,3AmF$, small, blue, almost regular octahedra, but polarising; (15) $VOF_2,2AmF + H_2O$ (Baker, Trans., 1878, 392), larger, dark blue prisms; (16) $4VOF_2,7AmF + 5H_2O$, still darker blue, lamellar aggregates; (17) $4VF_4,2AmF + xH_2O$, small, blue-green prisms, stable only in solutions, strongly acidified with hydrogen fluoride; (18) $3VOF_2,7KF$; (19) $VOF_2,2KF$; (20) $3VOF_2,8NaF + 2H_2O$. These three form bright blue, sparingly soluble, crystalline powders.

(III.) *Compounds derived from the Pentoxide.*—(21) $VOF_3,2KF$, colourless, crystalline powder; (22) $2VOF_3,3KF,HF$, white, lustrous prisms; (23) $VF_5,VOF_3,4KF$, colourless aggregates of very slender needles; (24) $VO_2F,2KF$, golden-yellow, lustrous, hexagonal prisms, (25) $2VO_2F,3KF$, bright yellow prisms; (26) $5VOF_3,9AmF,3HF$, colourless, dull lustrous prisms; (27) $VO_2F,3AmF$, larger, straw-coloured, probably rhombic crystals; (28) $4VO_2F,7AmF,HF$, white, lustrous aggregates; (29) $2Nb_2O_5,3KF + 5H_2O$, lustrous white, sparingly soluble, crystalline powder; (30) $Nb_2O_5,KF + 3H_2O$, colourless prisms. The compounds 14, 19, and 27 seem to be identical with those prepared by Piccini and Giorgis (*Atti d. R. Acc. dei Lincei*, 1888, 590, and *Gaz.*, **18**, 186).

The thermochemical relation of hydrogen fluoride to the sesquioxides of iron, chromium, and vanadium was determined. The following numbers were obtained for the heat of neutralisation in dilute aqueous solutions:—$(Fe_2O_6H_6,6HF + Aq) = 47500$ cal., $(Cr_2O_6H_6,6AF + Aq) = 50330$ cal., $(V_2O_6H_6,6HF + Aq) = 52240$ cal.

N. H. M.

Decomposition of Antimony Sulphide by Boiling Water. By W. Elbers (*Chem. Zeit.*, **12**, 355—356).—When antimonious sulphide is boiled with water, it is decomposed with the evolution of hydrogen sulphide and the formation of antimonious anhydride. In this way 0·05 gram of the sulphide was completely converted into the anhydride in 14 hours; the liquid then had a slightly alkaline reaction.

Mineralogical Chemistry.

Native Platinum from Canada. By G. C. HOFFMAN (*Jahrb. f. Min.*, 1888, ii, Ref., 386, from *Geol. Surv. Can. Rep.*, 2, 5).—Native platinum has been found with gold in several rivers in British Columbia. From the bed of Granite Creek, a tributary of the Similkameen river, grains were obtained varying in diameter from 1 to 4 mm., and weighing altogether 18·266 grams. The material was separated into a magnetic (I) and a non-magnetic portion (II), the compositions of which were as follows:—

	Pt.	Pd.	Rh.	Ir.	Cu.	Fe.	OsIr.	Chromite.	Total.
I.	78·43	0·09	1·70	1·04	3·89	9·78	3·77	1·27	99·97
II.	68·19	0·26	3·10	1·21	3·09	7·87	14·62	1·95	100·29

The sp. gr. of the magnetic portion was 16·095, and that of the non-magnetic portion 17·01. B. H. B.

The Pyroxenites of Morbihan. By C. BARROIS (*Jahrb. f. Min.*, 1888, ii, Ref., 413—414, from *Ann. soc. géol. du Nord*, 15, 69—96).—The pyroxenites of Morbihan form beds 0·1 to 2 metres in thickness in gneiss and mica-schists of Archæan age. The main constituent of these rocks is a pale green augite of the following composition:—

SiO_2.	CaO.	MgO.	Fe_2O_3.	Al_2O_3.	Na_2O.	K_2O.	Total.
51·5	24·3	11·9	8·5	5·0	1·1	trace	102·3

The augite is accompanied by zircon, titanite, and apatite in small quantities, by garnet and idocrase in varying amounts, and by quartz grains associated with felspar. Irregular grains of orthoclase only occur in certain beds, and microcline is also of exceptional occurrence. A fibrous actinolite is, however, present in large quantities, in many cases replacing the augite, so that rocks resembling nephrite are produced. Titaniferous iron ore and ferric hydroxide are also present. By the variety of the character and relative proportions of the constituents, numerous distinct types are distinguished, which may occur in the same bed. The author regards these pyroxenites as metamorphic limestones. B. H. B.

Riebeckite, and the New Formation of Albite in Granitic Orthoclase. By A. SAUER (*Chem. Centr.*, 1888, 1128, from *Zeit. deut. geol. Gess.*, 40, 138—152).—A new member of the hornblende-granite group has been found by the author in Socotra. This hornblende, named *riebeckite*, has the same composition as arfvedsonite, and is the analogue of ägirin of the augite series. From the analysis (No. 1 below) the formula $5FeSiO_3,4Na_2SiO_3,5Fe_2Si_3O_9$ has been calculated.

The Socotra granite is much disintegrated, and the author was thus enabled to examine more completely certain interchanges in the granitic orthoclases. The microscopical examination showed an opalescence from the edge towards the centre of the crystals, occasioned by the formation of albite, the crystals having been originally perfectly clear and without inclosures. The following are the analyses of riebeckite (1) and the secondary albite (2):—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	MnO.	CaO.	Na_2O.	K_2O.
(1.)	50·01	—	28·30	9·87	0·34	0·63	1·32	8·79	0·72
(2.)	70·24	17·18	0·64	—	—	—	—	6·86	5·19

J. W. L.

The Dachberg, a Volcano of the Rhone. By F. RINNE (*Jahrb. f. Min.*, 1888, ii, Ref., 406—407, from *Jahrb. preuss. geol. Landesanst.*, 1886, 1—22).—Near Rasdorf on the Rhone is situated the Dachberg, on the summit of which is an unmistakeable crater. The unaltered basalt at the edge of the crater is a dense, glassy felspar-basalt, consisting of plagioclase, augite, olivine, magnetite, biotite, and apatite. The chemical composition of the basalt is as follows:—

SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	MgO.	CaO.	Na_2O.
41·71	3·51	15·80	5·59	7·64	0·16	4·85	10·30	6·08

K_2O.	Li_2O.	SO_3.	Cl.	H_2O.	CO_2.	P_2O_5.	Total.	Sp. gr.
1·00	trace	0·12	0·46	2·22	2·01	trace	101·45	2·90

B. H. B.

Dolerite of Londorf. By A. STRENG (*Jahrb. f. Min.*, 1888, ii, Mem., 181—229).—The author has made an exhaustive mineralogical and chemical investigation of the typical dolerites of the Vogelsberg. The dolerite of Londorf, to which he has principally directed his attention, has the following percentage composition:—

SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	K_2O.
49·08	1·82	13·43	6·49	5·92	8·92	9·58	1·00

Na_2O.	P_2O_5.	H_2O.	Total.
3·42	0·51	0·32	100·49

From analyses of its constituents, the dolerite is calculated to be composed of 1·18 per cent. of apatite, 56·01 per cent. of andesine, 19·80 per cent. of augite, 20·11 per cent. of olivine, and 3·10 per cent. of magnetite and titaniferous iron ore. B. H. B.

Porphyrites at Gabian. By P. DE ROUVILLE and A. DELAGE (*Compt. rend.*, **107**, 665—667).—Near Gabian in Hérault there is a dyke which runs north-east and south-west and consists of two porphyrites.

One of these, which is by far the more abundant of the two, cuts through silurian, devonian, and carboniferous beds without producing any noteworthy metamorphism, and then penetrates into coal-measures which have undergone somewhat profound alteration. It follows that this dyke was formed after the deposition of the coal-measures, and the fact that pebbles in the overlying permian conglomerate consist of the material of the dyke, shows that it was formed before the deposition of the permian beds. This dyke is not homogeneous: it contains apatite, zircon, magnetite, oligoclase, black mica, orthoclase, amorphous matter, chlorite, calcite, damourite, and quartz.

The second porphyrite forms isolated masses in the main dyke, and is of later formation than the lower permian, since the latter beds are somewhat altered where they come in contact with the dyke. It contains large crystals, the nature of which could not be determined, well developed and distinct microliths of labradorite, magnetite, augite which has to a great extent been converted into chlorite, calcite, chlorite, damourite, quartz, and ferruginous products of decomposition.

C. H. B.

Composition of the Serpentine Rocks of Colle di Cassimoreno and Monte Ragola. By C. MONTEMARTINI (*Gazzetta*, **18**, 103—112).—At Colle di Cassimoreno and also in the neighbourhood of Monte Ragola, Chistoni found isolated masses of serpentine rock exhibiting strong magnetic polarity. The author is indebted to him for the two specimens he has examined.

The serpentine of Colle di Cassimoreno is massive and compact; of brecciated and porphyritic appearance, with lustrous, lamellar crystals of enstatite (bronzite) disseminated through the dark-green ground-mass. Besides these crystals, diopside and picotite also occur, together with magnetite, which forms one of the principal constituents of the rock. The hardness of the ground-mass is 6·5 and the sp. gr. at 13° varies from 2·73 to 2·76.

The powdered rock is ash-grey in colour, and like all serpentine rocks has a marked alkaline reaction. Heated in contact with the air, it assumes an ochreous tint. It is partly decomposed by the action of hydrochloric or sulphuric acid, with separation of gelatinous silica; the unattacked portion consists principally of the crystals of enstatite and picotite. The rock on analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Loss on ignition.	Total.
41·19	2·77	4·03	4·33	2·32	34·03	10·13	98·8

The enstatite, separated as far as possible from the other constituents of the rock, was analysed, and the results are given under I. In II the composition of the lherzolite from Germagnano in Piedmont is given for comparison:—

	SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.	H_2O.	Total.
I.	50·65	5·05	7·99	1·68	31·44	2·78	99·59
II.	52·19	2·15	8·85	2·96	31·84	1·77	99·76

These results show that the enstatite is bronzite.

The rock therefore consists of a serpentine formed by the decomposition of peridote together with enstatite, diopside, magnetite, and other minerals; this is also borne out by the microscopical and optical examination, full details of which are given. The rock also contains olivine, diallage, and amphibole.

The sample of rock from Monte Ragola, which was from the rock mass of the mountain itself, had no magnetic polarity, and was quite different in appearance from the one just described.

The ground-mass is light-green with dull-green nodules disseminated in it; these can easily be separated, and on examination were found to consist of altered bastite. A microscopical examination showed that the rock had all the characters of a serpentine formed by the alteration of a pyroxenic mineral. Neither the enstatite, diopside, nor spinelle which characterise the Cassimoreno serpentine could be discovered in it. Its sp. gr. at 14° is 2·54.

The analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Loss on ignition.	Total.
39·18	3·65	7·26	1·55	0·42	34·79	12·81	99·66

Chromium, nickel, and manganese were also detected.

C. E. G.

Organic Chemistry.

Action of Zinc Ethide on Nitroethane. By I. Bevad (*J. Russ. Chem. Soc.*, 1888, **20**, 125—135).—The object of this investigation was to decide whether "nitroethane" is really a nitro-compound (V. Meyer), a hydroxylamine-derivative, $CH_3\cdot CO\cdot NH_2O$ (Kissel), or an isonitroso-derivative, $HO\cdot CH_2\cdot CH\colon N\cdot OH$ (Alexéeff). When zinc ethide, ether, and nitroethane are mixed in an atmosphere of carbonic anhydride, the mixture becomes red, and after some time crystals are formed which disappear again in about a fortnight. On decomposing the product of reaction with water, distilling, and treating the distillate with hydrochloric acid, a solution is obtained which on evaporation gives crystals of a very hygroscopic salt. On decomposing this with alkalis, a colourless oil of sp. gr. 0·8935 at 0° is obtained, which proved to be *triethylhydroxylamine*, Et_3NO. It is somewhat soluble in water and soluble in all proportions in ether, alcohol, and benzene. Its compounds with hydrochloric, sulphuric, and acetic acids are extremely hygroscopic. The oxalate, $(Et_3NO)_2,H_2C_2O_4$, was obtained by mixing ethereal solutions of its constituents. Triethylhydroxylamine and its salts have powerful reducing properties, as shown by their behaviour with silver, cupric, and mercuric salts. The original ethereal distillate contains in addition, some unchanged nitroethane, but no other product is formed, if the substances employed are in molecular proportion.

The author concludes that nitroethane is a true nitro-compound. Its reaction with zinc ethide takes place in different stages. At first crystals are formed of the formula $2EtNO_2 + 7ZnEt_2$ (as shown by zinc determinations). When these crystals disappear, the compound $Et_3N(OZnEt)_2$ is formed; and this reacts with water as follows: $Et_3N(OZn{\cdot}C_2H_5)_2 + 4H_2O = Et_3N(OH)_2 + 2C_2H_6 + 2Zn(OH)_2$. The $Et_3N(OH)_2$ being unstable, however, is converted into the free base with elimination of water.

Nitromethane treated in the same way with zinc ethide gives methyldiethylhydroxylamine. When zinc ethide is added to bromonitroethane, a violent reaction takes place, and when this is over, if the product is distilled with water, secondary nitrobutane, $CHMeEt{\cdot}NO_2$, boiling at 138°, is formed. In this way from lower nitro-compounds those of higher homologues may be formed by synthesis. Nitrobenzene with zinc ethide gives no higher nitro-compound, reduction taking place with formation of aniline. If nitroethane were acethydroxamic acid, it should be formed from hydroxylamine hydrochloride and acetic anhydride; the experiments, however, made by the author with this object, gave a negative result. B. B.

Action of Chlorine on Isopropylethylene. By I. KONDAKOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 141—148).—Isopropylethylene (b. p. 21—22°) was brought in contact with chlorine by passing the gas into the vessel by means of a tube terminating at some distance from the surface of the liquid, in order to prevent the action from being too violent, and to keep the course of the reaction as uniform as possible from the beginning to the end. When no more drops were formed on the sides of the vessel, the process was stopped. Various temperatures from $-20°$ to $+16°$ were employed, but in all cases the products were the same. After washing and drying the product, a liquid was obtained which, when submitted to fractional distillation, boiled chiefly between 143° and 145°. A small part boiling at 100—143° was proved to be a monochloride. The principal portion boiling at 143—145°, was an additive product of isopropylethylene, $C_5H_{10}Cl_2$. Its sp. gr. at 0° is 1·1106 and 1·0923 at 17·5°. When heated in sealed tubes with fused potassium acetate and acetic acid at 120°, it is converted into a glycol; this boils at 212—219°; the quantity obtained, however, was so small, that no experiments could be made to prove that it was isopropylethylene glycol. Isopropylethylene, when acted on by alcoholic potash, yields a monochloro-derivative boiling between 91° and 96°. These experiments show that isopropyethylene and chlorine yield additive products only, as pointed out by Lwoff.

B. B.

Polymeride of Methyl Cyanide. By R. HOLTZWART (*J. pr. Chem.* [2], **38**, 343—344).—When an ethereal solution of methyl cyanide is acted on by sodium, a white powder is formed and methane is evolved; when treated with water, the powder yields a yellow oil which can be crystallised in white needles from a mixture of ether

and light petroleum. A better yield is obtained by digesting the powder with aqueous ether. The crystals melt at 52—53°, are soluble in ether, alcohol, benzene, and chloroform, sparingly so in water and light petroleum. The molecular formula is $C_4H_6N_2$. When digested with water, ammonia is evolved, and a crystalline precipitate, sparingly soluble in cold water, is formed, having the composition $C_8H_8N_2O$; and when treated with acetic chloride in ethereal solution, a yellow, amorphous precipitate of the composition $2C_4H_6N_2,COMeCl$ separates; this is decomposed by water, forming a white, crystalline powder of the formula $C_8H_9N_3$. The investigation is still in progress.
A. G. B.

Polymeride of Ethyl Cyanide. By E. v. MEYER (*J. pr. Chem.* [2], **38**, 336—343).—The white powder obtained by the action of sodium on ethyl cyanide (Abstr., 1888, 802) has been proved to be formed as follows:—(1) $Na_2 + 2EtCN = NaCN + C_2H_6 + C_2H_4Na{\cdot}CN$; (2) $C_2H_4Na{\cdot}CN + EtCN = C_6H_9NaN_2$. The oil which it yields on treatment with water crystallises in tables which melt at 47—48°, boil at 257—258° (uncorr.), are little soluble in cold water, decomposed by warm water, and soluble in ether and alcohol; the molecular formula $C_6H_{10}N_2$ has been obtained both by Raoult's method and by the vapour-density determination; when heated at 330—340° for several hours it is converted into ethyl cyanide. Hydrochloric acid decomposes it, half the nitrogen appearing as ammonium chloride and half as an oil soluble in ether; the ethereal solution is shaken with sodium hydroxide, dried over lime, and the pure oil precipitated by adding water. This oil has the composition C_6H_9NO, and is reconverted into the original substance when heated with strong ammonia. It would thus appear that the polymeride is *α-imidopropionylethyl cyanide*, $NH{:}CEt{\cdot}CHMe{\cdot}CN$, and the oil *α-propionylethyl cyanide*, or cyanodiethyl ketone, $COEt{\cdot}CHMe{\cdot}CN$. The former is converted into ammonia, carbonic anhydride, and diethyl ketone, when heated with strong hydrochloric acid at 150°, and the latter into propionic acid and ammonia when heated with aqueous potash. The imido-compound is converted into propylamine by reduction.
A. G. B.

Ammeline. By A. SMOLKA and A. FRIEDREICH (*Monatsh.*, **9**, 701—707).—When dicyanodiamide (1·5 grams) and carbamide (1·08 grams) are heated at 170—180° for 2½ hours, much ammonia is set free, and on treating the product with water an insoluble white residue remains, from which ammeline, $C_3H_5N_5O$ (yield 1·57 grams), may be obtained by dissolving it in alkali and reprecipitating with acetic acid repeatedly; finally recrystallising it from a hot aqueous solution of potash.

Ammeline can also be prepared by heating dicyanodiamide with cyanic or cyanuric acid. It may therefore be represented by one of the two formulæ, $N{:}C{\cdot}NH{\cdot}C(NH){\cdot}NH{\cdot}CO{\cdot}NH_2$ or

$$CO{:}N{\cdot}C(NH){\cdot}NH{\cdot}C(NH){\cdot}NH_2.$$

The authors consider that the first of these most probably represents the constitution of the compound, since ammeline, unlike biguanide-derivatives, of which the second formula represents a member, is not a strong base, and does not give coloured compounds with salts of cobalt and copper. G. T. M.

Sulphines and the Valency of Sulphur. By R. NASINI and A. SCALA (*Gazzetta*, **18**, 62—72).—The authors have been occupied for some time with the examination of organic sulphur compounds, especially with the object of proving the tetravalency of sulphur, and the appearance of Klinger and Maassen's work (Abstr., 1888, 357), whose results are diametrically opposed to theirs, compels them to publish a portion of their researches. Although various sulphur compounds containing alkyl radicles have been obtained, of the form SM_3A and $SM_2M_{,}A$, unfortunately their vapour-density cannot be determined, and it remains uncertain therefore whether the four monad radicles are united to the sulphur, or whether the compounds are molecular compounds.

Klinger and Maassen, in repeating Krüger's work, found that the sulphine containing one methyl- and two ethyl-groups was the same, whether it was prepared by the action of methyl iodide on ethyl sulphide or of ethyl iodide on ethyl methyl sulphide, that is, they denied Krüger's statement that two isomeric compounds of the formula Et_2MeS existed, capable of yielding distinct platinochlorides crystallising in different forms. Nasini and Scala state that they have prepared the iodides of the sulphine according to Krüger's directions, and converted them into the corresponding platinochlorides, one of which crystallises in the cubic system, whilst the other is monoclinic.

Ethylmethylethylsulphine platinochloride, $(EtMeEtSCl)_2,PtCl_4$, melts at 211—212° and forms monoclinic crystals,

$$a : b : c = 1{\cdot}15113 : 1 : 0{\cdot}794745 ;\ \beta = 49^\circ\ 17'\ 56''.$$

Forms observed, (110), ($\bar{1}$11), (001), (010); combinations, (110) ($\bar{1}$11) (001) and (110)($\bar{1}$11) (001)(010).

Diethylmethylsulphine platinochloride, $(Et_2MeSCl)_2,PtCl_4$, melts at 205°, and crystallises in the monometric or cubic system; combinations, (100)(111). These crystals, when superficially observed, may easily be taken for monoclinic, owing to the development of one face, but their optical properties prove that they belong to the monometric system, as when examined by polarised light there are no signs of double refraction. This leaves unsettled the question as to whether sulphur is tetravalent or not. C. E. G.

Trimethylethyleneglycol from Methyl Isopropenyl Carbinol. By I. KONDAKOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 32—34).—In a former paper, the author has shown that methyl isopropenyl carbinol when heated with dilute sulphuric acid (1 per cent. H_2SO_4), becomes converted into trimethylethylene glycol, whilst hydrochloric acid is without action at the ordinary temperature, but gives rise to products of condensation at a higher temperature. The author now finds that chlorine-derivatives of trimethylethylene yield trimethylethylene glycol, if left in contact with water in a closed flask at the ordinary temperature for several months. B. B.

Combination of Benzaldehyde with Polyhydric Alcohols. By MAQUENNE (*Compt. rend.*, **107**, 658—659).—The dibenzoic acetal of perseitol (perseite) previously described (this vol., p. 32), was made with alcohol of 85° to 90°, without addition of zinc chloride. It is assumed to be an acetal, because it resembles the product obtained by Meunier by the action of benzaldehyde on mannitol, and Friedel has pointed out that in all probability this is an acetal.

When a polyhydric alcohol containing an odd number of hydroxyl-groups is converted into an acetal, one of the hydroxyl-groups is left unattacked, and since the difference in composition between the acetals of two successive homologues can be detected by analysis, the conversion into acetals affords a convenient method of determining the number of hydroxyl-groups in a polyhydric alcohol.

C. H. B.

Constitution of Sorbinose. By H. KILIANI and C. SCHEIBLER (*Ber.*, **21**, 3276—3281).—Sorbinose behaves towards bromine and water similarly to levulose, and remains practically unchanged after a week; it contains therefore no aldehyde-group. When heated with nitric acid (sp. gr. = 1·39, 2 parts) for 40 hours at 35°, trihydroxyglutaric acid, $COOH\cdot[CH(OH)]_3\cdot COOH$ (this vol., p. 32), is formed. Potassium trihydroxyglutarate crystallises in monoclinic plates; $a : b : c = 1\cdot4641 : 1 : 0\cdot7094$; $\beta = 101° 3'$.

When sorbinose is reduced with hydriodic acid and amorphous phosphorus, it is converted, almost quantitatively, into hexyl iodide. Sorbinose has probably the constitution

$$OH\cdot CH_2\cdot[CH(OH)]_3\cdot CO\cdot CH_2\cdot OH.$$

N. H. M.

Changes suffered by Starch when Dissolved in Hot Glycerol. By K. ZULKOWSKI (*Chem. Centr.*, 1888, 1060, from *Ber. Oesterr. Gess. Chem. Ind.*, **10**, 2—4).—Starch, when heated in glycerol at 200°, produces a solution which gives a blue coloration with iodine at first, but which gradually changes to red. Addition of alcohol at this point precipitates erythrodextrin. If the heating is continued up to 210°, until the red coloration gives place to a brown one, alcohol precipitates achroodextrin. Other compounds are formed besides the two above named, and were separated by precipitation with barium hydroxide, &c., but were not further characterised.

J. W. L.

Derivatives of Allylamine. By C. PAAL (*Ber.*, **21**, 3190—3196; compare Gabriel, Abstr., 1888, 1267).—*Bromallylamine*, $C_3H_4Br\cdot NH_2$, is prepared by adding dibromopropylamine hydrochloride to excess of alcoholic potash, diluting the product with water, and distilling with steam. It is a colourless, mobile, very unstable oil, boils at 125° with partial decomposition, and mixes in all proportions with all ordinary solvents. When mixed with potassium carbonate, it is decomposed with separation of potassium bromide. When boiled for a long time with alcoholic potash, it seems to be, for the greater part, transformed into a hydroxy-base, but when the temperature is raised to 120—130°, it is completely decomposed. A crystalline salt, probably

$$C_3H_4Br{\cdot}NH{\cdot}C_3H_4{\cdot}NH_2,HBr,$$

is formed when bromallylamine is kept for a long time; the same salt remains when bromallylamine is distilled. Silver nitrate produces a white amorphous, and mercuric chloride a white crystalline precipitate in an aqueous solution of free bromallylamine. The *hydrochloride*, $C_3H_4Br{\cdot}NH_2,HCl$, crystallises in large needles or prisms, melts at 177—180°, and is readily soluble in water or hot alcohol. The *platinochloride*, $(C_3H_4Br{\cdot}NH_2)_2,H_2PtCl_6$, crystallises in yellow plates, and is readily soluble in hot water, but almost insoluble in absolute alcohol. The *aurochloride*, $C_3H_4Br{\cdot}NH_2,HAuCl_4$, crystallises in small, yellow needles, and decomposes when kept for some time in aqueous solution. The *hydrobromide*, $C_3H_4Br{\cdot}NH_2,HBr$, crystallises in large, colourless, quadratic prisms, melts at 223—224°, and is more sparingly soluble in alcohol and water than the hydrochloride. The *oxalate*, $C_3H_4Br{\cdot}NH_2,C_2H_2O_4$, crystallises in colourless plates, melts at 136—138°, and is readily soluble in water, but insoluble in alcohol and ether.

Tribromopropylamine hydrochloride, $C_3H_4Br_3NH_2,HCl$, prepared by adding bromine (1 mol.) to a well-cooled, concentrated aqueous solution of bromallylamine hydrochloride, crystallises from absolute alcohol in colourless needles. The free *base* is a heavy, yellow, very unstable oil with a pungent smell.

The *aurochloride*, $C_3H_4Br_3{\cdot}NH_2,HAuCl_4$, crystallises from water, in which it is moderately soluble, in golden-yellow plates, melting at 170°. The *platinochloride*, $(C_3H_4Br_3{\cdot}NH_2)_2,H_2PtCl_6$, crystallises from hot water in orange plates, and is decomposed when heated at 245°.

Isobutyldibromopropylamine hydrobromide, $C_4H_9{\cdot}NH{\cdot}C_3H_5Br_2HBr$, prepared by adding bromine (1 mol.) to a well-cooled glacial acetic acid solution of isobutylallylamine, crystallises from hot water, in which it is readily soluble, in slender needles, and is sparingly soluble in alcohol. The free *base* is a heavy, almost colourless, very unstable oil, with a feeble basic smell. When auric chloride is added to an aqueous solution of the hydrobromide, the *aurochloride* separates as a yellow oil, and then solidifies.

Butyldibromopropylamine hydrobromide, $C_4H_9{\cdot}NH{\cdot}C_3H_5Br_2,HBr$, can be prepared by treating butylbromallylamine with excess of dilute hydrobromic acid. It crystallises in large, concentrically grouped needles, and is readily soluble in water and hot alcohol. The *aurochloride* separates from an aqueous solution of the hydrobromide in flat needles, when auric chloride is added to an aqueous solution of the hydrobromide.

Butylbromallylamine, $C_4H_9NH{\cdot}C_3H_4Br$, can be prepared by boiling the isobutyldibromo-derivative with dilute alcohol for a long time, adding alkali, and distilling with steam. It can also be obtained by mixing the hydrobromide with excess of alcoholic potash in the cold, keeping the mixture for some time, diluting with water, and adding potassium carbonate, until the alcoholic solution of the base separates at the surface of the aqueous solution; the solution of the base is dried over potassium carbonate, poured into an alcoholic solution of oxalic acid, and the precipitated salt decomposed with alkali. It is a yellowish oil, with a camphor-like odour; it cannot be obtained in the pure state, as it is partially decomposed when distilled. The *oxalate*, $C_7H_{14}BrN,C_2H_2O_4$, crystallises in colourless needles, melts at 230—231°, and is moderately soluble in water.

Isoamyldibromopropylamine hydrobromide, $C_5H_{11}{\cdot}NH{\cdot}C_3H_5Br_2,HBr$, prepared by treating isoamylallylamine with bromine in glacial acetic acid solution, and then adding concentrated hydrobromic acid, crystallises in plates, melts at 230—231°, and is sparingly soluble in alcohol and cold water. The free *base* resembles the corresponding butyl base. The *platinochloride* is a reddish-yellow oil.

Amyldibromopropylamine hydrobromide, prepared by treating amylallylamine as described above, crystallises in needles, melts at 150°, and is moderately soluble in cold water and alcohol.

Isoamylbromallylamine, $C_5H_{11}{\cdot}NH{\cdot}C_3H_4Br$, prepared by treating isoamyldibromopropylamine hydrobromide with alcoholic potash, or by boiling the free base with dilute alcohol, is an oil; it is insoluble in water, and boils at about 150° with partial decomposition.

F. S. K.

Synthesis of Hydroxypropylenediisoamylamine. By E. Louïse (*Ann. Chim. Phys.*, **13**, 433—442).—*Hydroxypropylenediisoamylamine*, $C_{13}H_{29}NO$, is best prepared by heating propylenechlorhydrin (1 mol.) and diisoamylamine (at least 1½ mols.) at 100° in a closed vessel for 30 hours. The product is mixed with concentrated potash to decompose the diisoamylamine hydrochloride which is formed in the reaction, the mixture is again heated for 10 hours, and the oil which separates is dried over potassium carbonate and fractionated. The yield is 70 per cent. of the theoretical quantity, but it is impossible to get rid of the whole of the diisoamylamine by fractional distillation. The hydroxypropylene-derivative is obtained in the pure state by agitating the fractionated liquid with a small quantity of dilute, warm, hydrochloric acid, and decanting the supernatant oil. It is a colourless oil, with a somewhat disagreeable smell, and boils at 242—244°. It is sparingly soluble in water, but readily in alcohol, ether, and other solvents of the fatty series. All the simple salts, with the exception of the *picrate*, which is sparingly soluble, are syrupy liquids, and very readily soluble in water. The *platinochloride*, $(C_{13}H_{29}NO)_2,H_2PtCl_6$, separates from acidified alcohol in orange crystals, but the *aurochloride* is a yellow, sparingly soluble oil.

Propylenediisoamylamine benzoate, $C_{13}H_{28}N{\cdot}OBz$, is prepared by gradually adding a slight excess of benzoic chloride to a well-cooled, dry, ethereal solution of the alcohol, and, after evaporating the ether, heating the mixture at 100° for six hours in a sealed tube. The product is treated with boiling water, the cold mixture shaken with ether to remove benzoic acid, and the salt separated by adding potassium carbonate. It is a colourless oil, readily soluble in alcohol, ether, chloroform, &c., but insoluble in water. It is hydrolysed when boiled with potash, or when treated with strong acids, and is decomposed when distilled. This salt still has basic properties; its *oxalate*,

$C_{20}H_{33}NO_2,C_2H_2O_4$, crystallises from hot water or alcohol in slender, colourless needles, and is readily soluble in acetone and chloroform, but insoluble in ether. Most of its other salts do not crystallise and are very readily soluble, excepting the *platinochloride* and the *aurochloride*, which are only sparingly soluble.

Propylenediisoamylamine acetate, prepared in like manner, is a colourless oil, readily soluble in alcohol, ether, &c., but only sparingly in water. Its *oxalate* crystallises in needles, and is very readily soluble in alcohol and chloroform, but only moderately in water, and sparingly in ether. Its other salts are very readily soluble in water, and do not crystallise.
F. S. K.

Glyoxalbutyline and Glyoxalisobutyline. By J. Rieger (*Monatsh.*, 9, 603—612; compare Radziszewski, Abstr., 1883, 308, 728, 1086; 1884, 986).—*Glyoxalbutyline*, prepared according to the directions given by Radziszewski from glyoxal, ammonia, and normal butaldehyde, is a viscid, hygroscopic oil, having a sp. gr. of 1·0125 at 20°, and boiling under a pressure of 738 mm. at 266—268°. It is fairly soluble in water, and when an aqueous solution is treated with oxalic acid, the compound $(C_6H_{10}N_2)_2,C_2H_2O_4 + 2H_2O$ is formed; this crystallises in rhombic plates or long needles, and melts at 159—161°. The anhydrous oxalate, $(C_6H_{10}N_2)_2,C_2H_2O_4$, is precipitated as an amorphous, white powder on mixing alcoholic solutions of the acid and base. It partly sublimes at 170°, and melts with decomposition at 190—195°. The platinochloride, $2C_6H_{10}N_2,H_2PtCl_6$, crystallises in orange-red prisms, and on treatment with iodoparaffins gives the following bases:—

Oxalmethylbutyline, $C_6H_9MeN_2$, is a colourless, viscid liquid, having a sp. gr. of 0·9850 at 19·8°, and boils at 214—216° under a pressure of 722 mm. It dissolves readily in cold water, alcohol, ether, and chloroform. The platinochloride, $2C_6H_9MeN_2,H_2PtCl_6$, crystallises in orange-red, rhombic prisms.

Oxalethylbutyline, $C_6H_9EtN_2$, has a sp. gr. of 0·9593 at 16·5°, and boils at 218—222° under a pressure of 736 mm. The platinochloride is a yellow, amorphous powder.

Oxalpropylbutyline, $C_6H_9PrN_2$, is a liquid of sp. gr. 0·9393 at 18·9°. It boils at 226—228° under a pressure of 726 mm., and forms a platinochloride, insoluble in alcohol and ether, but readily soluble in hot water.

Oxalbutylbutyline, $C_4H_9{\cdot}C_6H_9N_2$, has a sp. gr. of 0·9379 at 18·9°, and boils at 242—245° under a pressure of 728 mm. It forms double salts with the chlorides of zinc, cadmium, and platinum, and on oxidation with hydrogen peroxide gives *butyloxamide*, $C_2H_3O_2N_2{\cdot}C_4H_9$, crystallising in lustrous needles, which sublime at 130°, and melt at 197—198°.

Oxalisobutylbutyline has a sp. gr. of 0·9403 at 13·4°, and boils at 231—233° under a pressure of 736 mm. The platinochloride forms orange-yellow needles, soluble in alcohol.

Oxalisoamylbutyline, $C_5H_{11}{\cdot}C_6H_9N_2$, has a sp. gr. of 0·9197 at 18·9°, and boils at 250—252° under a pressure of 724 mm. The platinochloride crystallises in rhombic needles.

Glyoxalisobutyline, prepared from isobutaldehyde, ammonia, and glyoxal, is a crystalline solid, melting at 125—126°, and boiling at 256—260°. It readily dissolves in hot water, alcohol, chloroform, and ether, and forms the salts $C_6H_{10}N_2,HCl$, melting at 105°, $C_6H_{10}N_2,HBr$, melting at 222°, and $C_6H_{10}N_2,C_2H_2O_4$, melting at 194—195°. By treatment with iodoparaffins, it furnishes the following bases:—

Oxalmethylisobutyline, C_6H_9MeN; this is a colourless, viscid oil, of sp. gr. 0·9576 at 16·6°, and boils at 205—206°. The platinochloride crystallises from water in orange-red plates, the compound $C_6H_9MeN_2,MeI$ in colourless, rhombic prisms, melting at 245—246°.

Oxalpropylisobutyline, $C_6H_9PrN_2$, which has a sp. gr. of 0·9299, and boils at 225—227°. The platinochloride crystallises in orange-red needles.

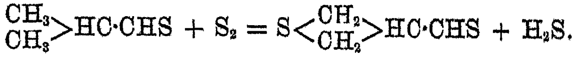
Oxalisoamylisobutyline; this has a sp. gr. of 0·9281 at 17·3°, and boils at 246—248° under a pressure of 738 mm. The platinochloride is scarcely soluble in alcohol, but dissolves readily in water.

All the oxalines described above turn yellow on exposure to the air, are miscible with alcohol, ether, and chloroform, and have characteristic unpleasant odours. G. T. M.

Action of Sulphur on Paraisobutaldehyde. By G. A. Barbaglia (*Gazzetta*, **18**, 85—88).—Unlike isobutaldehyde, sulphur has no action on the paraldehyde at 150°, but when heated with it for a long time (100 hours or more) at 180°, it becomes reddish-brown, and on opening the tube abundance of gas escapes, containing much hydrogen sulphide. The liquid has an acid reaction, and if left for a time separates into two layers. On submitting it to distillation, a liquid is obtained, which by means of fractional distillation can be separated into three portions; the first, distilling between 70° and 90°, was found on analysis to be isothiobutaldehyde; the second, distilling between 90° and 140°, has not yet been examined; whilst the third, 140—160°, is isobutyric acid. The reaction is probably in the first place—

$$4CHMe_2{\cdot}COH + S_2 = 2CHMe_2{\cdot}CSH + 2CHMe_2{\cdot}COOH,$$

but at the high temperature necessary for the reaction the excess of sulphur acts on the isothiobutaldehyde, converting it into polysulphide, with evolution of hydrogen sulphide—



$$\begin{matrix}CH_3\\CH_3\end{matrix}{>}HC{\cdot}CHS + S_2 = S{<}\begin{matrix}CH_2\\CH_2\end{matrix}{>}HC{\cdot}CHS + H_2S.$$

In all probability this product exists in the intermediate portion of the distillate. C. E. G.

Action of Ammonia on Methylethylacraldehyde. By E. Hoppe (*Monatsh.*, **9**, 634—657; compare Waage, Abstr., 1884, 172).—On passing ammonia into an ethereal solution of methylethylacraldehyde at 0°, a substance separates in white flakes, but is of so unstable a nature that it is impossible to isolate it. When heated in sealed tubes at 100° with excess of alcoholic ammonia, methylethylacraldehyde yields a viscid liquid which has a bitter taste and an odour resembling parvoline. No definite compound can be isolated from it, but its solution in hydrochloric acid gives white or yellow precipitates with most of the salts of the heavy metals. When heated in sealed tubes at 200° for 12 hours, the substance decomposes, and on opening the tube much ammonia is evolved. After several heatings in sealed tubes, no more ammonia is produced, and the following bases can be isolated from the residue:—(1) Picoline; (2) parvoline identical with that obtained by Waage, and yielding on oxidation α-β-pyridinedicarboxylic acid; (3) a new base, $C_{12}H_{19}N$, which forms a clear, mobile liquid having a pale blue fluorescence, a bitter taste, and a smell resembling parvoline but less intense. It dissolves readily in alcohol and ether, but is only slightly soluble in water. The platinochloride crystallises in orange-red, monoclinic prisms, is very soluble in alcohol, but only slightly so in water. G. T. M.

Action of Sulphurous Acid on Methylethylacraldehyde. By E. Ludwig (*Monatsh.*, 9, 658—674).—The author has further investigated the compound obtained by Lieben and Zeisel from sodium hydrogen sulphite and methylethylacraldehyde (Abstr., 1883, 570), and finds that it is most conveniently prepared by the direct addition of sulphurous acid to the unsaturated aldehyde. 10 grams of the aldehyde and 30 c.c. of water were introduced into a tube, and saturated with sulphurous acid at 0°; after sealing, the tube was heated at 80° for four hours, and the contents then neutralised with barium carbonate. The filtered solution, on concentration in a vacuum at 30°, gave barium hydroxyhexanedisulphonate, $C_6H_{12}O{:}(SO_3)_2Ba + 2H_2O$. The salt dissolves readily in water, is only slightly soluble in alcohol, and is very unstable. On heating with baryta-water, methylethylacraldehyde and barium sulphite are formed. If the contents of the tube, after heating, are diluted with an equal volume of water, and three-quarters of the liquid distilled off, the residue on neutralisation with barium carbonate and concentration in a vacuum over sulphuric acid gives the barium salt of capraldehydesulphonic acid, $(C_6H_{11}O{\cdot}SO_3)_2Ba$, as an amorphous mass. Capraldehydesulphonic acid can also be prepared by allowing aqueous sulphurous acid to react with methylethylacraldehyde at ordinary temperatures for several days, when all the oil disappears. From the solution, after saturation with barium carbonate and oxidation with bromine-water, barium sulphocaproate, $C_6H_{10}SO_5Ba$, crystallising in hexagonal plates may be isolated. *Sulphocaproic acid* may also be prepared from barium hydroxyhexanedisulphonate. The silver salt, $C_6H_{10}SO_5Ag_2$, crystallises in small plates, the calcium salt, $C_6H_{10}SO_5Ca + 1\frac{1}{2}H_2O$, in scales. On reduction with sodium amalgam in solutions containing free sulphuric acid, both hydroxyhexanedisulphonic acid and capraldehydesulphonic acid yield a sulphonic acid of hexyl alcohol, the sodium salt of which, $C_6H_{13}SO_4Na$, obtained in a slightly impure condition, forms an amorphous hygroscopic mass, and yields on distillation with lime a mixture of hexyl and hexenyl alcohols boiling at 149·6—151·6°. G. T. M.

Action of Potassium Cyanide on Ethyl α-Bromopropionate. Preparation of the Isomeric Symmetrical Dimethylsuccinic Acids. By N. Zelinsky (*Ber.*, **21**, 3160—3172).—Ethyl α-cyanopropionate and ethyl dimethylsuccinate are obtained when ethyl α-bromopropionate (250 grams) is boiled for about six hours with finely divided potassium cyanide (96 grams) in alcoholic solution (130 grams), the whole being constantly shaken. The yield is greater when the mixture is heated by a stream of hot air. The product is washed with water, dried, and fractionated. A small quantity of a crystalline substance is also formed in this reaction.

Ethyl α-cyanopropionate, CN·CHMe·COOEt, is a colourless liquid, boils at 197—198°, is not miscible with water, and yields a very hygroscopic sodium-derivative.

Ethyl dimethylsuccinate (compare Scherks, Abstr., 1882, 38) can be prepared by gradually adding ethyl α-bromopropionate (56 grams) to a mixture of sodium (0·72 gram) and ethyl α-cyanopropionate (4 grams) in alcoholic solution. It boils at 272—273° (compare Scherks, *loc. cit.*), and yields dimethylsuccinic acid melting at 192°, and the isomeric acid melting at 123—124°, when heated for 6—8 hours with hydrochloric acid (compare Otto and Beckurts, Abstr., 1885, 753; Otto and Rössing, Abstr., 1888, 45; also Bischoff and Hjelt, Abstr., 1888, 1057). Both acids yield the same anhydride when distilled. The anhydride crystallises in small plates melting at 87°. When the anhydride is boiled for a short time with a small quantity of water, it is almost entirely converted into the acid of lower melting point, but a small quantity of the isomeric acid is also formed.

F. S. K.

Solubility of the Silver, Calcium, and Barium Salts of Normal Caproic and Diethylacetic Acids. By P. Keppich (*Monatsh.*, **9**, 589—602; compare *ibid.*, **6**, 565).—The solubilities of the different salts were determined by Raupenstrauch's method. The formulæ deduced from these determinations are as follows:—

Silver normal caproate.... $S = 0{\cdot}07768 + 0{\cdot}0008268t + 0{\cdot}000031213t^2$.

Calcium normal caproate.. $S = 2{\cdot}727 - 0{\cdot}01475(t - 0{\cdot}7) + 0{\cdot}0002203\,(t - 0{\cdot}7)^2$.

Barium normal caproate .. $S = 9{\cdot}47 - 0{\cdot}08975\,(t - 0{\cdot}5) + 0{\cdot}0014983\,(t - 0{\cdot}5)^2$

Silver diethylacetate ..... $S = 0{\cdot}402 + 0{\cdot}000847\,(t - 0{\cdot}7) + 0{\cdot}000038\,(t - 0{\cdot}7)^2$

Calcium diethylacetate ... $S = 30{\cdot}119 - 0{\cdot}2617\,(t - 0{\cdot}7) + 0{\cdot}001498\,(t - 0{\cdot}7)^2$.

Barium diethylacetate is so intensely soluble in water, that the author did not succeed in obtaining any analytical results.

G. T. M.

Chlorine-derivatives of Ethyl Acetoacetate. By P. Genvresse (*Compt. rend.*, **107**, 687—689).—When chlorine is passed into ethyl acetoacetate, the temperature rises to 165° but afterwards falls, and the chief products are the di- and tri-chlorinated derivatives, together with small quantities of higher substitution products.

When the dichloro-derivative is heated in sealed tubes with dilute hydrochloric acid, it yields unsymmetrical dichloracetone, water, and alcohol, and hence it has the constitution $CHCl_2 \cdot CO \cdot CH_2 \cdot COOEt$. When treated with chlorine at 170°, it yields the tri-derivative, together with small quantities of the tetra- and penta-derivatives.

The trichloro-derivative, when heated with dilute hydrochloric acid in sealed tubes at 170°, yields trichloracetone, $CCl_3 \cdot COMe$, alcohol, and carbonic anhydride, so that its constitution is $CCl_3 \cdot CO \cdot CH_2 \cdot COOEt$, and not $CHCl_2 \cdot C(OH){:}CCl \cdot COOEt$, as supposed by Mewes.

Ethyl tetrachloracetoacetate boils with partial decomposition at 229—231° under ordinary pressure, and with less decomposition at 153—157° under a pressure of 40 mm. It is colourless, and heavier than water; when heated with dilute hydrochloric acid under pressure, it yields carbonic anhydride, alcohol, and unsymmetrical tetrachloracetone, so that its constitution is $CCl_3 \cdot CO \cdot CHCl \cdot COOEt$.

Ethyl pentachloracetoacetate boils at 240—244° under ordinary pressure, or at 164—168° under a pressure of 35 mm., and is a colourless liquid heavier than water. When heated at 160° with dilute hydrochloric acid, it yields carbonic anhydride, alcohol, and pentachloracetone, so that its constitution is $CCl_3 \cdot CO \cdot CCl_2 \cdot COOEt$.

If ethyl acetoacetate is subjected to the action of chlorine at 150° to 220° for 10 days, derivatives containing 7 and 9 atoms of chlorine are obtained. The former, $CCl_3 \cdot CO \cdot CCl_2 \cdot COOC_2H_3Cl_2$, is a syrupy almost colourless liquid which boils at 270—272° with much decomposition under ordinary pressure, or with slight decomposition at 220—225° under a pressure of 110 mm. The derivative with 9 atoms of chlorine, $CCl_3 \cdot CO \cdot CCl_2 \cdot COOC_2HCl_4$, is a syrupy liquid which does not solidify at —23°, and boils at 225—230° under a pressure of 40 mm.

Methyl acetoacetate yields similar derivatives. C. H. B.

Dihydroxystearic Acid obtained by the Oxidation of Oleic Acid with Potassium Permanganate in Alkaline Solution.

By N. SPIRIDONOFF (*J. Russ. Chem. Soc.*, 1887, **19**, 646—654).—The dihydroxystearic acid was prepared by Syrneff and Saytzeff's method from ordinary oleic acid, and the present paper contains a determination of its constants. Solubility in ethyl alcohol of 99·5 per cent. at 19°, 100 pts. of solution contain 0·59 pt. of the acid, dry ethyl ether at 18° = 0·19 pt. The ethyl salt (m. p. 93·8—100°) was obtained by the action of hydrogen chloride on an alcoholic solution of the acid. Solubility in alcohol of 91·5 per cent., 100 pts. of the solution at 16° contain 4·58 pts.; at 18° = 4·72 pts.; ethyl ether at 18° = 1·75 pts. The methyl salt (m. p. 105—106·5°), 100 pts. of the alcoholic solution at 18·5° contain 3·34 pts.; dry ether at 19° = 1·03 pts. The acetyl-derivative was obtained by the action of acetic anhydride at 150° on the acid. It is a colourless, viscid liquid, and its composition is $C_{18}H_{34}Ac_2O_4$. Oxidation with potassium permanganate in alkaline solution yielded, as the chief products, caprylic, suberic, and azelaïc acids, together with some unchanged dihydroxystearic acid. This was proved by the analysis of the free acids and their salts. The same acids are found among the products of oxidation of oleic acid, and are therefore only products of the oxidation of dihydroxystearic acid. B. B.

Action of Allyl Iodide and Zinc on Ethyl Malonate. By V. Matvéeff (*J. Russ. Chem. Soc.*, 1887, **19**, 643—646).—Following the method by which Schukoffsky prepared the ethyl salt of diethylmalonic acid (Abstr., 1888, 1179), the author by the mutual action of allyl iodide, zinc, and ethyl malonate, has obtained *ethyl diallylmalonate*, $C(C_3H_5)_2(COOEt)_2$, together with free propylene. The ethyl salt is an oily liquid boiling at 239—241°, and having the sp. gr. 0·99181 at 20°, 0·98707 at 30°, and 3·98085 at 35°. The free acid obtained by hydrolysis of the ethyl salt, is described, and also the corresponding sodium, calcium, and silver salts. B. B.

Action of Maleïc Acid on Aniline. By I. Ossipoff (*J. Russ. Chem. Soc.*, 1888, **20**, 83—97).—Referring to the work done by Perkin, Michael, Wing, and Palmer, and especially by Anschütz and Wirtz, on the constitution of maleïc acid, the author tried to solve the problem in the following manner:—Hydrogen sodium maleate was dissolved in water and boiled with aniline in a flask furnished with a reflux condenser, when crystals were formed which were greenish-yellow, melted at 141—143°, and left no ash on incineration. They are only sparingly soluble in ether, chloroform, benzene, and light petroleum, but easily in alcohol. After purification they become white, and the melting point rises to 144—145°. Elementary analysis, however, proved that the substance is not homogeneous; the principal constituent is the aniline salt of phenylaspartic acid or its isomeride. The product was treated with baryta-water, and the barium, lead, and silver salts prepared. With acetic anhydride, it yields acetanilide. With diphenylamine, it gives a substance melting at 207—208°, probably phenylaspartanil. The liquid from which the crystals have separated contains a mixture of sodium salts. The author concludes that maleïnanil is the anil of maleïc acid, and phenylaspartanil the anil of a lactone isomeric with phenylaspartic acid. B. B.

Isomerism of Fumaric and Maleïc Acids. By I. Ossipoff (*J. Russ. Chem. Soc.*, 1888, **20**, 97—108).—A purely theoretical paper based on the results described above. B. B.

Methyl and Ethyl Salts of Ethylenediamidoformic Acid and their Nitro-derivatives. By A. P. N. Franchimont and E. A. Klobbie (*Rec. Trav. Chim.*, **7**, 258—262).—The methyl salt, $C_2H_4(NH{\cdot}COOMe)_2$, is easily obtained in almost theoretical quantity on mixing methyl carbonate (2 mols.) with ethylenediamine (1 mol.). It is very soluble in boiling water, alcohol, and chloroform, but less soluble in ether and benzene, and melts at 132—133°. It dissolves in concentrated nitric acid with development of heat, and on adding water to this solution a white powder is precipitated, having the melting point of the original compound, but containing 21·23 per cent. N, the original compound having only 16·41 per cent. It is nearly insoluble in cold, but more soluble in hot water, very soluble in chloroform and benzene, but only slightly in ether and alcohol. From all solvents it separates in slender needles.

The ethyl salt has already been described by Fischer and Koch under the name ethylenediurethane. The authors have obtained it along with various bye-products by heating a mixture of ethyl carbonate and ethylenediamine at about 200° for 16 hours, as a colourless substance soluble in ether. The nitro-derivative is obtained in like manner to that of the methyl salt. It is a compound of very similar properties, melting at 83—84°. Analysis shows that it is a dinitro-derivative. Distilled with aqueous potash, it gives a distillate, which on the addition of potassium carbonate separates into two layers. The upper contains ethyl alcohol, and the lower ethylene dinitramine. This nitro-derivative therefore has the constitution $C_2H_4[N(NO_2)\cdot COOEt]_2$. H. C.

Ureides and their Nitro-derivatives. By A. P. N. Franchimont and E. A. Klobbie (*Rec. Trav. Chim.*, **7**, 236—257).—The authors distinguish—(1.) Ureides of bibasic acids, in which each of the two NH-groups is between two CO-groups; these do not yield nitro-derivatives. (2.) Ureides of monobasic acids, in which one of the NH-groups is between two CO-groups, and the other between a CO-group and the hydrocarbon residue; these give mononitro-derivatives. (3.) Ureides in which each NH-group is attached to a hydrocarbon residue, and neither lies between two CO-groups. These last compounds yield dinitro-derivatives, and the name "*ureines*" is proposed for them. A number of the nitro-derivatives of (2) and (3) have been considered in a former paper (Abstr., 1888, 1180), and the present is a continuation of this work.

Nitrohydantoïn when boiled with 25 times its weight of water loses 1 mol. of carbonic anhydride, and takes up 1 mol. of water, being converted into nitramidoacetamide, which on further evaporation of the aqueous solution yields glycolamide. Nitro-lactylcarbamide treated in the same manner loses carbonic anhydride and nitrous oxide, and yields an acid solution, which gives with cobalt acetate the reaction for lactic acid.

Nitroacetonylcarbamide is prepared by evaporating acetonylcarbamide with five times its weight of nitric acid, and recrystallising the residue from absolute alcohol or benzene. It forms slender, colourless needles, melting at 140—141°. Its probable constitution is

$$CMe_2<\begin{matrix}CO\text{——}NH\\N(NO_2)\cdot CO\end{matrix}>.$$

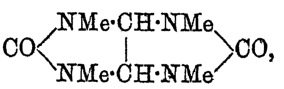
When boiled with 25 times its weight of water, it loses carbonic anhydride and nitrous oxide, and appears to yield α-hydroxybutyramide and α-hydroxybutyric acid.

Ethylenedinitrureine (*ethylenedinitrocarbamide*),

$$CO<\begin{matrix}N(NO_2)\cdot CH_2\\N(NO_2)\cdot CH_2\end{matrix}>,$$

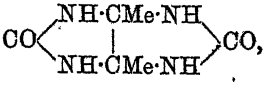
gives a compound with 4 mols. NaOH, soluble in water and insoluble in alcohol, and with 4 mols. $AgNO_3$ a white compound which detonates violently on heating. On boiling with water, it yields ethylenedinitramine; this compound forms salts containing 2 mols. of the metal. Heated with dilute sulphuric acid, it loses nitrous oxide, and gives aldehyde and glycol. Reduction experiments have up to the present led to no definite results.

Acetylenetetramethyldiureine (tetramethylglycolurile),

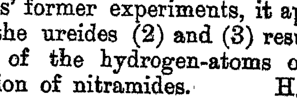


is prepared by evaporating on a water-bath aqueous solutions of glyoxal and dimethylcarbamide, to which a few drops of hydrochloric acid have been added. It crystallises in long, colourless, brittle needles, of bitter taste, melting at 217°, very soluble in water, alcohol, and chloroform, and slightly soluble in ether and benzene. On treatment with strong nitric acid, it is converted into *acetylenetrimethylmononitrodiureine* by the displacement of one of the methyl-groups by the nitro-group. The nitro-derivative crystallises in fine, colourless needles, melting at 225—226°, not very soluble in water or alcohol, and still less so in ether and benzene.

Dimethylacetylenediureine (dimethylglycolurile),



separates as a white powder when a mixture of 20 parts of diacetyl, 50 parts of water, and 35 parts of carbamide is left for 24 hours. It is slightly soluble in water, from which it crystallises in slender needles or small prisms; it is very slightly soluble in alcohol, and not at all in ether, chloroform, or benzene. With nitric acid, it yields a dinitro-derivative, which on boiling with water loses carbonic anhydride and nitrous oxide, and gives diacetyl and carbamide. This nitro-derivative probably has the constitution



From the above and the authors' former experiments, it appears that the action of nitric acid on the ureides (2) and (3) results in the displacement of one or more of the hydrogen-atoms of the NH-groups by NO_2, and the formation of nitramides. H. C.

Identity of Methronic Acid and Sylvanecarboxyacetic Acid. By R. Fittig and A. Hantzsch (*Ber.*, **21**, 3189—3190; compare Fittig and Schloesser, Abstr., 1888, 1089, Polonowsky, *ibid.*, 1175).—The acid obtained from glyoxal and ethyl acetoacetate (compare

Polonowsky, Abstr., 1888, 1067) is identical with methronic acid prepared from ethyl acetoacetate and sodium succinate. The same monobasic acid is obtained by the distillation of carbopyrotritaric acid, methronic acid, and sylvanecarboxyacetic acid. F. S. K.

Isomeric Changes on Synthesising Aromatic Compounds by means of Aluminium Chloride. By J. SCHRAMM (*Monatsh.*, 9, 613—625).—When isobutyl bromide (300 grams) is allowed to drop very slowly into a mixture of benzene (900 grams) and aluminium chloride (300 grams) kept cool with ice, a butylbenzene (yield 60 per cent.) having a sp. gr. of 0·8718 at 15°, and boiling at 167—167·5° under a pressure of 736 mm., is formed. It does not agree in its properties with the isobutylbenzene boiling at 170—170·5°, sp. gr. 0·8578 at 15°, formed by Fittig's method (Gossin, Abstr., 1884, 1312), for the product, on treatment with 1 mol. of bromine in presence of iodine, gives a monobromobutylbenzene boiling at 230—231·5° under a pressure of 736 mm., readily solidifying on cooling, and melting at 13—14°, whilst the monobromobutylbenzene from the butylbenzene prepared by Fittig's method, boils at 232—233·5°, and does not solidify at −20°. The product of the synthesis is therefore *trimethylphenylmethane* (*tertiary butylbenzene*), CMe_3Ph. Gossin's butylbenzene, boiling at 152—155°, was not formed.

Tertiary butyl chloride (50 grams), benzene (150 grams), and aluminium chloride (50 grams) under similar conditions give tertiary butylbenzene (yield 60 per cent.). In this case no isomeric change takes place, but normal butyl chloride (75 grams), benzene (300 grams), and aluminium chloride (80 grams) give secondary butylbenzene, CHMeEtPh, boiling at 173·5—174·5°, under a pressure of 735 mm.), and having a sp. gr. of 0·8669 at 15°; it is identical with the butylbenzene which Radziszewski prepared from α-phenylethyl bromide and zinc ethyl. Isoamyl chloride (170 grams), benzene (360 grams), and aluminium chloride (170 grams) give an *amylbenzene* (20 per cent. yield) which boils at 187·5—188·5 under a pressure of 737 mm., and has a sp. gr. of 0·8683 at 15°. It therefore does not correspond with the isoamylbenzene which Essner (Abstr., 1882, 46) prepared from isoamyl bromide and bromobenzene, and must consequently be represented by one of the formulæ $CHMePh{\cdot}CHMe_2$ or CMe_2EtPh, isomeric change having taken place.

It follows from the above that when the primary monochloroderivatives of the fatty series act on benzene in presence of aluminium chloride, the phenyl-group does not take up the position of the halogen, but links itself to another carbon-atom, thereby forming a secondary or tertiary hydrocarbon. The isomeric change is not analogous to that of normal- into iso-propyl bromide in presence of aluminium chloride, as observed by Kekulé and Schrötter (*Ber.*, **12**, 2280), moreover Essner has shown that isoamyl chloride does not behave similarly. On the contrary, the author finds that isobutyl chloride in presence of aluminium chloride splits up into hydrogen chloride and butylene, and holds the opinion that the isomeric changes depend on a reaction similar to that observed by Bahlsohn (Abstr., 1879, 785), who found that ethylbenzene could be prepared from benzene and ethylene in presence of aluminium chloride. He therefore concludes that the chloroparaffin splits up into hydrogen chloride and the corresponding olefine, which reacts with the benzene in the following way:—$PhH + Me_2C{:}CH_2 = CPhMe_3$, the phenyl-group attaching itself to the carbon-atom, which is directly united to the smallest number of hydrogen-atoms. G. T. M.

Orthocresol. By A. Claus and U. A. Jackson (*J. pr. Chem.* [2], **38**, 321—336).—Wroblewsky is mistaken in regarding the golden-yellow needles obtained by the action of nitrous acid on bromorthotoluidine as bromocresol, for they are really nitrobromorthocresol. During the action, parabromorthocresol is formed as well as the nitro-compound; to separate them, the acid liquid is distilled with steam and the yellow oil thus obtained, which partially solidifies on cooling, treated with weak sodium carbonate solution; the red solution thus formed is shaken with ether, which dissolves the bromocresol; the alkaline solution is then precipitated with weak hydrochloric acid, and the precipitate sublimed, when *nitrobromorthocresol*, [$OH : Me : Br : NO_2 = 1 : 2 : 4 : 6$], is obtained, forming beautiful golden-yellow needles, melting at 88° (uncorr.), and having all the properties of Wroblewsky's bromorthocresol. The *sodium* salt crystallises in red prisms, having a green lustre.

Amidobromorthocresol, [$OH : Me : Br : NH_2 = 1 : 2 : 4 : 6$], is formed when the nitro-compound is reduced with stannous chloride and strong hydrochloric acid in alcoholic solution; it crystallises from ether as a white mass which rapidly becomes brown, and sublimes in colourless needles melting at 110° (uncorr.); its *hydrochloride* is described.

Parabromorthocresol, [$OH : Me : Br = 1 : 2 : 4$] may be prepared from bromorthotoluidine as above, or by dropping a chloroform solution of bromine into a similar solution of orthocresol containing one-tenth of its weight of iron wire. It crystallises from hot water and from alcohol in colourless needles which sublime unchanged; it melts at 64° (uncorr.), and boils at 235° (uncorr.). When orthoparadibromocresol (Werner, Abstr., 1886, 1015) is oxidised by chromic acid in an acetic acid solution, *metabromotoluquinone*, [$Me : Br : O : O = 1 : 3 : 2 : 5$], is precipitated in yellow flocks, which crystallises from ether in yellow prisms, subliming as needles, which melt at 93° (uncorr.), and are sparingly soluble in water, freely so in other solvents; when an ethereal solution of it is shaken with a hydrochloric acid solution of stannous chloride until it is decolorised, the corresponding *quinol* is obtained; this forms white laminæ which melt at 112° (uncorr.) and dissolve easily in the usual solvents; the *acetyl*-derivative melts at 57° (uncorr.). By chlorinating a glacial acetic acid solution of parabromorthocresol, *chlorobromorthocresol*, [$OH : Me : Br : Cl = 1 : 2 : 4 : 6$], is obtained; it crystallises in colourless needles melting at 48° (uncorr.), and yields chlorotoluquinone on oxidation (comp. Abstr., 1886, 614). *Parachlororthocresol*, [$OH : Me : Cl = 1 : 2 : 4$], is obtained by chlorinating a glacial acetic acid solution of orthocresol containing some iron; the oil crystallises with difficulty, and by sublimation yields crystals melting at 33° (uncorr.), and boiling at 220° (uncorr.).

The authors describe orthocresolparasulphonic acid and its *potassium* (2 mols. H_2O) and *barium* salts; orthocresolorthosulphonic acid and its *potassium* salt (1 mol. H_2O); orthocresolorthoparadisulphonic acid and its *potassium* (2 mols. H_2O), *barium*, *copper*, and *lead* salts; but these acids have been described before. *Bromocresolparasulphonic acid*, $[OH : Me : Br : SO_3H = 1 : 2 : 4 : 6]$, is obtained as its *potassium* salt (1 mol. H_2O) by brominating potassium orthocresolparasulphonate, and as its *barium* salt by treating this with barium chloride; the free acid melts in its water of crystallisation at 95° (uncorr.).; the *calcium* (3 mols. H_2O), *copper*, *lead* (3 mols. H_2O) and *silver* salts are described. The parabromorthocresolorthosulphonic acid is obtained from orthocresolorthosulphonic acid in a similar way. A. G. B.

Dinitrortho-xylenols. By E. Nölting and B. Pick (*Ber.*, **21**, 3158—3160).—Dinitrortho-xylenol, $[OH : Me_2 : (NO_2)_2 = 1 : 3 : 4 : 2 : 6]$, is obtained when the yellow ammonium salt formed in the preparation of nitro-xylene (compare Jacobsen, Abstr., 1884, 737) is decomposed with acids; it can also be prepared by nitrating 1 . 2 . 4-ortho-xylidine and diazotising the product. It crystallises in yellow needles, melts at 127°, and is readily soluble in boiling alcohol, but only sparingly in water and cold alcohol. The ammonium salt is sparingly soluble in cold, but more readily in hot water. The isomeric compound, $[OH : Me_2 : (NO_2)_2 = 1 : 2 : 3 : 4 : 6]$, is obtained in like manner from 1 . 2 . 3-ortho-xylidine. It crystallises from alcohol in small, yellow needles, melts at 82°, and forms an *ammonium* salt which crystallises in needles and is moderately soluble in water. Concentrated aqueous solutions of the ammonium salts described above give orange or yellow crystalline precipitates with barium or calcium chloride and other inorganic salts. F. S. K.

Benzene-derivatives of High Molecular Weight. By F. Krafft and J. Göttig (*Ber.*, **21**, 3180—3188; compare Krafft, Abstr., 1887, 252; 1888, 1087).—*Hexadecylphenetoïl*, $C_{16}H_{33}{\cdot}C_6H_4{\cdot}OEt$, is prepared by heating hexadecylphenol with ethyl iodide and alcoholic potash. It crystallises from alcohol in plates and melts at 43—44°. It yields parethoxybenzoic acid, melting at 195°, when heated at about 120° with nitric acid of sp. gr. 1·12.

Acethexadecylanilide, $C_{16}H_{33}{\cdot}C_6H_4{\cdot}NHAc$, prepared by treating amidohexadecylbenzene with acetic chloride, melts at 104—104·5°, and boils at about 295° (15 mm.).

Orthomethylhexadecylbenzene, $C_{16}H_{33}{\cdot}C_6H_4Me$, is obtained by heating a mixture of sodium (10 grams), orthobromotoluene (34 grams), and cetyl iodide (48 grams) at about 140°. It crystallises from a well-cooled mixture of ether and alcohol, melts at 8—9°, and boils at 238·5—239° (15 mm.). It resembles hexadecylbenzene in its behaviour towards solvents, and the melted substance is fluorescent. The corresponding *meta*-derivative, prepared in like manner, melts at 11—12°, boils at 236·5—237° (15 mm.), and resembles hexadecylbenzene in its behaviour towards solvents. The *para*-derivative melts at 27·5° and boils at 239·5—240° (15 mm.). The melted substance solidifies to a mass of crystals, but does not melt again at 27·5° until it has been either well cooled or brought into contact with a crystal of the original substance. It yields toluylic acid when heated at 120—130° with nitric acid of sp. gr. 1·12.

Sodium paramethylhexadecylbenzenesulphonate, $C_{16}H_{33}\cdot C_6H_3Me\cdot SO_3Na$, is obtained in nacreous plates when the preceding compound is dissolved in fuming sulphuric acid, the product poured into ice-cold water, the acid extracted with ether and treated with sodium chloride.

Paramethylhexadecylphenol, $C_{16}H_{33}.C_6H_3Me\cdot OH$, prepared by melting the preceding compound with potash and a little water at 150°, crystallises from alcohol, melts at 62°, and boils at 267—268° (15 mm.).

Paramethylhexadecylphenetoïl, obtained by heating the phenol with ethyl iodide and alcoholic potash, melts at 26·5.°

Amidoparamethylhexadecylbenzene, $C_{16}H_{33}\cdot C_6H_4Me\cdot NH_2$, is obtained when paramethylhexadecylbenzene is dropped into cool, fuming nitric acid, and the resulting nitro-compound, melting at about 40°, reduced with stannous chloride. It melts at about 54° and boils at 264—265° (15 mm.).

Dimethylhexadecylbenzene, $[Me_2 : C_{16}H_{33} = 1 : 3 : 4]$, prepared by heating bromometaxylene and cetyl iodide with sodium, crystallises from a well-cooled mixture of ether and alcohol, melts at 33·5° and boils at 249·5—250°.

Trimethylhexadecylbenzene, $[Me_3 : C_{16}H_{33} = 1 : 3 : 5 : 6]$, prepared in like manner from bromomesitylene, seems to melt at about 40° and boils at 258—258·5° (15 mm.). F. S. K.

Constitution of Styphnic Acid. By S. KOSTANECKI and B. FEINSTEIN (*Ber.*, 21, 3119—3123).—Consecutive dinitroresorcinol is best prepared by the method Stenhouse and Groves employed in the case of dinitroorcinol. (This Journal, 1877, i, 545.)

Styphnic acid is obtained by boiling consecutive dinitroresorcinol with dilute nitric acid and by the action of very strong nitric and sulphuric acids on the symmetrical dinitro-derivative in the cold. The acid has therefore the constitution $[(OH)_2 : (NO_2)_3 = 1 : 3 : 2 : 4 : 6]$, ascribed to it by Nölting and Collin (Abstr., 1883, 1004).

N. H. M.

Action of Carbon Bisulphide on Dimethylaniline in Presence of Nascent Hydrogen.—By J. WIERNIK (*Ber.*, 21, 3204—3207).—When dimethylaniline and carbon bisulphide are treated with zinc-dust and hydrochloric acid, tetramethyldiamidophenylmethane melting at 90° and thioformaldehyde are formed. The former compound is identical with that obtained by Tröger (Abstr., 1888, 287), who took it for the ethane-derivative. This, however, crystallises in slender needles and melts at 50° (Schoop, Abstr., 1881, 160). N. H. M.

1.2.3-Metaxylidine and its Identity with Wroblewsky's Orthoxylidine. By E. NÖLTING and B. PICK (*Ber.*, **21**, 3150—3154; compare Grevingk, Abstr., 1885, 144, and Nölting and Forel, Abstr., 1886, 58).—Metaxylidine can be obtained from commercial xylidine as follows:—The bases are converted into the sulphates, the solution is allowed to crystallise, and the mixture of bases obtained from the mother-liquor from the last crop of crystals is fractionated. The portion distilling at 212—216° is treated with acetic anhydride, and the mixture of acetyl-derivatives boiled for a few hours with four times its weight of 25 per cent. sulphuric acid. On cooling, the greater part of the metaceto-xylide separates unchanged, and the remainder can be obtained by extracting the diluted mother-liquor with ether. The acetyl-derivative is then decomposed by heating at 150° with concentrated hydrochloric acid or at 200° with three times its weight of 70—75 per cent. sulphuric acid. Metaxylidene can also be prepared from commercial xylidine by heating the mixture of bases obtained from the mother-liquor from the sulphates (see above) for 24 hours with an equal weight of glacial acetic acid and distilling the product. The portion passing below 300° is then treated with acetic anhydride and the acetyl-derivative boiled with 25 per cent. sulphuric acid and isolated as described above. The fraction passing above 300° contains a small quantity of metaceto-xylide, which can be separated by heating with 25 per cent. sulphuric acid as already described. The *sulphate*, $(C_8H_9NH_2)_2,H_2SO_4$, crystallises in needles, and is decomposed into *hydrogen xylidine sulphate*, $C_8H_9NH_2,H_2SO_4 + 2\frac{1}{2}H_2O$, when the aqueous solution is evaporated.

1.2.3-Metaxylidine is only with difficulty converted into the acetyl-derivative; the latter melts at a comparatively high temperature, and is hydrolysed only with difficulty. The sulphate is very readily soluble. In these respects, this base differs from all the isomeric compounds.

The compounds described by Wroblewsky (*Ber.*, **18**, 2904, 3106; **19**, 235) as ortho-xylidine is identical with 1.2.3-metaxylidine.

F. S. K.

Metaxylylamidomethane. By W. HINRICHSEN (*Ber.*, **21**, 3082—3086).—Metaxylonitrile, prepared from metaxylidine by Sandmeyer's reaction, melts at 23—25°. *Metaxylylamidomethane* (*metaxylobenzylamine*), $C_6H_3Me_2\cdot CH_2\cdot NH_2$, prepared by treating a hot alcoholic solution of metaxylonitrile (10 grams) with sodium (16 grams), boils at 218—219°, is readily soluble in alcohol and ether, sparingly in water, and absorbs carbonic anhydride and water on exposure to the air. The *hydrochloride*, $C_9H_{13}N,HCl$, crystallises in needles or plates and melts at 210°. The *hydriodide* is crystalline. The *platinochloride*, $(C_9H_{13}N)_2,H_2PtCl_6$, crystallises in small, yellow needles, melting at 226—228° with decomposition. The *mercurochloride*, $C_9H_{13}N,HHgCl_3$, crystallises in large plates or needles, melts at 205°, and is very sparingly soluble in water. The *sulphate* crystallises from water in needles, melting at 254°. The *picrate*, $C_9H_{13}N,C_6H_3N_3O_7$, crystallises in yellow plates and melts at 223° with decomposition. The *nitrate* crystallises in slender needles melting at 157—158°. The salt, $C_9H_{13}N,CdI_2$, prepared by adding a solution of potassium cadmium iodide to a solution of the base, is crystalline and moderately soluble in water. The *cadmioiodide*, $(C_9H_{13}N)_2,2HI,CdI_2$, prepared by adding a solution of potassium cadmium iodide to an aqueous solution of the hydrochloride, is only moderately soluble in alcohol and very sparingly so in water.

Metaxylyl carbinol (metaxylobenzyl alcohol), $C_6H_3Me_2{\cdot}CH_2{\cdot}OH$, is prepared by treating the preceding compound with nitrous acid and distilling the product with steam. It is a colourless, aromatic-smelling liquid, boils at about 232°, solidifies when cooled in a freezing mixture and melts at 22°.

Dimethylbenzaldehyde (metaxylobenzaldehyde), $C_6H_3Me_2{\cdot}CHO$, is formed when the alcohol is oxidised with sulphuric acid and potassium dichromate. The product is distilled with steam and purified by means of the crystalline sodium hydrogen sulphite compound. It is a colourless oil, boils at 223—225°, smells like benzaldehyde, and turns yellowish on exposure to the air. F. S. K.

Action of Amines on Nitrogenous Organic Compounds.

By B. LACHOWICZ (*Monatsh.*, 9, 695—700).—When hydrobenzamide is gently warmed with the amines, decompositions occur which may be represented by the general equation $N_2(CHPh)_3 + 3RNH_2 = 2NH_3 + 3CHPh{:}NR$. By means of this reaction, the author has formed the following derivatives of benzylidene:—

$C_7H_6{:}NPh$, prepared from aniline, agrees with the description given of it by Cech (Abstr., 1878, 408), except that its melting point is 49°, whereas Cech gives it as 42°.

$C_7H_6{:}N{\cdot}C_6H_4Cl$, prepared from metachloraniline, is a viscid liquid which boils at 338°.

$C_7H_6{:}NC_6H_3Cl_2$, prepared from paradichloraniline (m. p. 63°), crystallises from alcohol in thin plates melting at 84°.

$C_7H_6{:}N{\cdot}C_6H_4{\cdot}NO_2$, prepared from paranitraniline, crystallises in yellow needles melting at 115°; the compound prepared from metanitraniline crystallises in yellow needles melting at 73°.

$C_7H_6{:}N{\cdot}C_7H_7$, prepared from orthotoluidine, forms an oil, boiling at 309—310° (745 mm.).

$C_7H_6{:}N{\cdot}C_{10}H_7$, prepared from α-naphthylamine, crystallises from alcohol in yellow needles melting at 73°. The compound from β-naphthylamine forms yellow needles melting at 101°.

$CHPh(C_5NH_{10})_2$, prepared from piperidine, melts at 81°.

The amides of the acids react with hydrobenzamide with evolution of ammonia, strong bases such as piperidine and formamide being similarly decomposed. G. T. M.

Condensation Products from Bases of the Para-series with Para- and Meta-nitrobenzaldehyde.

By A. BISCHLER (*Ber.*, 21, 3207—3219; compare Abstr., 1888, 287).—*Diacetyl-β-paranitrophenyl-diparamidotolylmethane*, $NO_2{\cdot}C_6H_4{\cdot}CH(C_7H_6{\cdot}NHAc)_2$, prepared by boiling the base with a slight excess of acetic anhydride for one or two hours, crystallises from dilute alcohol in light yellow grains melting at 136°. It is readily soluble in cold alcohol and ether. The *benzoyl-derivative*, $C_7H_5NO_2(C_7H_6{\cdot}NHBz)_2$, is obtained by heating the base with benzoic anhydride at 120—130°; it forms yellow needles, melts at 152°, and is readily soluble in warm alcohol and ether.

β-Metanitrophenyldiparamidotolylmethane,

$$NO_2{\cdot}C_6H_4{\cdot}CH(C_7H_6{\cdot}NH_2)_2,$$

is prepared by adding strong sulphuric acid to an intimate mixture of metanitrobenzaldehyde and paratoluidine sulphate; after three to four days it is treated with much water and heated; it is then filtered, made alkaline, and steam distilled. The oily residue, which solidifies when cold, is crystallised from hot alcohol. It crystallises in yellowish needles, melts at 85—86°, dissolves very readily in chloroform, readily in hot alcohol, rather readily in ether and benzene. The *hydrochloride* forms voluminous, yellowish needles, readily soluble in hot alcohol; hot water decomposes it. The *platinochloride*, $C_{21}H_{21}N_3O_2,H_2PtCl_6$, crystallises in yellow, voluminous needles, sparingly soluble in alcohol. The *acetyl-compound*, $NO_2{\cdot}C_6H_4{\cdot}CH(C_7H_6{\cdot}NHAc)_2$, separates from the aqueous alcoholic solution in pale yellow needles, melts at 103—104°, and dissolves readily in warm alcohol and benzene. The *benzoyl-compound*, $C_{35}H_{29}N_3O_4$, forms groups of yellowish needles, melts at 146°, and is readily soluble in alcohol, less so in ether.

Metamidophenyldiparamidotolylmethane, $C_{21}H_{23}N_3$, obtained by reducing the nitro-compound with tin and hydrochloric acid, crystallises in white plates, readily soluble in alcohol and ether. The *hydrochloride* forms white plates; the *platinochloride* crystallises in small, yellow plates, sparingly soluble in hot water.

α-Metanitrophenyldiparamidotolylmethane, $C_{21}H_{21}N_3O_2$, is prepared by the action of hydrochloric acid on metanitrobenzaldehyde and paratoluidine. It melts at 125—128°. The salts are decomposed by water.

Paranitrophenyldiparamidophenylisobutylmethane,

$$NO_2{\cdot}C_6H_4{\cdot}CH(C_6H_3Bu{\cdot}NH_2)_2,$$

prepared from paranitrobenzaldehyde, paramidoisobutylbenzene sulphate, and strong sulphuric acid, crystallises in lustrous, yellow needles, melts at 125—126°, and is readily soluble in chloroform, benzene, and hot alcohol. The *hydrochloride* forms light yellow plates, readily soluble in hot alcohol; the *platinochloride* crystallises in yellow plates. The *acetyl-compound* crystallises in yellow grains, melts at 114°, and dissolves readily in benzene and in warm alcohol and ether. The *benzoyl-derivative* forms long, yellowish needles, melts at 125—126°, and is readily soluble in ether, benzene, chloroform, and boiling alcohol.

Metanitrophenyldiparamidophenylisobutylmethane, $C_{27}H_{33}N_3O_2$, forms light yellow plates, melts at 64—65°, and resembles the para-compound in solubility. The *benzoyl-derivative* crystallises from hot, aqueous alcohol in yellowish plates, melts at 113—114°, and is readily soluble in hot alcohol.

Paranitrophenyldiamidometaxylylmethane,

$$NO_2 \cdot C_6H_4 \cdot CH(C_8H_8 \cdot NH_2)_2,$$

prepared from paranitrobenzaldehyde (10 grams), unsymmetrical metaxylidine (10 grams), and sulphuric acid, crystallises in light yellow, lustrous, hair-like needles, melts at 89—90°, and dissolves readily in hot alcohol, in ether, benzene, and chloroform. The *hydrochloride* forms pale yellow, flat needles, dissolves readily in hot alcohol, and is decomposed by water. The *platinochloride* separates in yellow crusts. The *acetyl-derivative* forms small, light yellow grains melting at 88°; the *benzoyl-derivative* crystallises in voluminous, lustrous, pale yellow needles melting at 191—192°; both compounds dissolve easily in hot alcohol, less readily in ether.

Metanitrophenyldiamidometaxylylmethane, $C_{23}H_{25}N_3O_2$, crystallises from alcohol in pale yellow, slender plates, melts at 91—92°, and resembles the para-compound in solubility. The *hydrochloride* crystallises from alcoholic hydrochloric acid in pale yellow plates; the *platinochloride* forms a greyish-yellow, crystalline precipitate. The *acetyl-compound* separates from ether in small, light grey needles, melting at 131—132°; the *benzoyl-compound* forms voluminous, yellowish needles, and melts at 185—186°. N. H. M.

Halogen-substituted Acetamido-derivatives of the Aromatic Series and their derived Piazines. By P. W. ABENIUS and O. WIDMAN (*J. pr. Chem.* [2], 38, 296—312).—The substance of the formula $C_9H_7Br_2NO$, formed by digesting alcoholic potash (1 mol.) and bromacetodibromorthotoluidide (1 mol.) (see next Abstract); is very sparingly soluble in hot alcohol, but may be recrystallised from glacial acetic acid in colourless, hexagonal laminæ melting at 277°. It is an indifferent substance, soluble in neither alkalis nor strong mineral acids. Its constitution is most probably

$$C_6H_2Br_2Me \cdot N{<}{\genfrac{}{}{0pt}{}{CO \cdot CH_2}{CH_2 \cdot CO}}{>}N \cdot C_6H_2Br_2Me.$$

A. G. B.

Action of Bromine on Orthacetotoluidide at a High Temperature. By P. W. ABENIUS and O. WIDMAN (*J. pr. Chem.* [2], 38, 285–295).—*Bromacetodibromorthotoluidide*, $C_6H_2Br_2Me \cdot NH \cdot CO \cdot CH_2Br$, is obtained when orthacetotoluidide (10 grams) is heated at 160° and bromine (32 grams) added drop by drop; the product solidifies on cooling to a hard, brittle, black resin, which, when treated with chloroform, yields, besides an oil, the bromo-compound, as white, prismatic needles; the needles recrystallised from glacial acetic acid, melt at 207°; they are sparingly soluble in hot alcohol, more so in benzene. As this compound can be synthesised from bromacetic chloride and dibromorthotoluidine, its constitution is as expressed by the above formula. If it is digested for an hour with alcoholic potash (in mol. proportion), it loses a molecule of hydrogen bromide, and a sparingly soluble substance of the formula $C_9H_7Br_2NO$ separates; but when heated with a considerable excess of alcoholic potash in a reflux apparatus, it is decomposed with formation of dibromorthotoluidine and potassium bromacetate. *Dibromorthotoluidine platinochloride* crystallises in sparingly soluble, yellow needles.

Diacetyldibromorthotoluidide, $C_6H_2Br_2Me{\cdot}NAc_2$, prepared by heating dibromorthotoluidine for several hours with an excess of acetic anhydride, forms white needles, very soluble in alcohol, and melting at 88°. When only gently warmed with acetic anhydride, a substance melting at 200° is obtained, and is doubtless acetyldibromorthotoluidide, but has not yet been analysed.

Acetylglycolyldibromorthotoluidide, $C_6H_2Br_2Me{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}OAc$.—Perfectly pure bromacetyldibromorthotoluide (2 grams) is heated with acetamide (6 grams) at 150—170° until blackening begins; the mass is washed with water to remove excess of acetamide and hydrobromic acid, and the residual acetyl compound recrystallised from alcohol; it forms white needles melting at 172°. This substance was also obtained by heating bromacetodibromorthotoluidide with silver acetate. When heated with weak aqueous potash, it is dissolved and converted into *glycolyldibromorthotoluidide*, $C_6H_2Br_2Me{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}OH$, which crystallises as the solution cools in colourless laminæ, having curved edges; with a stronger solution of potash, the acetyl compound is converted into the laminæ without being dissolved. The laminæ crystallise from alcohol in slender, colourless needles, which melt at 182°, and are more easily soluble in weak alkali than in water; they are precipitated from the alkaline solution on neutralising it with hydrochloric acid. This compound is also obtained when the acetyl-derivative is heated with aqueous soda or with weak hydrochloric acid. A. G. B.

Phenylenediazosulphide. By P. JACOBSEN (*Ber.*, **21**, 3104—3107).—*Orthophenylenediazosulphide*, $C_6H_4{<}\substack{N\\S}{>}N$, is formed when the diazo-compound of diamidophenyl disulphide is boiled with water (Abstr., 1887, 961), and in much larger amount by the action of nitrous acid on amidophenyl mercaptan. It crystallises in plates, melts at 36—37°, has an agreeable, aromatic odour, and distils readily with steam; it is soluble in strong hydrochloric acid.

N. H. M.

Azo-xylenes, Diamido-dixylyls and Colouring Matters derived therefrom. By E. NÖLTING and T. STRICKER (*Ber.*, **21**, 3138—3149).—*Consecutive azortho-xylene*, $C_6H_3Me_2{\cdot}N{:}N{\cdot}C_6H_3Me_2$ [$Me_2 : N = 1 : 2 : 3$], is obtained when zinc-dust (20 grams) is gradually added to a boiling alcoholic solution (100 c.c.) of orthonitro-xylene (20 grams) and 32 per cent. soda (20 grams). After filtering and concentrating the solution, the product is washed with dilute hydrochloric acid and recrystallised several times from alcohol. It can also be obtained by oxidising the hydrazo-compound (see below) with ferric chloride or hydrogen peroxide in alcoholic solution. It crystallises in orange-yellow needles, melts at 110—111°, and is readily soluble in alcohol, ether, and benzene. The *hydrazo*-compound can be prepared by treating the azo-derivative with hydrogen sulphide or by reducing orthonitro-xylene as described above, employing 25 grams of zinc-dust. It crystallises from alcohol in colourless needles, melts at 139—141°, quickly oxidises on exposure to the air, and is soluble in the ordinary solvents—although not so readily as the azo-compound.

Unsymmetrical azortho-xylene, [Me_2 : N = 1 : 2 : 4], is prepared as described in the case of the isomeric compound, except that much more alcohol and very little soda must be employed, otherwise a red condensation product is formed (see below). It can also be obtained by reducing nitrortho-xylene with the theoretical quantity of sodium amalgam. It crystallises from alcohol, in which it is more sparingly soluble than the 1 : 2 : 3 compound, in red needles, and melts at 140—141°.

The *hydrazo*-compound, prepared by reducing an alcoholic solution of nitro-xylene with sodium amalgam or by treating the azo-compound with zinc-dust and soda, ammonium sulphide, or sodium amalgam, crystallises from alcohol in yellowish needles, melts at 106—107°, and is tolerably stable in the air.

Unsymmetrical azometaxylene, [Me_2 : N = 1 : 3 : 4], melting at 129°, can be obtained by reducing an alcoholic solution (300 c.c.) of the nitro-compound (25 grams) with zinc-dust (25—30 grams) and 32 per cent. soda (15 grams). (Compare Schultz, Abstr., 1884, 902.) The *hydrazo*-compound is obtained by boiling a mixture of alcohol (250 grams), nitro-xylene (30 grams), 32 per cent. soda (30 grams), and zinc-dust (40 grams), until the solution becomes almost colourless, and treating the crude product with hydrogen sulphide in alcoholic ammonia solution. It crystallises from alcohol in colourless needles, and melts at 120—122°.

Symmetrical azometaxylene, [Me_2 : N = 1 : 3 : 5], prepared by reducing an alcoholic solution (60 c.c.) of nitrometaxylene (10 grams) with zinc-dust (10 grams) and 32 per cent. soda (10 grams), crystallises in orange needles, is readily soluble in the usual solvents, and melts at 136—137°. The *hydrazo*-compound is prepared by treating nitrometaxylene (10 grams) with soda (3 grams) and zinc-dust (15 grams) in alcoholic solution (50 c.c.). It crystallises from alcohol in colourless needles, melts at 124—125°, and quickly oxidises on exposure to the air. It can also be obtained by reducing the azo-compound with ammonium sulphide.

Azoparaxylene, [Me_2 : N = 1 : 4 : 2], obtained by treating nitroparaxylene (20 grams) with zinc-dust (16—20 grams) and 32 per cent. soda (16 grams) in alcoholic solution (200 c.c.), crystallises in yellow needles and melts at 119°. The azo-xylene prepared by Werigo (*Zeit. f. Chem.* [2], 1, 312) is probably identical with this compound. The *hydrazo*-compound, prepared by reducing nitroparaxylene (30 grams) with 32 per cent. soda (25 grams) and zinc-dust (45 grams) in alcoholic solution (250 c.c.), crystallises from alcohol in colourless needles, melts at 145°, and is moderately stable in the air.

The hydrochlorides of the corresponding diamidodixylyls were prepared by heating the hydrazo-xylenes with moderately dilute hydrochloric acid, either alone or in alcoholic solution, adding excess of soda, extracting the base with ether, and saturating the dried ethereal solution with hydrogen chloride.

Hydrazometaxylene, [Me_2 : N = 1 : 3 : 4], by this treatment, yields chiefly azo-xylene and xylidine; the last-named compound is separated from the diamidodixylyl by distilling with steam. Hydrazortho-xylene, [Me_2 : N = 1 : 2 : 4], is hardly acted on at all when boiled with acids, and the hydrochloride of the corresponding diamidodixylyl was obtained by boiling an alcoholic solution of the azo-compound with hydrochloric acid and stannous chloride, separating the xylidine by distilling with steam and saturating an ethereal solution of the base with hydrogen chloride.

Nitrortho-xylene, [$Me_2 : NO_2 = 1 : 2 : 4$], yields a red, and nitrometa-xylene, [$Me_2 : NO_2 = 1 : 3 : 4$], a brownish-red condensation product when treated with alcoholic soda. The red compound is almost insoluble in ordinary solvents and, when reduced with stannous chloride and hydrochloric acid, is converted into dimethyldiamidostilbene. (Compare Bender and Schultz, Abstr., 1887, 268.)

All the bases obtained from the nitro-xylenes, after diazotising, yield with naphthionic acid α-naphthol-α-sulphonic acid and β-naphthol-disulphonic acid R, compounds which dye unmordanted vegetable fibres. The diphenyl-derivatives are reddish dyes with a more or less blue or yellowish shade, whereas the stilbene-derivative yields a bluish-violet dye with α-naphthol-α-sulphonic acid. The toluidines from meta- and para-nitrotoluene were also prepared; these bases yield red dyes with the above-named sulphonic acids. F. S. K.

Nitroso-derivatives of Resorcinol Azo-dyes. By S. v. KOSTANECKI (*Ber.*, **21**, 3109—3114).—*Nitrosophenylazoresorcinol*, $C_{12}H_9N_3O_3$, is readily obtained by adding a mixture of phenylazoresorcinol (1 mol.) dissolved in dilute alkali and sodium nitrite (1 mol.) to cooled, dilute sulphuric acid. The product is filtered, washed, and crystallised from alcohol. It separates in lustrous, brownish-red plates which, when heated at 168°, detonate; it dissolves sparingly in hot water, readily in benzene, and still more readily in chloroform; ether dissolves it sparingly. It dissolves in alkalis with yellowish-brown, and in strong sulphuric acid with olive-green colour, and yields an intense olive-green colour with iron mordants. Similar dyes were prepared from ortho- and para-toluidine, xylidine, pseudocumidine, meta- and para-nitraniline, amidoazobenzene, and naphthionic acid.

Nitrosopseudocumylazoresorcinol, $C_{15}H_{15}N_3O_3$, crystallises from chloroform in brown plates, decomposes when heated above 190°, and dissolves in alkalis and in strong sulphuric acid, yielding brownish-yellow and brownish-red solutions respectively.

When nitrosophenylazoresorcinol is reduced with tin and hydrochloric acid, diamidoresorcinol is formed.

Phenylazonitrosoresorcinol, $C_{12}H_9N_3O_3$, isomeric with nitrosophenylazoresorcinol, is obtained by adding nitrosoresorcinol dissolved in aqueous sodium carbonate to a solution of diazobenzene chloride cooled with ice. It crystallises from alcohol in golden plates which decompose at 225°. The solution in dilute soda is reddish-yellow; the sulphuric acid solution is olive-brown. When reduced, it yields the same diamidoresorcinol as that obtained from nitrosophenylazoresorcinol. N. H. M.

Isomeric Phenyldiazoresorcinols. By S. v. KOSTANECKI (*Ber.*, **21**, 3114—3119).—Symmetrical diamidoresorcinol, $C_6H_2(NH_2)_2(OH)_2$, is isolated in a manner similar to the consecutive derivative (preceding Abstract); it is identical with Typke's isodiamidoresorcinol (Abstr., 1883, 917). The *sulphate* (with 2 mols. H_2O) crystallises from very dilute alcohol in needles.

Symmetrical phenyldiazoresorcinol is formed when resorcinol (1 mol.) is added to a diazotised solution of aniline (2 mols.), and the whole poured into an excess of dilute alkali. Consecutive phenyldiazoresorcinol is obtained by adding a mixture of diazobenzene chloride (2 mols.) and resorcinol (1 mol.) to aqueous sodium acetate or sodium carbonate. The consecutive compound is best prepared as follows:—Aniline (2 mols.) is dissolved in dilute hydrochloric acid (5 mols.) and diazotised with sodium nitrite. When an excess of nitrous acid is no longer present, resorcinol (1 mol.) is added, the whole added to a dilute solution of sodium acetate or carbonate, and after being kept for some time, filtered, dried, and crystallised from a mixture of chloroform and alcohol. The isomerides have the properties already ascribed to them (Liebermann and v. Kostanecki, Abstr., 1884, 1146).

Phenylazoresorcinol is best prepared by adding resorcinol (1 mol.) to the diazotised solution of aniline hydrochloride (1 mol.), pouring the mixture in a thin-stream into an excess of dilute alkali, precipitating the phenylazoresorcinol with acid, and crystallising it from dilute alcohol. The theoretical yield is readily obtained.

N. H. M.

α-Ethylenephenylhydrazine. By O. BURCHARD and A. MICHAELIS (*Ber.*, **21**, 3202—3204).—*α-Ethylenephenylhydrazine*, $C_2H_4(NPh\cdot NH_2)_2$, is prepared by adding the calculated amount of ethylene bromide to finely powdered sodium phenylhydrazine covered with benzene. After 10 minutes the mixture becomes warm, and in a short time the reaction becomes so violent that the flask has to be cooled with ice water. The product is treated with water, and the benzene separated and extracted, first with very dilute hydrochloric acid, to remove any phenylhydrazine which is present, and then with strong hydrochloric acid. The base is precipitated from the aqueous solution with soda and crystallised twice from alcohol. It forms colourless prisms or plates, melts at 90°, and is readily soluble in hot alcohol and ether, and in dilute acids. It gradually reduces Fehling's solution when heated. The *hydrochloride*, $C_{14}H_{18}N_6,2HCl$, crystallises in needles of a silky lustre. When the base is treated with alcohol and then with acetaldehyde, heat is developed, and the condensation product, $C_2H_4(NPh\cdot N:CHMe)_2$, separates in long, white needles which melt at 82°. The corresponding *benzylidene-derivative* crystallises from hot glacial acetic acid in slender needles, melts at 193°, and is very sparingly soluble in ether and alcohol. N. H. M.

Di-phenylmethyltriazole. By J. A. BLADIN (*Ber.*, **21**, 3063—3065).—Di-phenylmethyltriazole,  $\left\langle\begin{matrix}N\cdot NPh\\ CMe\cdot N\end{matrix}\right\rangle C\cdot C\left\langle\begin{matrix}NPh\cdot N\\ N\cdot CMe\end{matrix}\right\rangle$, is obtained when cyanophenylhydrazine (Senf, Abstr., 1887, 929) is heated for a few minutes with excess of acetic anhydride. It crystallises from alcohol in colourless prisms, melts at 222—223°, and is readily soluble in chloroform, moderately so in alcohol, but only sparingly in benzene and ether, and insoluble in water. It is very stable, and is not decomposed when boiled with alcoholic potash or strong acids. The *hydrochloride*, $C_{18}H_{16}N_6,2HCl$, separates as a crystalline powder when concentrated hydrochloric acid is added to a boiling alcoholic solution of the base. It is almost insoluble in fuming hydrochloric acid, and is decomposed by water. The *platinochloride*, $C_{18}H_{16}N_6,H_2PtCl_6 + \frac{1}{2}H_2O$, crystallises in orange-yellow plates, becomes anhydrous at 125°, and is decomposed by water.

F. S. K.

Action of Sodium Hypobromite on Nitrogen-derivatives in the Benzene Series. By G. DENIGÈS (*Compt. rend.*, **107**, 662).—When an alkaline solution of sodium hypobromite is boiled for a few minutes with a solution of hippuric acid or a hippurate, gas is evolved, and a reddish-yellow precipitate is formed. Benzoic acid gives no reaction, and glycocine decolorises the hypobromite with evolution of nitrogen.

With sodium hypobromite, benzamide and benzonitrile give no reaction in the cold, but a kermes-red precipitate on heating. Aniline gives an orange precipitate, and the reaction is almost as delicate as that with hypochlorites. Methylaniline and dimethylaniline give a greenish-yellow precipitate in the cold and a red precipitate on heating. Toluidine behaves like aniline, but the precipitate is darker in colour. Anilides give no reaction in the cold, but a reddish precipitate is formed on boiling, and an odour of methyl cyanide can be perceived. Metaphenylenediamine, diamidobenzoic acid, and toluylenediamine yield maroon-red precipitates in both cold and hot solutions. Ferrocyanides, ferricyanides, and nitroprussides yield a precipitate of ferric hydroxide. Pyridine gives no reaction, and pure quinoline also gives no reaction, but if, as is frequently the case, it contains aniline, an orange precipitate is formed.

C. H. B.

Aromatic Derivatives of Oxamide and Oxamic Acid. By J. MAUTHNER and W. SUIDA (*Monatsh.*, **9**, 736—750; compare Abstr., 1886, 886; *Ber.*, **3**, 227).—When ethyl oxalate and orthotoluidine are heated together in molecular proportions, ethyl oxalorthotoluidate is formed, together with a little oxaltoluidide, the latter remaining undissolved on treatment with alcohol. On heating either alone or with acetic chloride, the free acid is converted into oxalorthotoluidide, which can also be obtained by heating together orthotoluidine (1 mol.) and anhydrous oxalic acid (2 mols.) at 220°. Oxalorthotoluidide melts at 207—208° and appears to be identical with the polyformotoluide described by Ladenburg.

Oxanilidediorthocarboxylic acid, $C_2O_2(NH{\cdot}C_6H_4{\cdot}COOH)_2$, may be obtained by the oxidation of oxalorthotoluidide with permanganate as well as by heating a mixture of anthranilic acid (2 mols.) and ethyl oxalate (1 mol.) at 140—150°. When sulphuric acid is added to an ammoniacal solution, the acid is thrown out in the form of a pulverulent precipitate. The copper salt, $C_{16}H_{10}N_2O_6Cu + CuO$, has a bright green colour; the silver salt, $C_{16}H_{10}N_2O_6Ag_2$, forms an insoluble, white precipitate.

Oxalxylidic acid, $C_8H_9{\cdot}NH{\cdot}CO{\cdot}COOH$, is formed by heating at 180—190° a mixture of α-amidometaxylene (1 mol.) and ethyl potassium oxalate (1 mol.). It crystallises in needles containing 1 mol. H_2O and melts at 128—129°. The silver salt, $C_{10}H_{10}AgNO_3$, and the calcium salt are both soluble in water and crystallise in needles. On heating the free acid, it is converted into *oxalxylidide*, $C_{10}H_{20}N_2O_2$, which crystallises from acetic acid and benzene in flat needles melting at 210°.

Oxal-ψ-cumidic acid, $C_9H_{11}{\cdot}NH{\cdot}CO{\cdot}COOH$, is prepared by heating at 200° a mixture of ψ-cumidine melting at 63° (1 mol.) and ethyl oxalate (1 mol.). It crystallises in needles containing 1 mol. H_2O and melting at 167°. The sodium salt, $C_{11}H_{12}NO_3Na + 3H_2O$, crystallises in scales; the potassium salt, $C_{11}H_{12}NO_3K,C_{11}H_{13}NO_3$, in needles; the calcium salt, $(C_{11}H_{12}NO_3)_2Ca + H_2O$, is a crystalline powder; the acid silver salt, $C_{11}H_{12}NO_3Ag,C_{11}H_{13}NO_3$, forms bundles of needles, and the normal salt, $C_{11}H_{12}NO_3Ag$, is a crystalline powder. On heating the free acid, it is converted into *oxal-ψ-cumidide*, which can be directly prepared by the action of anhydrous oxalic acid on the base, and crystallises from acetic acid in needles melting at 230°.

G. T. M.

Phthalimidine. By C. GRAEBE (*Annalen*, **247**, 288—301).—Phthalimidine is prepared by the reduction of phthalimide by tin and hydrochloric acid. The tin is precipitated from the crude product by strips of zinc, and the phthalimidine is deposited as the nitroso-compound on the addition of a concentrated solution of sodium nitrite. Nitrosophthalimidine is decomposed by strong hydrochloric acid, yielding a mixture of phthalimidine and its hydrochloride. The conversion of the nitroso-compound into phthalide and the properties of some of the phthalimidine-derivatives have already been described (Abstr., 1885, 167 and 979). Phthalimidine melts at 150°, and boils at 336—337° under 730 mm. pressure. It is freely soluble in alcohol, ether, and chloroform. On the addition of bromine to the solution in chloroform, the tribromide, $(C_8H_4NO)_2Br_3$, is deposited; it melts at 150° with decomposition. The *hydrochloride*, C_8H_7ON,HCl, *picrate* (m. p. 140°), and *aurochloride*, $(C_8H_7ON)_2,HAuCl_4$, are crystalline. *Phthalimidine silver*, C_8H_6ONAg, is deposited from ammoniacal solutions in crystals. *Acetylphthalimidine*, C_8H_6ONAc, melts at 151°, and does not yield a nitroso-derivative.

Nitrosophthalimidine is decomposed by sodium hydrogen sulphide, yielding *thiophthalide*, C_8H_6OS; this is freely soluble in alcohol and ether, melts at 60°, and is converted into a thio-derivative of hydroxymethylbenzoic acid by solution in alkalis and reprecipitation by acids. *Nitrophthalimidine* melts at 210°, and is deposited from alcoholic solution in pale yellow scales. It is soluble in alkalis: acids precipitate from the alkaline solution the compound $C_8H_8O_4N_2$; this is freely soluble in alcohol, ether, and in hot water. *Dinitrophthalimidine* melts at 195°.

W. C. W.

Substituted Phthalimidines. By C. GRAEBE and A. PICTET (*Annalen*, **247**, 302—306).—Methylphthalimide, $C_8H_4O_2NMe$, and methylphthalimidine, $C_8H_6O_4NMe$, have been previously described by the authors (Abstr., 1884, 1019). Methylphthalimide melts at 132° and boils at 285—286°. Ethyl phthalimide melts at 79° and boils at 282·5° under 726 mm. pressure. Ethyl phthalimidine melts at 45°. The *aurochloride*, $(C_{10}H_{10}ON)_2,HAuCl_4$, forms golden prisms melting at 145°. Phenyl phthalimidine, C_8H_6ONPh, prepared by reducing an alcoholic solution of phthalanil with tin and hydrochloric acid, is identical with Hessert's phthalidanil, obtained by the action of aniline on phthalide. W. C. W.

Action of Hypophosphorous Acid on Benzaldehyde. By J. VILLE (*Compt. rend.*, **107**, 659—661).—*Dihydroxybenzylenephosphinic acid*, $PO(CHPh·OH)_2·OH$, is obtained by the action of hypophosphorous acid on benzaldehyde, and crystallises in white, radiating lamellæ, which can be purified by solution in potassium hydroxide and reprecipitation by hydrochloric acid. It is only slightly soluble in water, chloroform, or benzene, but dissolves readily in ethyl alcohol or ether, and is still more soluble in methyl alcohol. With acids it forms crystallisable salts, and its solution has no reducing action on copper sulphate or ammoniacal silver solutions. It begins to melt at 165°, and forms a yellowish liquid, which if more strongly heated gives off hydrogen phosphide and leaves a bulky, carbonaceous residue. When heated in sealed tubes at 130° for several hours with dilute sulphuric acid, it yields benzaldehyde and phosphoric acid.

Dihydroxybenzylenephosphinic acid is monobasic. The *silver salt* forms a white, crystalline precipitate which blackens when exposed to light, and is insoluble in water and nitric acid, but dissolves readily in ammonia. The *ethyl salt* is almost insoluble in water, and is only slightly soluble in ether or chloroform, but it dissolves readily in ethyl alcohol, from which it crystallises in brilliant prisms. It is slowly saponified by cold solutions of potassium hydroxide, and if the liquid is acidified, the free acid separates in crystals. With hot potassium hydroxide, the reaction is more complex, and benzaldehyde and phosphoric acid are obtained.

When the ethyl salt is treated with acetic chloride, it yields the compound $PO(CHPh·OAc)_2·OEt$, a viscous, transparent substance, soluble in alcohol or ether, from which it separates in very white crystals. The acetyl-derivative is slowly saponified by potash in the cold, and if the product is acidified, dihydroxybenzylenephosphinic acid separates, and the solution contains acetic acid. With hot potash, the products are benzaldehyde, phosphates, and acetates.

C. H. B.

On Mono- and Di-nitroparazobenzoic Acids. By Madame A. RODSIANKO (*J. Russ. Chem. Soc.*, 1888, **20**, 18—29).—The action of nitric acid on parazobenzoic acid was studied, and the product compared with the nitro-compound obtained from azobenzoic acid by Zinin. Solid nitrotoluene is oxidised by chromic mixture to paranitrobenzoic acid, and this on treatment with sodium amalgam yields parazobenzoic acid; the latter, after having been dried between blotting paper, still contains 30—35 per cent. of water. It is treated with 16 times its weight of nitric acid of sp. gr. 1·535, gradually warming the mixture, until the temperature reaches 79°, and all the acid is dissolved. On adding water, 90—94 per cent. of a solid product is precipitated. This is washed with water, and recrystallised successively from glacial acetic acid, and several times from alcohol. The product consists of *nitrazobenzoic acid*, $C_{14}H_9(NO_2)N_2O_4$, and forms a pale yellow, crystalline powder consisting of rhombic scales. It is highly electric. It does not melt, but decomposes at 270°. It is insoluble in water, ether, and benzene, soluble in acetic acid and in 26·2 parts of hot, and 280·4 parts of cold alcohol. It forms two series of salts; the acid salts are stable, but the normal salts are decomposed by water, with formation of acid salts. The normal potassium salt, $K_2C_{14}H_7(NO_2)N_2O_4 + 3H_2O$, loses its water at 120°, and is decomposed by carbonic acid, yielding the acid salt. The calcium salt, $CaC_{14}H_7(NO_2)N_2O_4$, and the barium and silver salts have an analogous composition. The ethyl salt, obtained from the silver salt and ethyl iodide, forms pale yellow, rhombic scales melting at 98°.

Dinitroparazobenzoic acid is obtained when 30 parts of nitric acid of sp. gr. 1·535 is employed for 1 part of azobenzoic acid, and the mixture heated nearly to the boiling point. It is purified like the mononitro-acid, and forms tufts of slender yellow needles. It decomposes at 257° without melting. Like the mononitro-compound, it is soluble only in acetic acid and in 16·5 parts of hot, and 160·3 parts of cold alcohol. Its stable normal salts have a composition corresponding with that of the potassium salt, $K_2C_{14}H_6(NO_2)_2N_2O_4 + 4H_2O$. The calcium and barium salts contain 5 mols. H_2O; the silver salt is anhydrous. The ethyl salt forms slender, yellow, silky needles melting at 128°. Finally, azobenzoic acid, obtained by the decomposition of nitrobenzil (Zinin), was treated with nitric acid, and a product obtained which proved to be identical with the mononitroparazobenzoic acid, described above. The two azobenzoic acids are therefore identical. B. B.

Reissert's Pyranilpyroïc Acid. By R. ANSCHÜTZ (*Ber.*, **21**, 3252—3256); A. REISSERT (*Ber.*, **21**, 3257).—Anschütz's paper is a reply to one of Reissert's (Abstr., 1888, 954). Reissert mentions that the most important evidence in favour of his views depends on the knowledge of the constitution of anilsuccinic and β-anilpropionic acids, and that this point is not discussed by Anschütz. N. H. M.

Nitro-derivatives of Isophthalic Acid. By A. CLAUS and S. WYNDHAM (*J. pr. Chem.* [2], **38**, 313—320).—*Dinitroisophthalic acid* is formed when isophthalic acid (5 parts) is heated with fuming nitric acid (1 part) in a sealed tube for six hours at 150—180°. It is but little soluble in cold water, more freely in hot water, and in alcohol and ether; it forms colourless needles or short prisms, arranged in papillary aggregates, and containing 5 mols., H_2O, half of which is lost over sulphuric acid; the anhydrous acid melts at 215° (uncorr.). The *sodium* and *potassium* salts (2 mols. H_2O), the *barium* salt

(7 mols. H_2O), the *calcium* and *magnesium* salts (4 mols. H_2O), and the *lead* and *silver* salts are described. As the same dinitro-compound can be obtained by nitrating symmetrical nitroisophthalic acid, one of the nitro-groups is in the position 5, but the position of the other remains an open question.

Diamidoisophthalic acid, $C_6H_2(NH_2)_2(COOH)_2$, obtained by reducing the above acid, crystallises with 1½ mol. H_2O in shining, flat needles, of a very light-brown tint, becoming darker on exposure to light, and not melting below 300°; its aqueous solution deposits a black tarry matter when incautiously evaporated, and acquires a mushroom-like odour after a time.

Dibromisophthalic acid, obtained when symmetrical nitroisophthalic acid is heated with bromine for several hours at 300° in a sealed tube, crystallises in colourless needles melting at 155° (uncorr.), sparingly soluble in water, freely in alcohol and ether, and subliming with the same crystalline form. The *calcium* and *silver* salts form anhydrous crystals.

Nitroisophthalic acid ($NO_2 : COOH : COOH = 4 : 1 : 3$), may be obtained by oxidising 4-nitrometatoluic acid with potassium permanganate; it crystallises with 3 mols. H_2O in small white needles, easily soluble in hot water, in alcohol and ether. The anhydrous acid melts at 246° (uncorr.); its *sodium*, *potassium* (1 mol. H_2O), *barium* (4 mols. H_2O), *calcium* (½ mol. H_2O) and *magnesium* (6 mols. H_2O), *lead* and *silver* (7½ mols. H_2O) salts are all described. A. G. B.

Phenylglycinorthocarboxylic Acid: Glycocine-derivatives. By J. MAUTHNER and W. SUIDA (*Monatsh.*, 9, 727—735).—Instead of employing 2 mols. of the base to one of chloracetic acid in the preparation of glycocine-derivatives, as in the ordinary method, the authors replace the second molecule of the base, which is needed to combine with the hydrochloric acid liberated, by an equivalent quantity of a metallic carbonate, whereby not only is material saved, but the reaction is hastened.

Phenylglycinorthocarboxylic acid, $COOH{\cdot}C_6H_4{\cdot}NH{\cdot}CH_2{\cdot}COOH$, is prepared by boiling a mixture of anthranilic acid (25 grams) chloracetic acid (20·6 grams), sodium carbonate (32·8 grams) and water (1 litre) for several hours, the water as it evaporates being replaced. After cooling, the product is supersaturated with hydrogen chloride acid and allowed to remain for one day, when the acid separates as a bright-yellow, crystalline powder which melts with frothing at 207°. It dissolves readily in alcohol, acetic acid, and ether, but is insoluble in benzene and chloroform. The acid potassium salt, $C_9H_8NO_4K$, crystallises from dilute alcohol in microscopic scales. The calcium salt is anhydrous, and furnishes aniline on distillation. The barium salt, $C_9H_7NO_4Ba + 2H_2O$, crystallises in needles; the silver salt, $C_9H_7NO_4Ag_2$, is insoluble in water, and the ethyl salt, $C_9H_8NO_4Et$, forms an oil which crystallises on standing.

If chloracetic acid (50 grams) soda (53 grams) and excess of ammonia are boiled for 7—8 hours, glycocine is formed (16 to 18 per cent. of theory). If the ammonia be omitted, glycollic acid (yield 75 per cent. of theory) is the product. G. T. M.

Orthonitranilinesulphonic Acid and some of its Derivatives. By R. NIETZKI and Z. LERCH (*Ber.*, **21**, 3220—3223).—Orthonitranilinesulphonic acid (Goslich, Abstr., 1876, i, 929) is prepared by treating acetanilide (1 part) with fuming sulphuric acid, containing 18 to 20 per cent. of anhydride (3 parts), and ordinary sulphuric acid (2 parts). The calculated amount of nitric acid, previously mixed with an equal volume of sulphuric acid, is then gradually added, the whole being kept at 0°. The product is poured on to a little ice, when it solidifies to a mass of yellow needles. It is extremely soluble in water, less so in alcohol or in dilute sulphuric or hydrochloric acid. When the potassium salt is boiled with an excess of potash for a long time, ammonia is evolved, and the potassium salt, $OK\cdot C_6H_3(NO_2)\cdot SO_3K$ (Kolbe and Graebe, *Annalen*, **147**, 76), is obtained.

Nitrodiazobenzenesulphonic acid,  $NO_2\cdot C_6H_3<\substack{N:N\\SO_3}>$, obtained by treating the aqueous solution of the amido-acid with hydrochloric acid and potassium nitrite, crystallises in slender, light-yellow needles, dissolves sparingly in water, and detonates rather violently when heated.

Orthophenylenediaminesulphonic acid, $C_6H_3(NH_2)_2\cdot SO_3H$, is formed when the nitranilinesulphonic acid is reduced with tin and hydrochloric acid. When exposed to air, it becomes greenish-blue, and gives a reddish-brown colour with ferric chloride. The acid is not identical with Sachsse's acid (this Journal, 1877, ii, 751), but possibly is with the one prepared by Post and Hartung (Abstr., 1880, 394).

Orthonitrophenylhydrazineparasulphonic acid,

$$NH_2\cdot NH\cdot C_6H_3(NO_2)\cdot SO_3H,$$

is obtained by adding orthonitrodiazobenzenesulphonic acid to a well-cooled, strongly acid stannous chloride solution. It dissolves in water and in aqueous alkalis and alkaline carbonates. When reduced with hot acid stannous chloride solution, the corresponding *amidohydrazinesulphonic acid* is formed. The *hydrochloride* crystallises in plates, and dissolves readily in water, but only sparingly in strong hydrochloric acid. N. H. M.

The Sulphonic Acid of Methyl Phenylcarbamate. By E. NÖLTING (*Ber.*, **21**, 3154—3155).—The compound obtained by Hentschel (Abstr., 1885, 792) by treating methyl phenylcarbamate with fuming sulphuric acid, is probably the acid,

$$COOMe\cdot NH\cdot C_6H_4\cdot SO_3H.$$

This substance can also be obtained by adding soda (1 mol.) to a warm aqueous solution of sodium sulphanilate (1 mol.), and methyl chloroformate (1 mol.). The amidosulphobenzoic acid prepared by Hentschel (Abstr., 1884, 1016) is probably sulphophenylcarbamic acid, $SO_3H\cdot C_6H_4\cdot NH\cdot COOH$. When methyl phenylcarbamate is heated at about 260° with lime, aniline, monomethylaniline, dimethylaniline, and carbanilide are formed. F. S. K.

Diphenic Anhydride and Orthodiphenyleneketonecarboxylic Acid. By C. Graebe and C. Aubin (*Annalen*, **247**, 257—288).—Diphenic acid is convered into diphenic anhydride,  $<\substack{C_6H_4\cdot CO\\ C_6H_4\cdot CO}>O$, by the action of acetic chloride or acetic anhydride (Abstr., 1887, 589), also by boiling with stannic chloride or phosphorus trichloride, or by the action of phosphorus pentachloride containing oxychloride at 120°. Concentrated sulphuric acid, zinc chloride, and an excess of boiling phosphorus oxychloride convert diphenic acid into orthodiphenyleneketonecarboxylic acid,  $<\substack{CO\text{--}\\ C_6H_4}>C_6H_3\cdot COOH$.

Monomethyl and ethyl diphenates are prepared by boiling diphenic anhydride with methyl or ethyl alcohol. They crystallise in colourless plates, dissolve freely in alcohol, and distil without decomposition. The ethyl salt melts at 88° and the methyl salt at 110°. *Diphenic chloride*, $C_{14}H_8Cl_2$, prepared by the action of phosphorus pentachloride on the anhydride at 180°, is a crystalline substance soluble in benzene, ether, and acetic acid. It melts at 93—94°, and distils without decomposition. On reduction, diphenic chloride yields phenanthraquinol, which changes into phenanthraquinone by oxidation.

Diphenic anhydride is converted into the *aminic acid*,

$$COOH\cdot C_6H_4\cdot C_6H_4\cdot CONH_2,$$

by boiling it with ammonia. This substance melts at 193° and decomposes on distillation, yielding *diphenimide*,  $<\substack{C_6H_4\cdot CO\\ C_6H_4\cdot CO}>NH$. The imide is deposited from hot alcohol in colourless needles, soluble in chloroform. It melts at 219—220°. Warm strong ammonia converts the imide into *diphenamide*, $NH_2\cdot CO\cdot C_6H_4\cdot C_6H_4\cdot CO\cdot NH_2$. The amide melts at 208—209°, and is insoluble in sodium hydroxide.

Phenylhydrazine unites with diphenic anhydride, forming *anilidodiphenamic acid*, $C_{20}H_{16}O_3N_2$, melting at 174°. At 200°, the acid begins to lose water and slowly changes into anilidodiphenimide,  $<\substack{C_6H_4\cdot CO\\ C_6H_4\cdot CO}>N\cdot NHPh$. This substance melts at 150°, and is insoluble in alkaline carbonates.

The salts of orthodiphenylcarboxylic acid have been previously described (Abstr., 1887, 589). The acid yields a mono- and a trichloride on treatment with phosphorus pentachloride. The *monochloride*, $C_{14}H_7O_2Cl$, melts at 128°, and the trichloride at 95°. The trichloride dissolves in alcohol, and the solution deposits crystals of the composition $<\substack{C_6H_4\\ CCl_2}>C_6H_3\cdot COOEt$. Reduction with zinc and acetic acid converts the trichloride into fluorenecarboxylic acid. The *acetoxime* melts at 263°, and decomposes at a high temperature. The *hydrazone*,  $<\substack{C_6H_4\text{———}\\ C(N_2HPh)}>C_6H_3\cdot COOH$, crystallises in yellow needles or prisms, and is soluble in alcohol and ether. It melts at 205° and decomposes at 210°.

Orthofluorenecarboxylic acid,  $<\substack{CH_2\\ C_6H_4}>C_6H_3\cdot COOH$, melts at 175°, and dissolves freely in ether, alcohol, and acetic acid. The methylic salt melts at 64°.

Hydroxyfluorenecarboxylic acid,  $<\genfrac{}{}{0pt}{}{C_6H_4}{CH(OH)}>C_6H_3 \cdot COOH$, prepared by the action of zinc-dust on an ammoniacal solution of diphenyleneketonecarboxylic acid, is soluble in alcohol, ether, benzene, chloroform, and in hot water. It melts at 203°. The substance which Graebe and Mensching (Abstr., 1880, 812) described as a phthaleïn of diphenic acid, is a condensation product of phenol and diphenyleneketonecarboxylic acid, and is probably represented by the formula  $<\genfrac{}{}{0pt}{}{C(C_6H_4 \cdot OH)_2}{C_6H_4}>C_6H_3 \cdot COOH$.

On heating a mixture of resorcinol and stannic chloride at 115°, a yellowish-brown crystalline powder is produced. The solution in alkalis has a yellowish-red colour and exhibits an intense green fluorescence.

W. C. W.

Nitro-derivatives of Tetramethyldiamidodiphenylmethane. By P. VAN ROMBURGH (*Rec. Trav. Chim.*, 7, 226—235).—*Tetramethyldiamidodiphenylmethane* was prepared by heating methylal and dimethylaniline with zinc chloride. It melts at 90°, gives a violet compound with trinitrobenzene melting at 114°, and a dark red compound with metadinitrobenzene melting at 74°, the first containing equal molecular proportions, the second 2 mols. of the amine to one of dinitrobenzene. Added in acetic acid solution to nitric acid (sp. gr. 1·48—1·5), it is converted into *tetranitrodimethyldinitramidodiphenylmethane*, $CH_2[C_6H_2(NO_2)_2 \cdot NMe \cdot NO_2]_2$. This nitramine is a yellow, crystalline substance, which darkens in colour at 210° and decomposes at 217—220°. It is nearly insoluble in alcohol, ether, petroleum, carbon bisulphide, and chloroform, dissolves readily in acetic acid and acetone, but is best recrystallised from nitric acid. Precipitated as a white powder from the nitric acid solution by the addition of water, and boiled with 12·5 per cent. aqueous potash, it gives a brown solution which on evaporation was found to give off methylamine. When boiled with phenol, it gives *tetranitrodimethyldiamidodiphenylmethane*, an orange-coloured compound melting with decomposition at 250°. It is slightly soluble in alcohol, petroleum, and benzene, but more soluble in acetone, acetic acid, chloroform, and ethyl acetate. When treated with nitric acid, it is reconverted into the nitramine.

The latter, when oxidised with chromic anhydride, yields a compound exactly resembling that obtained by the nitration of tetramethyldiamidobenzophenone; on treatment with phenol, this gives a tetranitrodimethyldiamidobenzophenone melting at 225°. Admitting the formula which the author proposed for the nitramine derived from benzophenone, that of the one now in question will be

$$NO_2 \cdot \overset{4}{N}Me \cdot C_6H_2\overset{3,5}{(NO_2)_2} \cdot \overset{1}{C}H_2 \cdot C_6H_2\overset{2,6}{(NO_2)_2} \cdot \overset{4}{N}Me \cdot NO_2.$$

The compound obtained from this by boiling with phenol was also oxidised in acetic acid solution with chromic anhydride, and gave a *tetranitrodiamidobenzophenone*, crystallising in small yellow needles from acetic or phenol, and melting with decomposition at 250—260°.

H. C.

Action of Primary Aromatic Amines on Benzil. By F. X. BANDROWSKI (*Monatsh.*, 9, 685—694; compare Voigt, Abstr., 1885, 1067).—Benzil forms condensation products with the amines when they are heated together in open vessels at 100—150°. With aniline and orthotoluidine, only monosubstituted, but with paratoluidine and α-naphthylamine, a mixture of both mono- and di-substituted compounds were obtained. All the compounds of benzil described below are characterised by not forming salts with dilute acids and by the ease with which they are reconverted into their generators.

Anilbenzil, $COPh\cdot CPh:NPh$, melts at 105°, and gives characteristic colours with alcohohic potash (violet) and with cold concentrated sulphuric acid (blood-red, turning to green).

Orthotolilbenzil, $COPh\cdot CPh:N\cdot C_7H_7$, crystallises from alcohol in yellow plates which melt at 104°, and readily dissolve in ether and benzene.

Paratolilbenzil crystallises in yellow prisms melting at 116—117°.

Paraditolilbenzil, $C_7H_7\cdot N:CPh\cdot CPh:N\cdot C_7H_7$, is a bright yellow, crystalline powder melting at 161°, and more soluble in alcohol than paratolilbenzil.

α-Naphthilbenzil, $COPh\cdot CPh:N\cdot C_{10}H_7$, crystallises from alcohol in golden-yellow needles melting at 138—139°. It dissolves readily in benzene, less readily in ether, and with difficulty in light petroleum.

Di-α-naphthilbenzil, $C_{10}H_7\cdot N:CPh\cdot CPh:N\cdot C_{10}H_7$, is insoluble in alcohol, but crystallises from a mixture of benzene and light petroleum in dark yellow needles melting at 218—219°.

Orthotolilbenzoïn, $OH\cdot CHPh\cdot CPh:N\cdot C_7H_7$, is obtained by heating together equal quantities of benzoïn and orthotoluidine for three-quarters of an hour at 150°. It crystallises from alcohol in light yellow needles, readily soluble in ether, and melts at 141°.

G. T. M.

Derivatives of Ethyl Phenacylbenzoylacetate. By S. KAPF and C. PAAL (*Ber.*, 21, 3053—3063). The compound melting at 142—145°, obtained together with benzoic and benzylpropionic acid by hydrolysing ethyl phenacylbenzoylacetate (compare Abstr., 1888, 839) is diphenacyl (diphenyl ethylene diketone) (compare Nölting and Kohn, Abstr., 1886, 349; Claus and Werner, Abstr., 1887, 827; and Hollemann, Abstr., 1888, 275). It can be obtained by mixing ethyl phenacylbenzoylacetate (1 mol.) with a small quantity of alcohol, adding an 8 per cent. aqueous solution of potash (1½ mol.) and keeping the mixture for 8 to 10 days at the ordinary temperature; the whole is then filtered, the residue extracted with cold ethyl acetate to remove the unchanged ethereal salt, and recrystallised from alcohol or from a mixture of benzene and light petroleum. The yield is 20—25 per cent. of the ethereal salt employed.

Diphenacyldihydrazone, $C_2H_4(CPh:N_2HPh)_2$, prepared by boiling the diketone with phenylhydrazine, crystallises from alcohol in slender, colourless needles, melts at 180° with decomposition, and is readily soluble in ether, benzene, and hot glacial acetic acid. The impure compound is unstable, especially in the light. The *dioxime*, $C_2H_4(CPh:N\cdot OH)_2$, prepared by boiling a dilute alcoholic solution of the diketone with hydroxylamine, crystallises from dilute alcohol in colourless needles or plates, melts at 203—204°, and is readily soluble in glacial acetic acid, alcohol, ether, alkalis, and mineral acids, but sparingly in benzene and light petroleum.

$\alpha\alpha'$-Diphenylfurfuran (*loc. cit.*) is obtained when the diketone is heated at 130—150° with concentrated hydrochloric acid. It gives a dark grey coloration with isatin and sulphuric acid, and dissolves in concentrated sulphuric acid, forming a green solution which, on heating, changes to reddish-brown with a bluish-green fluorescence. Diphenacyl gives the same reaction with concentrated sulphuric acid.

Diphenyltetrahydrofurfuran,  $O<\begin{matrix}CHPh\cdot CH_2\\CHPh\cdot CH_2\end{matrix}>$, prepared by treating a hot alcoholic solution of diphenylfurfuran with sodium, is a colourless, viscid oil boiling at 230—232°. It is insoluble in water but mixes with most of the ordinary solvents in all proportions.

2 : 5 *Diphenylthiophen*, $C_4SH_2Ph_2$, obtained by heating diphenacyl (1 part) with phosphoric sulphide ($1\frac{1}{2}$ parts) at 160—186°, crystallises from alcohol or acetic acid in yellowish or colourless plates, melts at 152—153°, is readily soluble in most of the ordinary solvents and distils unchanged. It shows the indophenin and Laubenheimer's reaction.

When ethyl phenacylbenzoylacetate is heated at 150—200° with glacial acetic acid and excess of phosphoric sulphide, an acid melting at 216°, probably diphenylthiophencarboxylic acid, is obtained.

Ethyl $\alpha\alpha$*-diphenylfurfuran-*β*-carboxylate*, $C_4HPh_2O\cdot COOEt$, is obtained when finely-divided ethyl phenacylbenzoylacetate is boiled with alcohol and excess of moderately concentrated hydrochloric acid. It separates from dilute alcohol in large crystals.

Phenylacetylenebenzoylacetic acid (*loc. cit.*) yields a monobromo-substitution product which crystallises in colourless needles melting at 200°. When the acid is treated with phosphoric chloride in chloroform or carbon bisulphide solution, and the product poured into well-cooled methyl alcohol, it yields a *methyl* salt which crystallises in orange needles and contains chlorine. A yellow, crystalline *hydrazone*, $C_{29}H_{40}N_4O$, is formed when the acid is warmed with phenylhydrazine; it melts at about 100°, is insoluble in water and resinifies when treated with most ordinary solvents. The acid also combines with hydroxylamine.

Ethyl diphenylpyrroline-β*-carboxylate*,

$$C_4NH_2Ph_2\cdot COOEt\ [= 2:5:3],$$

is obtained when ethyl phenacylbenzoylacetate is heated with ammonium acetate and glacial acetic acid. It crystallises from acetic acid in colourless needles, melts at 159°, and distils unchanged when heated in small quantities. It is readily soluble in alcohol, ether, benzene, and glacial acetic acid, sparingly in light petroleum, and insoluble in water. It dissolves in warm, concentrated sulphuric acid with a reddish-brown coloration which changes to reddish-violet with a blue fluorescence when the solution is heated more strongly.

2 : 5-Diphenylpyrrolinecarboxylic acid (*loc. cit.*) melts at 216°. The compound described as ethyl αα-diphenylpyrroline-β-carboxylate (*loc. cit.*) is the *amide*,  $<\begin{matrix}NH\cdot CPh\\CPh{:}CH\end{matrix}>C\cdot CONH_2$. αα-Diphenylpyrroline can be obtained by boiling ethyl diphenylpyrrolinecarboxylate with alcoholic potash, by boiling diphenacyl with ammonium acetate and glacial acetic acid, and by heating the diketone at 150—160° with alcoholic ammonia. It is also obtained by distilling diphenylpyrrolecarboxylic acid over heated lime, but considerable decomposition takes place (compare Baumann, Abstr., 1887, 735, and Holleman, *loc. cit.*). It gives the same coloration with concentrated sulphuric acid as the ethereal salt described above.

Ethyl triphenylpyrrolinecarboxylate,

$$C_4NHPh_3{\cdot}COOEt\ [Ph_3 : COOEt = 1 : 2 : 5 : 3],$$

prepared by boiling ethyl phenacylbenzoylacetate with aniline and glacial acetic acid, crystallises from glacial acetic acid in yellowish, slender needles, melts at 169—170°, and is only sparingly soluble in most ordinary solvents.

Triphenylpyrrolinecarboxylic acid, $C_4NHPh_3{\cdot}COOH$, prepared by boiling the ethereal salt with alcoholic potash, crystallises from glacial acetic acid in needles, melts at 273°, and is rather sparingly soluble in most of the ordinary solvents. It sublimes with only slight decomposition and gives a reddish-brown solution when heated with concentrated sulphuric acid.

2 : 5-Triphenylpyrroline (compare Baumann, *loc. cit.*) and a compound melting at 140—142° are obtained when the preceding compound is distilled over heated lime. The substance melting at 140—142° crystallises in colourless needles or plates, and has the same composition as triphenylpyrroline. F. S. K.

Derivatives of α-β-Dichloronaphthalene. By P. Hellström (*Ber.*, **21**, 3267—3271).—*Dinitrodichloronaphthalene*, $C_{10}H_4Cl_2(NO_2)_2$, is prepared by the action of a mixture of fuming nitric and strong sulphuric acids (equal parts) on dichloronaphthalene. It crystallises in spherical aggregates of bright yellow, slender, flat needles, melts at 169·5°, and dissolves very sparingly in ether, very readily in boiling glacial acetic acid. When distilled with phosphorus pentachloride, a compound, possibly hexachloronaphthalene, is obtained which crystallises in long, bright yellow needles melting at 135—136°.

α-β-Dichloronaphthaquinone, $C_{10}H_4O_2Cl_2$, obtained by adding a solution of α-β-dichloronaphthalene in glacial acetic acid to a solution of chromic acid in glacial acetic acid (Guareschi, *Ber.*, **19**, 1154), melts at 181°, sublimes in long, yellow needles, and is rather sparingly soluble in alcohol. It yields with hydroxylamine a compound which crystallises in reddish-brown needles, and carbonises at 215°. When a solution of the quinone is treated with aniline, *dichloranilidonaphthaquinone*, $C_{10}H_3O_2Cl_2{\cdot}NHPh$, is formed. It is a red, crystalline substance, melts at 254—255°, and is very sparingly soluble in glacial acetic acid, less soluble in alcohol; it sublimes in carmine-red needles with a greenish-bronze lustre.

The above results show that α-β-dichloronaphthalene is not identical with the so-called α-dichloronaphthalene. N. H. M.

Disubstituted Naphthalenes from the Isomeric Chlorophenylparaconic Acids. By H. Erdmann and R. Kirchhoff (*Annalen*, **247**, 366—380).—The isomeric chlorophenylparaconic acids yield chlor-α-naphthols on distillation, just as phenylparaconic acid yields α-naphthol (Abstr., 1884, 906). The naphthols are converted into the corresponding dichloronaphthalenes by the action of phosphorus pentachloride. Metachlorophenylparaconic acid yields the 1 : 1'-chloronaphthol.

Ortho- and para-chlorobenzaldehydes are prepared by converting the chlorotoluenes into chlorobenzal chlorides, and decomposing the product by the action of anhydrous oxalic acid at 160°. The metachlorobenzaldehyde is obtained from metamidobenzaldehyde. When the chlorobenzaldehydes are heated at 120—140° with succinic anhydride and potassium acetate in molecular proportion, chlorophenylparaconic acids are produced.

The *ortho*-acid, $C_{11}H_9ClO_4 + 1\frac{1}{2}H_2O$, crystallises in needles, and melts at 146—147°. 100 parts of boiling water dissolve 1·4 parts of the acid. The *para*-acid crystallises with $\frac{1}{2}$ mol. H_2O. 1 part by weight of the acid dissolves in 100 parts of water at 100°, and in 500 at 16°. The acid melts at 119—120°. The *meta*-acid forms prisms and melts at 160—161°.

Chloronaphthol, [Cl : OH = 4 : 1'], crystallises in plates and melts at 131·5°. The acetate melts at 53°, and the picrate at 160°. Both salts are crystalline.

The 2 : 1'-chloronaphthol melts at 123°, and the picrate at 139°. The acetate is an uncrystallisable oil. By the action of ammonium calcium chloride at 260°, the chloronaphthol is converted into chloronaphthylamine. The hydrochloride melts at 235—239°, and yields a crystalline precipitate with platinum chloride. 3 : 1'-chloronaphthol crystallises in prisms, and melts at 94°. The acetate forms rhombic plates, and melts at 47°. The picrate crystallises in needles, and melts at 165°.

The three dichloronaphthalenes obtained by the action of phosphorus pentachloride on the chloronaphthols have the following melting points:—

Cl : Cl = 4 : 1' melts at 107°, and is identical with 1 : 4' dichloronaphthalene; 2 : 1' dichloronaphthalene melts at 61·5°; and 3 : 1' at 48°. The two last compounds have been previously described by Cleve and others. W. C. W.

Dimethyl-α-Naphthylamine and Diethyl-α-Naphthylamine. By P. Friedländer and P. Welmans (*Ber.*, **21**, 3123—3130).—Dimethyl-α-naphthylamine (Hantzsch, Abstr., 1880, 813) boils at 272—274° (uncorr.), and is very strongly refractive.

Amidodimethylnaphthylamine, $NH_2{\cdot}C_{10}H_6{\cdot}NMe_2$, is prepared by reducing the nitroso-compound, or from the azo-derivative. It dissolves readily in the usual solvents and in dilute mineral acids, and separates from the aqueous solution as an oil; it quickly becomes resinous when exposed to air. The *acetyl-derivative* crystallises in pointed plates, melts at 194—195°, and dissolves readily in alcohol and glacial acetic acid, sparingly in ether.

Nitrosodimethyl-α-naphthylamine, $NO{\cdot}C_{10}H_6{\cdot}NMe_2$, is obtained by adding a strong solution of sodium nitrite (7 grams) to dimethylnaphthylamine (17 grams) dissolved in hydrochloric acid (30 c.c.) in presence of ice. The solid product is freed from adhering liquid by suction, dissolved in cold alcohol, and precipitated with ether. The substance, which is probably the hydrochloride of the base, is readily soluble in a little water, but is decomposed when the solution is diluted. The free base is precipitated as an oily precipitate which gradually solidifies when sodium carbonate is added to the solution of the hydrochloride. It quickly decomposes into dimethylamine and nitrosonaphthol.

Dimethylnaphthylaminecarboxylic acid, $COOH{\cdot}C_{10}H_6{\cdot}NMe_2$, prepared by heating the base (2 mols.) with carbonyl chloride (1 mol.) at 60—70° for three to four hours, crystallises from alcohol in white, pointed needles melting at 163—165°. The *platinochloride*,

$$(COOH{\cdot}C_{10}H_6{\cdot}NMe_2)_2,H_2PtCl_6,$$

crystallises in yellow needles. The salts of the alkalis are readily soluble, and do not crystallise well.

Bromodimethylnaphthylamine hydrobromide crystallises from water in presence of hydrogen bromide in quadratic plates of a silvery lustre. The *free base* is a strongly refractive oil which boils at 260° with decomposition.

Dimethylnaphthylaminesulphonic acid, $SO_3H{\cdot}C_{10}H_6{\cdot}NMe_2$, prepared by heating the base with sulphuric acid (4 parts) at 150°, crystallises in lustrous plates, dissolves sparingly in water, readily in ether and alcohol. The *sodium*, *potassium*, *calcium*, and *barium salts* form crystalline precipitates.

Dimethylnaphthylamine is readily attacked by nitric acid, yielding two nitro-compounds melting respectively at 87—88° and 126—128°.

Tetramethyldiamidodinaphthylphenylmethane, $CHPh(C_{10}H_6{\cdot}NMe_2)_2$, is obtained by heating dimethylnaphthylamine (2 mols.), benzaldehyde (1 mol.), and zinc chloride at 110—120°, dissolving the product in the smallest possible amount of benzene, and adding ether. It separates in lustrous crystals, melts at 188—189°, dissolves sparingly in alcohol and ether, readily in glacial acetic acid, benzene, carbon bisulphide, and in dilute mineral acids. The *platinochloride* is sparingly soluble.

Hexamethyltriamidodinaphthylphenylmethane,

$$NMe_2{\cdot}C_6H_4{\cdot}CH(C_{10}H_6{\cdot}NMe_2)_2,$$

prepared by the action of dimethylparamidobenzaldehyde on dimethylnaphthylamine, forms white needles melting at 178—179°.

Diethyl-α-naphthylamine is readily obtained by heating naphthylamine with aqueous soda and ethyl bromide or iodide at 110—120°, and is purified in a manner similar to dimethylnaphthylamine. It forms a clear oil which gradually becomes brown, and boils at

283—285° (uncorr.). Sp. gr. = 1·005. The *sulphate* crystallises in thick prisms readily soluble in water. The *carboxylic acid*, prepared by the action of carbonyl chloride on the base, forms white plates melting at 166°.

When naphthylamine is heated with ethyl bromide (1·5 part) and alcohol at 120° (Smith, Trans., 1882, 180), a product consisting essentially of monethylnaphthylamine is formed. N. H. M.

α-Naphtholbidiazobenzene and α-Naphthylaminebidiazobenzene. By C. Krohn (*Ber.*, **21**, 3240—3242).—*α-Naphtholbidiazobenzene*, $OH \cdot C_{10}H_5(N_2 \cdot Ph)_2$, $[OH : N_2Ph : N_2Ph = 1 : 2 : 4]$, is readily obtained by adding a solution of diazobenzene chloride (2 mols.) to a slightly alkaline solution of α-naphthol (1 mol.). After 12 hours, the compound separates as a brown powder, and is extracted with boiling, dilute alkali. It is purified by crystallisation from aniline, and will then crystallise well from any solvent. It melts at 183°, and dissolves very readily in chloroform, readily in ether, benzene, and in boiling aniline, sparingly in light petroleum, alcohol, and glacial acetic acid; the solution in strong sulphuric acid is dark-green. When reduced with tin and hydrochloric acid, aniline and diamido-α-naphthol are formed.

α-Naphthylaminebidiazobenzene, $[NH_2 : N_2Ph : N_2Ph = 1 : 2 : 4]$, is prepared by adding a strong aqueous solution of diazobenzene chloride (1 mol.) to an alcoholic solution of naphthylazobenzene (1 mol.) containing sodium acetate; in 12 hours the reaction is finished. It crystallises from aniline in red needles, melts at 189°, and dissolves readily in chloroform, sparingly in most other solvents. The *acetyl-derivative* is yellow, and melts at 265°; the solution in sulphuric acid is brown. When α-naphthylaminebidiazobenzene is reduced with tin and hydrochloric acid, aniline and a triamidonaphthalene are formed; the latter reacts with phenanthraquinone in presence of glacial acetic acid, yielding an azine which dissolves in strong sulphuric acid, forming a green solution. The azo-group is, therefore, in the ortho-position to the amido-group. N. H. M.

Naphthoic Acids. By A. G. Ekstrand (*J. pr. Chem.* [2], **38**, 241—285; compare this vol., p. 52).—The *acetyl*-derivative of amido-α-naphthoic acid (m. p. 211°) forms microscopic needles, melting above 280°; the *calcium* salt crystallises with 3 mols. H_2O in very soluble, violet needles; the *hydrochloride* forms anhydrous, violet needles, soluble in warm water and alcohol, melting above 290°; the *sulphate* and *nitrate* are also described. When the acetyl-derivative is treated with nitric acid (sp. gr. 1·42), *nitracetylamido-α-naphthoic acid* is produced; it melts at 259°, and is easily soluble in alcohol.

When chlorine is passed through a glacial acetic solution of the same amido-α-naphthoic acid containing some iodine, a mixture of ammonium chloride and *dichloronaphthaquinonecarboxylic acid*, $C_{10}H_3O_2Cl_2 \cdot COOH$, is obtained. This acid crystallises in violet needles melting at 255°; when treated with ammonia it is converted into red needles of a *diammonium* salt, $ONH_4 \cdot C_{10}H_3O_2Cl \cdot COONH_4$, of *chlorhydroxynaphthaquinonecarboxylic acid.* From this the acid is obtained by heating with sodium hydroxide solution until all ammonia is expelled, and then adding hydrochloric acid; it crystallises in orange-yellow, rhombic tables melting at 246°; the *acid ammonium* salt is obtained by the action of mineral acids on the diammonium salt.

Chloronitro-α-naphthoic acid, obtained from chlor-α-naphthoic acid (1 : 1′), crystallises in broad prisms melting at 227°; its *ethyl* salt melts at 84°. By reduction, this acid yields *chloramido-α-naphthoic acid*, which crystallises in needles, beginning to melt at 210°, but not fully melted until 285°; its *hydrochloride* is described.

Dichloronitro-α-naphthoic acid is obtained from dichloro-α-naphthoic acid, (COOH : Cl : Cl = 1 : 1′ : 4′), and melts at 165°; it has a very bitter taste.

The *sodium* salt of dinitro-α-naphthoic acid, of melting point 265° (Abstr., 1884, 1361), crystallises with 6 mols. H_2O, and the *barium* salt with 2½ mols. H_2O; the calcium salt is soluble in 138 parts of water at the ordinary temperature. The compound formed when this acid is reduced with hydrogen sulphide in an ammoniacal solution (Abstr., 1886, 949; 1887, 373) contains sulphur as part of the molecule; it would thus appear to be a *sulphide* of *diazinenaphthoic acid*, $S\left[<\genfrac{}{}{0pt}{}{N}{N}>C_{10}H_5\cdot COOH\right]_3$. When the dinitro-acid is reduced with tin and hydrochloric acid, diamidonaphthalene is formed, and at the same time, if the acid is first dissolved in glacial acetic acid, a black powder which appears to be *di-imido-α-naphthoic acid*, $COOH\cdot C_{10}H_5<\genfrac{}{}{0pt}{}{NH}{NH}>$.

The *ethyl* salt of trinitro-α-naphthoic acid (m. p. 283°) crystallises from alcohol in small brown prisms, which melt at 131°; the *calcium* salt crystallises in brown laminæ or needles, with 5 mols. H_2O.

When nitro-α-naphthamide (Abstr., 1886, 948) is reduced with tin and hydrochloric acid, *chloronaphthostyril* is produced; it crystallises in green or yellowish-green needles, which melt at 265° and sublime.

Chloronaphtholactone, $C_{10}H_5ClOCO$ (compare Abstr., 1886, 716), is formed when chlorine is passed through a carbon bisulphide solution of naphtholactone containing some iodine; it melts at 184—185°; when it is dissolved in weak soda solution and hydrochloric acid added, slender needles melting at 190—191° are obtained; these are *chlorhydroxy-α-naphthoic acid.* The *calcium* salt is anhydrous. If the naphtholactone is dissolved in nitric acid (sp. gr. 1·42) and some fuming acid added, *nitronaphtholactone* is formed; it crystallises from glacial acetic acid in slender, yellow needles, melting at 242°, and sparingly soluble in alcohol; by treating it like the chloronaphtholactone, a *nitrohydroxynaphthoic acid* is obtained in rhombic tables, melting at 242°; its *calcium* salt contains 5½ mols. H_2O.

A. G. B.

Action of Sulphuric Acid on α-Nitronaphthalene. By W. Palmaer (*Ber.*, **21**, 3260—3264).—Nitronaphthalene is heated on a water-bath with ordinary sulphuric acid (2 parts) and fuming acid (1 part); after 10 hours, the product is poured into water, when the α-sulphonic acid separates. The filtrate is neutralised with chalk and evaporated down; on cooling, the calcium salts of the α- and β-acids separate. The mother-liquor from the calcium salts is treated with potassium carbonate, and the potassium salts converted into chlorides. On crystallising from various solvents, two *chlorides*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_2Cl$, melting respectively at 167° and 126°, were separated. The chloride of higher melting point forms slender, yellowish needles, sparingly soluble in glacial acetic acid; when heated with water in closed tubes, the *acid* is obtained in readily soluble needles. The *ethyl salt*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_3Et$, forms thin, yellow needles, melting at 106—107°. The *amide*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_2{\cdot}NH_2$, crystallises in small, yellowish-white needles, melting at 223°. When the chloride is distilled with phosphorus pentachloride, dichloronaphthalene melting at 61° is formed. The chloride is, therefore, a derivative of the δ-acid (α-nitro-β-sulphonic acid). The *potassium salt*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_3K + \frac{1}{2}H_2O$, forms very readily soluble, yellow needles; the *sodium salt* crystallises in spherical aggregates of needles; the *silver salt* crystallises in readily soluble, well-formed needles; the barium salt (with $3\frac{1}{2}$ mols. H_2O) forms groups of needles; the anhydrous barium salt dissolves in 9·1 parts of boiling water, and in 377 parts of water at 17°. The *calcium salt* forms long, soft needles, very soluble; the *lead* (with 3 mols. H_2O), *magnesium* (with 9 mols. H_2O), *manganese* (with 10 mols. H_2O), *copper* (with 8 mols. H_2O), and *zinc* (with 10 mols. H_2O) *salts* were also prepared.

The sulphochloride, melting at 126°, forms monoclinic crystals identical with the chloride of β-nitronaphthalenesulphonic acid; $a : b : c = 0{\cdot}9956 : 1 : 0{\cdot}8308$; $\beta = 81° 28'$. N. H. M.

γ-Amidonaphthalenesulphonic Acid. By P. T. CLEVE (*Ber.*, **21**, 3271—3276). *Potassium γ-amidonaphthalenesulphonate*,

$$NH_2{\cdot}C_{10}H_6{\cdot}SO_3K,$$

and the *ammonium salt* are very readily soluble; the *sodium salt* forms readily soluble scales; the *silver salt*, with 1 mol. H_2O, separates in white microscopic needles; the *calcium* and *barium* (with 1 mol. H_2O) *salts* are readily soluble, and crystallise respectively in needles and thin plates; the *lead salt* forms very lustrous prisms.

γ-Diazonaphthalenesulphonic acid, $C_{10}H_6<^{N:N}_{SO_3}>$, crystallises in rather large, yellow crystals.

γ-Amidonaphthalenesulphonamide, $NH_2{\cdot}C_{10}H_6{\cdot}SO_2{\cdot}NH_2 + H_2O$, prepared by reducing the nitrosulphonamide with hydriodic acid, crystallises in small groups of lustrous needles, melts at 131°, and dissolves readily in dilute hydrochloric acid. The *hydrochloride* forms sparingly soluble, yellow prisms. The *acetyl-derivative*,

$$NH_2{\cdot}SO_2{\cdot}C_{10}H_6{\cdot}NHAc,$$

crystallises from boiling water in tufts of needles, which melt at 220—221°. The *carbamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_{10}H_6{\cdot}SO_2{\cdot}NH{\cdot}CO{\cdot}NH_2$, is formed by the action of potassium cyanide on the hydrochloride of the amide. It is amorphous, melts at 273°, is readily soluble in aqueous soda, almost insoluble in water.

γ-Chloronaphthalene sulphochloride, $C_{10}H_6Cl·SO_2Cl$, is prepared by heating the diazosulphonic acid with hydrochloric acid, neutralising the product with potassium carbonate, and treating the potassium salt with phosphorus pentachloride. It is crystallised from light petroleum. It melts at 106°. *Potassium chloronaphthalenesulphonate* crystallises in thin, lustrous scales, rather soluble in boiling water; the *silver salt* forms small, stellate groups of needles; the *barium salt*, with 3 mols. H_2O, forms very sparingly soluble, microscopic needles. The *ethyl salt* crystallises from alcohol in long needles melting at 76—79°. The *amide* forms small, triangular scales, melts at 168°, and is very sparingly soluble in water. N. H. M.

δ-Amidonaphthalenesulphonic Acid. By P. T. Cleve (*Ber.*, **21**, 3264—3267).—*Potassium δ-amidonaphthalenesulphonate*,

$$NH_2·C_{10}H_6·SO_3K,$$

forms very soluble, thin scales; the *sodium salt* (with ½ mol. H_2O) forms readily soluble, thin needles; the *ammonium salt* crystallises in very soluble, thin plates; the *calcium salt* (with 2 mols. H_2O) is a readily soluble powder and becomes quickly coloured when exposed to air; the *barium salt* crystallises in rather sparingly soluble, flat needles. The *zinc salt* (with 4 mols. H_2O) forms lustrous, yellow, rather sparingly soluble, well-formed needles; the *magnesium*, *lead*, and *silver salts* are also described. The *diazo-acid*, $C_{10}H_6N_2SO_3$, prepared by the action of nitrogen trioxide on the anhydrous acid suspended in absolute alcohol, is a powder. When aqueous alcohol is used, an intensely violet dye of the formula

$$SO_3H·C_{10}H_6·N_2·C_{10}H_5(NH_2)·SO_3H + 2\tfrac{1}{2}H_2O$$

is obtained; this is soluble in water and becomes brown when treated with alkali. The *sulphonamide*, $NH_2·C_{10}H_6·SO_2·NH_2$, is prepared by boiling the nitrosulphonamide dissolved in glacial acetic acid with hydriodic acid; it crystallises in slender, yellowish needles, and melts at 181°. The *hydrochloride*, $NH_2·SO_2·C_{10}H_6·NH_2,HCl + H_2O$, forms slender needles; the hydriodide forms lustrous, yellowish needles soluble in water and alcohol; the *acetyl-derivative*,

$$NHAc·C_{10}H_6·SO_2·NH_2,$$

crystallises from boiling water in slender, white needles melting at 213°. The *carbamide*, $NH_2·CO·NH·C_{10}H_6·SO_2·NH·CO·NH_2$, is prepared by the action of potassium cyanate on the sulphate of the amide; it is an amorphous powder, melts at 225°, and dissolves very sparingly in water, alcohol, glacial acetic acid, &c., readily in aqueous soda.

Amidothionaphthol, $2C_{10}H_6·NH_2·SH + EtOH$, is obtained by heating the amide with hydriodic acid and phosphorus; the thin, lustrous plates of amidothionaphthol hydriodide are treated with ammonia and the oil dissolved in alcohol. It separates in sparingly soluble needles melting at 127°. N. H. M.

Constitution of Isomeric Naphthalene-derivatives. Part I. αα-Disubstituted Compounds. By H. ERDMANN (*Annalen*, **247**, 306—366).—The naphthylaminesulphonic acids yield α- or β-naphthylamine on the elimination of the sulphonic groups, and α- or β-naphthalenesulphonic acids on the elimination of the amide-groups. The disubstitution products of naphthalene are divided into four classes for the purpose of classification: namely, 3-αα-naphthylaminesulphonic acids; 3-ββ-; 4-α-β-; and 4-β-α-naphthylaminesulphonic acids.

In the preparation of αα-nitronaphthalenesulphonic acid [1 : 4′] from α-nitronaphthalene by Cleve's process, the more soluble isomeride [1 : 1′] is obtained as a bye-product.

The properties of [1 : 4] αα-naphthylaminesulphonic acid have been described by Piria (as *naphthionic acid*) (*Annalen*, **78**, 31), and by Witt (Abstr., 1886, 364). The author has previously shown (Abstr., 1888, 290) that the acid which Witt (Abstr., 1886, 554) obtained by the action of fuming sulphuric acid on α-naphthylamine-hydrochloride is the [1 : 4′] naphthylaminesulphonic acid. The [1 : 1′] acid is obtained from Schöllkopf's patent naphthylaminesulphonic acid S, which consists chiefly of the sparingly soluble sodium salt of this acid. The pure acid forms white needles. 238 parts of boiling water or 4800 parts of water at 21° dissolve 1 part by weight of the acid. The cold, aqueous solution produces a violet coloration in solutions of auric or ferric chloride. The sodium salt crystallises in compact tables or plates, and the potassium salt crystallises in plates. One litre of water dissolves 26·7 grams of the sodium salt at 100° and 11·3 at 24°; also 149 grams of the potassium salt at 100° and 35·6 at 19°. The lead salt crystallises in plates and the silver salt in feathery crystals. Benzaldehyde unites with the sodium salts of the αα-naphthylaminesulphonic acids, forming sodium benzalnaphthylaminesulphonate. The sodium salt of the [1 : 4] acid crystallises with 1 mol. H_2O in golden plates, the [1 : 4′] salt is white, contains 2 mols. H_2O, and is distinguished from the preceding salt by its ready solubility in water. An analogous [1 : 1′] compound is not formed.

Dilute sulphuric acid at 180° converts each of the three isomeric αα-naphthylaminesulphonic acids into α-naphthylamine. In preparing the diazo-compounds, the sulphonic acids must be in a finely divided state, the solutions must be cold and strongly acid, and during the operation the nitrous acid must be present in slight excess. The [1 : 4] diazonaphthalenesulphonic acid is yellow, the [1 : 4′] is grey, and the [1 : 1′] forms greenish-yellow prisms. The latter compound is distinguished from the others by melting without detonation. Reduction with tin and hydrochloric acid converts the diazo-compounds into αα-naphthylhydrazinesulphonic acids. The [1 : 4] acid forms white needles, soluble in hot water, but more freely soluble in hot hydrochloric acid. The sodium salt, $C_{10}H_6(N_2H_3)\cdot SO_3Na + 4H_2O$, crystallises in plates. The [1 : 4′] acid forms plates or groups of needles. Its sodium salt crystallises with 3½ mols. H_2O. The [1 : 1′] acid is deposited in slender plates. The potassium and sodium salts are anhydrous. The latter is characterised by its sparing solubility in water. The ammonium salt is freely soluble.

The three isomeric acids yield α-naphthalenesulphonic acid on boiling with an acid solution of cupric chloride.

The 1 : 4- and 1 : 4′-*naphtholsulphonic acids* are prepared by dissolving the corresponding diazonaphthalenesulphonic acids in boiling sulphuric acid diluted with four times its weight of water. The former has been described by Neville and Winther (Trans., 1880, 632). The latter is a deliquescent, crystalline substance, and melts between 110° and 120°. Under similar conditions, [1 : 1′] diazonaphthalenesulphonic acid yields an anhydride, *naphthosultone*,  $C_{10}H_6<\begin{smallmatrix}-O-\\SO_2\end{smallmatrix}>$. The sultones bear the same relation to γ-hydroxysulphonic acids that the lactones do to γ-hydroxycarboxylic acids. Naphthosultone crystallises in prisms, melts at 154° and boils above 360° with partial decomposition. It is soluble in chloroform and in warm benzene. At the ordinary temperature, alkalis do not act on the sultone, but at 130° alcoholic ammonia converts it into the ammonium salt of [1 : 1′] naphtholsulphonic acid, $OH{\cdot}C_{10}H_6{\cdot}SO_3NH_4$. The ammonium salt is freely soluble in water, and the solution gives a precipitate with lead salts, and also on boiling with an excess of sodium hydroxide, the basic sodium salt $C_{10}H_6SO_4Na_2 + 1\frac{1}{2}H_2O$. The free acid crystallises with 1 mol. H_2O, and produces with ferric chloride a deep green coloration changing to red.

The conversion of [1 : 4]- and [1 : 4′]-naphthylaminesulphonic acids into the corresponding dichloronaphthalenes has been previously described by the author (Abstr., 1888, 290), but the [1 : 1′]-diazosulphonic acid, on treatment with phosphorus pentachloride, yields *chloronaphthosultone*, $C_{10}H_5ClSO_3$. This compound forms yellow needles, and melts at 174—175°. It is not attacked by alkaline solutions at the ordinary temperature.

[1 : 4]-Dihydroxynaphthalene is identical with α-naphthahydroquinol; [1 : 4′]-dihydroxynaphthalene has been described by Bernthsen and Semper (Abstr., 1887, 674). The [1 : 1′]-dihydroxynaphthalene is obtained from naphthosultone by fusion with potassium hydroxide. It crystallises in needles or plates and melts at 137—138°, and dissolves freely in ether, benzene, and toluene. The *diacetate*, $C_{10}H_6(OAc)_2$, melts at 147—148°.

Two αα-dinitronaphthalenes are known; [1 : 4′] melts at 218° and [1 : 1′] at 170°.

Aguiar (*Ber.*, 7, 309) has described the preparation and properties of [1 : 4′]- and [1 : 1′]-diamidonaphthalenes from the corresponding dinitronaphthalenes. W. C. W.

The Dextrorotatory Terebenthene. By L. Pesci (*Chem. Centr.*, 1888, 1097—1098, from *Ann. Chim. Farm.*, 7, 353—358).—The terebenthene was obtained from American turpentine by fractionating in a vacuum, and was found to be the principal product; sp. gr. = 0·8641, boiling point 156—157°. Specific rotation $[\alpha]_D$ = + 13·945°. The American turpentine contains also lævorotatory substances.

Nitroterebenthene was prepared by treating the terebenthene with potassium nitrite and dilute sulphuric acid, the green oily product was shaken with ammonia, washed with dilute hydrochloric acid, and distilled twice in a current of steam. It is a yellow liquid, having the odour of peppermint oil. Sp. gr., 1·0499; specific rotation, $[\alpha]_D = +2·984$. By reduction with zinc and acetic acid, the same amidoterebenthene, $C_{10}H_{15}NH_2$, was obtained as the author prepared from the lævorotatory terebenthene. The hydrochlorides of both show the same specific rotation: $[\alpha]_D = -48·508°$ and $-48·629°$.

The *hydrochloride of lævoterebenthene* possesses the specific rotation $[\alpha]_D = -30·687°$, melting point 125°. *Lævoterebenthene hydrobromide:* specific rotation $[\alpha]_D = -27·802°$ and melting point 87°.

Dextroterebenthene hydrochloride and *hydrobromide* are optically inactive. Their melting points are 125° and 91° respectively. These facts go to prove the non-identity of the two terebenthenes.

J. W. L.

Hydroxycamphoronic Acids. By J. Kachler and F. V. Spitzer (*Monatsh.*, **9**, 708—726).—The two isomeric hydroxycamphoronic acids, formed by the action of aqua regia on camphoronic acid, correspond in their crystalline form with the two modifications which Kachler obtained by heating camphoronic acid with bromine and subsequent treatment with water. Further investigations of the compounds obtained by the action of bromine show that they are not chemically identical as previously suggested. In order to isolate the isomerides, the mixture of acids dissolved in a small quantity of warm water is treated with aqueous baryta until the solution gives only a feebly acid reaction. Ammonia is added until the solution is distinctly alkaline, and the mixture shaken for some time, when bibasic barium α-hydroxycamphoronate separates out, the β-salt remaining in solution.

α-Hydroxycamphoronic acid, $C_9H_{14}O_7$, crystallises in monoclinic plates or prisms. It is only slightly soluble in ether, dissolves readily in cold water and alcohol, softens at 100°, and melts at 216·5° (corr.). On long exposure to air, or more quickly over sulphuric acid, the crystals lose water and are converted into the anhydride $C_9H_{12}O_6$, which, on heating, loses more water, forming the anhydride $C_9H_{10}O_5$. This is a crystalline powder, which dissolves readily in alcohol and water, and melts at 135—137°. Both anhydrides are reconverted into the acid by boiling with water. The salts of the α-acid are mostly easily soluble in water. The acid potassium salt, $C_9H_{13}KO_7$, crystallises in stout needles, the dipotassium salt, $C_9H_{12}K_2O_7 + \frac{1}{2}H_2O$, in scales; when heated at 100°, the latter yields the compound $C_9H_{10}K_2O_6$. The calcium salt, $C_9H_{12}CaO_7 + 4H_2O$, crystallises in bundles of needles; the barium salt, $C_9H_{12}BaO_7$, in thin plates only, slightly soluble in water; the silver salt, $C_9H_{12}Ag_2O_7 + H_2O$, forms minute crystals; the copper and lead salts are anhydrous. All the above-mentioned salts in the anhydrous condition lose the elements of a molecule of water when heated. The ethyl compound, $C_9H_{11}EtO_6$, crystallises in rhombic plates melting at 158° (corr.). If heated, it gives the anhydride of α-hydroxycamphoronic acid and alcohol, and on passing ammonia through the ethereal solution, the salt $C_6H_{10}EtO_6·NH_4$, crystallising in needles, melting at 168—170°, is formed.

β-Hydroxycamphoronic acid is not so soluble as its isomeride. When air-dried, it has the formula $C_9H_{14}O_7$, melts at 250·9° (corr.), but loses water on heating, forming an anhydride, and furnishes mono-, di-, and tri-basic salts, of which the tribasic salts of lead and barium are insoluble. The potassium salt, $C_9H_{12}K_2O_7 + \frac{1}{2}H_2O$, is hygroscopic. The barium salt, $C_9H_{12}BaO_7 + 4H_2O$, crystallises in needles. The ethyl-derivative, $C_6H_{10}EtO_6$, forms needles melting at 158·5—159·5° (corr.), and resembles its isomeride, forming with ammonia the compound $C_9H_{10}EtO_6{\cdot}NH_4$, melting at 165°.

The authors find that when camphoronic acid is heated with bromine no bromo-derivative is produced, but the above-mentioned anhydrides which, on treatment with water, yield a mixture of α- and β-hydroxycamphoronic acid. G. T. M.

Syringin. By G. Körner (*Chem. Centr.*, 1888, 1098—1099, from *Rend. R. Inst. Lombardo* [2], **21**, 563—572).—The author finds that syringin, formerly considered as a glucoside, is hydroxymethylconiferin, $C_{17}H_{24}O_7$. He prepares it according to Kromayer's method (*Die Bitterstoffe*, 1861, 56). It crystallises from water in long, slender, white needles, which are only sparingly soluble in cold water, but readily in hot. It contains water of crystallisation, which is given off at 100°. Melting point 191—192°. It does not form insoluble compounds with solutions of metallic salts; it reacts with mineral acids similarly to coniferin. By the action of emulsin, syringin is split up into dextrose and *syringenin*, $OH{\cdot}C_6H_2(OMe_3)_2{\cdot}C_3H_4{\cdot}OH$ (*hydroxymethylconiferyl alcohol*); the latter resembles coniferyl alcohol.

By oxidising syringin with potassium permanganate, *glucosyringic acid*, $C_{15}H_{20}O_{10}$, is formed, crystallising from water in slender, colourless needles with 2 mols. H_2O. It is sparingly soluble in cold water, readily in hot. Melting point about 208°. When crystallised from alcohol, it melts at 214°. Thus prepared it contains no combined water. The lead salt is but little soluble; the salts of potassium and barium crystallise in needles. By heating glucosyringic acid with dilute sulphuric acid, it splits up into dextrose and *syringic acid*, $C_9H_{10}O_5$. This decomposition is also effected by the action of emulsin at 30°.

By the oxidation of syringin with cold, very dilute chromic acid, *glucosyringinaldehyde* is formed; it is soluble in water, but only sparingly in alcohol, and insoluble in ether. It combines with phenylhydrazine, the compound crystallising in needles, and melting at 156°.

The aldoxime is decomposed by emulsin or dilute sulphuric acid into glucose and *syringinaldehyde*, $C_9H_{10}O_4$, which has the smell of vanilla. It reacts readily with phenylhydrazine and hydrogen sulphites, forming soluble compounds. Syringic acid is sparingly soluble in cold water, more readily in hot water, soluble in alcohol. It is monobasic and melts at 202°. The barium salt crystallises with 3 mols. H_2O. The *methyl* salt, $C_9H_9O_5Me + H_2O$, is soluble in hot water, and melts at 83·5°. Syringic acid, when heated with hydrogen iodide a little above 100°, decomposes with liberation of methyl iodide. With sodium methyl oxide and methyl iodide it forms *methyl methylsyringate*, $C_{11}H_{14}O_5$, melting at 82·5°. *Methylsyringic acid*, $C_{10}H_{12}O_5$, melts at 168°, and is somewhat soluble in hot water. Distillation with calcium hydroxide produces trimethylpyrogallol. By heating syringic acid above 225°, dimethylpyrogallol, $OH{\cdot}C_6H_3(OMe)_2$, is formed; with ferric chloride it gives at first a blood-red coloration, which changes into copper-red needles. Cedriret was observed in the solution. Methylsyringic acid was identified as trimethylgallic acid.

J. W. L.

Arganin. By S. Cotton (*J. Pharm.* [5], **18**, 298—302).—This bitter principle is extracted from the kernel of the nut borne by the argan tree, of the order *Sapotaceæ*, growing in Morocco and Madagascar. The almond itself is bitter but contains over 66 per cent. of a sweet, fixed oil, which congeals at 0°, and has a density of 0·914. The bitter principle, insoluble in oil, ether, chloroform, carbon bisulphide, and light petroleum, is easily soluble in water and 90° alcohol; and somewhat less soluble in absolute alcohol. It is extracted by treating the crushed kernels with ether or some other solvent to remove the oil, then extracting with 99° alcohol with the aid of heat. The alcoholic solution is then treated fractionally with ether at intervals, so as to obtain the arganin in crystals. After some days, the liquid is decanted and the crystals are dissolved in boiling absolute alcohol, from which they recrystallise on cooling. Very short, brilliant prisms are thus obtained, which become gummy on the filter from exposure to the moisture of the air.

J. T.

Homopterocarpin and Pterocarpin from Red Sandal Wood. By P. Cazeneuve and L. Hugounenq (*Compt. rend.*, **107**, 737—740).—When homopterocarpin is heated just to the point at which decomposition begins, it yields creosote and a small quantity of catechol, and when distilled with zinc powder, it yields a small quantity of a volatile oil with an odour of coumarin, together with benzene, toluene, methane, ethylene, and carbonic oxide. The principal product of the action of hydrochloric acid on homopterocarpin (Abstr., 1887, 972) is a black, uncrystallisable resin, which dissolves in alkalis and forms fluorescent solutions; the hydrochloric acid retains in solution a small quantity of an amorphous, red colouring matter, which dissolves in alkalis with fluorescence and probably belongs to the fluoresceïn-group. Hydriodic acid produces similar results. When heated in sealed tubes with 10 per cent. sulphuric acid, homopterocarpin undergoes an isomeric change, and is converted into an opaline, yellowish, non-crystallisable resin, similar in appearance to amber, whilst the sulphuric acid remains unaltered. Homopterocarpin is not affected by aqueous potash at 200°, but is attacked by fused potash at 250—300°, and yields a small quantity of a volatile oil with an odour of coumarin, and phloroglucinol, but no acid. Ordinary nitric acid attacks homopterocarpin in the cold, with formation of an amorphous, green, unstable nitroso-derivative, which contains 3·5 per cent. of nitrogen. Fuming nitric acid acts with considerable energy, and on the addition of water an insoluble red resin separates. The aqueous solution when evaporated yields a crystalline product, from which cold water extracts oxalic acid, whilst hot water dissolves a substance which crystallises in yellow needles melting at 162°, and has all the properties of trinitro-orcinol. It yields a barium salt $C_7H_2(NO_2)_3O_2Ba + 3H_2O$, which crystallises in yellow needles, and explodes above 150°. The product of the action of nitric acid also contains a non-crystallisable isomeric trinitro-orcinol. If homopterocarpin is treated with excess of bromine, the compound $C_{24}H_{18}Br_6O_6$ is obtained; it dissolves in benzene and separates in crystalline plates melting at 270°, when the benzene is mixed with an equal volume of ether. The interaction of equal molecular proportions of homopterocarpin and bromine in solution in chloroform yields a mono-derivative, $C_{24}H_{23}BrO_6$, which separates from boiling alcohol in white crystals. Phenylhydrazine and acetic anhydride have no action on homopterocarpin. From these results, it follows that the formula originally ascribed to homopterocarpin must be doubled, and it would seem to be a condensed poly-orcinol, but its constitution is not yet definitely determined.

Pterocarpin yields similar results, but the action of nitric acid is more energetic. It yields a crystalline monobromo-derivative, $C_{20}H_{15}BrO_6$, and hence its true formula is $C_{20}H_{16}O_6$. Pterocarpin is in all probability a lower homologue of homopterocarpin.

C. H. B.

Dipicolylmethane. By A. LADENBURG (*Ber.*, **21**, 3099—3104).—*Dipicolylmethane*, $CH_2(CH{\cdot}C_5NH_4)_2$, is obtained by heating a mixture of picoline (from the mercury salt) with methylal in molecular proportion, in presence of zinc chloride for 10 hours, at 280—290°. The product is treated with dilute hydrochloric acid, heated on a water-bath for some time, made alkaline, and distilled. The residue is extracted repeatedly with ether, and the base extracted from the ethereal solution with dilute hydrochloric acid. The solution is treated with mercuric chloride as long as any resin is precipitated, filtered, freed from mercury by means of hydrogen sulphide, made alkaline with soda, and extracted with ether. The base is distilled under reduced pressure. It is a light-yellow oil, insoluble in water, readily soluble in alcohol and ether, and boils at 319—323° under 760 mm. pressure. Sp. gr. = 1·0281 at 0°. The *hydrochloride* forms deliquescent needles; the *platinochloride*, $C_{13}H_{14}N_2,H_2PtCl_6$, crystallises from water in sparingly soluble, lustrous plates which melt at 215° with decomposition; the *aurochloride*, $(C_{13}H_{14}N_2)_3,H_4Au_3Cl_{13} + 1\frac{1}{2}H_2O$, separates as an oil which solidifies to small needles; the *mercurochloride*,

$$C_{13}H_{14}N_2,H_2Hg_4Cl_{10},$$

crystallises like ammonium chloride, or in large plates, and melts at 161°; the *picrate*, *cadmioiodide*, *periodide*, and *bismuthoiodide* were prepared.

Dipipecolinemethane, $C_{13}H_{26}N_2$, prepared by reducing the above compound with sodium and alcohol, forms a white, crystalline mass, melts at 52—54°, and boils at 195° under 26 mm. pressure. It dissolves readily in benzene and ether, very readily in alcohol, and is rather sparingly soluble in water. It is a strong base, but yields mostly oily salts. The *hydrochloride*, $C_{13}H_{26}N_2,2HCl$, is crystalline. *Tetramethyldipipecolyl methiodide*, $C_{13}H_{24}Me_2N_2,2MeI$, forms white crystals, very readily soluble in water; the *aurochloride*, $C_{13}H_{24}Me_2N_2,H_2Au_2Cl_8$, crystallises in needles melting at 170—171°, with decomposition. The constitution of the base is probably $CH_2(CH_2{\cdot}C_5NMeH_9)_2$.

N. H. M.

The Two Bidesyls. By J. C. GARRET (*Ber.*, 21, 3107—3108).—Both bidesyls (Knoevenagel, Abstr., 1888, 706) yield *tetraphenylpyrroline*, $C_{28}H_{21}N$, when heated with alcoholic ammonia at 150°. This crystallises in large needles, melts at 211—212°, and is almost insoluble in alcohol. On one occasion, the preparation from isobidesyl melted at 234—235°, but was otherwise identical with the other preparations.

N. H. M.

Methylstilbazole and its Reduction-products. By F. BACHÉR (*Ber.*, 21, 3071—3082).—*Methylstilbazole*, $C_{14}H_{13}N$, is formed when α-γ-lutidine is heated at 215° with benzaldehyde (1 mol.) and anhydrous zinc chloride. The product is mixed with alcohol, acidified with hydrochloric acid, distilled with steam to free it from benzaldehyde and hydrocarbons, and the residual oily liquid separated. After adding excess of soda, the mixture is distilled with superheated steam; the unchanged lutidine which passes over first is collected separately, and the new base, which is very slightly volatile, is extracted from the latter portions of the distillate with ether, the solution dried over potash, evaporated, and the base distilled. The yield is about 15·4 per cent. of the theoretical quantity. It is a yellow, viscid, strongly refractive oil, boils at 321—326° with slight decomposition, and is readily soluble in alcohol, ether, chloroform, and carbon bisulphide, but insoluble in water.

The *hydrochloride* and the *hydrobromide* cannot be obtained in crystals, but the *hydriodide*, prepared by dissolving the base in fuming hydriodic acid, crystallises from hot alcohol in microscopic, yellow needles melting at 210—211°. The *periodide* is crystalline, and readily soluble in alcohol, but insoluble in water. The *picrate*, $C_{14}H_{13}N,C_6H_3N_3O_7$, crystallises from hot alcoholic hydrochloric acid in microscopic, yellow needles, melts at 192—193° with previous softening, and is very sparingly soluble in hot dilute hydrochloric acid. The *mercurochloride*, $C_{14}H_{13}N,HHgCl_3$, crystallises in needles, has no well-defined melting point, and is soluble in dilute hydrochloric acid. The *platinochloride*, $C_{14}H_{13}N,H_2PtCl_6$, crystallises in small, yellow needles with 1 mol. H_2O, melts at 183°, decomposes at 188°, and is soluble in hot dilute alcohol, but very sparingly soluble in hot hydrochloric acid. The *aurochloride*, $C_{14}H_{13}N,HAuCl_4$, prepared by precipitating a boiling solution of the hydrochloride, crystallises in golden needles, melts at 141—142°, and is sparingly soluble in boiling water. Potassium bismuth iodide, potassium cadmium iodide, and stannous chloride produce precipitates in a hydrochloric acid solution of the base. The *bromide*, $C_{14}H_{13}Br_2N$, prepared by treating the base with bromine (1 mol.) in carbon bisulphide solution, separates from hot alcohol in small, nodular crystals, and melts at 139—140°.

Dihydromethylstilbazole, $C_{13}H_{15}N$, is prepared by heating methylstilbazole (1 part) with fuming hydriodic acid (10 parts) at 160°, treating the resulting periodide with sulphurous anhydride, decomposing the iodide with soda, and distilling the base with steam. It is a colourless oil boiling at 290—295°. The *picrate*, $C_{14}H_{15}N,C_6H_3N_3O_7$, crystallises in small, citron-yellow needles, melts at 154—156°, and is readily soluble in hot alcohol, but only sparingly in ether. The *platinochloride*, $C_{14}H_{15}N,H_2PtCl_6$, is crystalline, melts at 168° with decomposition, and is very sparingly soluble in water, but more readily in dilute alcohol. The *mercurochloride*, $C_{14}H_{15}N,HHgCl_3 + H_2O$, crystallises from hot, dilute hydrochloric acid, in which it is readily soluble, in large needles, and melts at 93—95°. The remaining salts cannot be obtained in a crystalline condition.

Methylstilbazoline, $C_{14}H_{21}N$, is prepared by reducing a boiling alcoholic solution of methylstilbazole with sodium and distilling the product with steam; it is a colourless oil, boils at 286—291°, and becomes yellow on keeping. It is readily soluble in alcohol and ether, but sparingly in water, to which it imparts an alkaline reaction. It yields an oily nitrosamine, and all the salts examined were also oily compounds.

Methylpyridinecarboxylic acid, $C_5NH_3Me{\cdot}COOH$, is obtained in small quantity when α-γ-lutidine is oxidised with the calculated quantity of a 1½ per cent. solution of potassium permanganate, but the principal product is lutidinic acid. Methylpyridinecarboxylic acid crystallises from hot alcohol, in which it is only moderately soluble, in small plates, decomposes at about 260° and is very readily soluble in water. It gives no reaction with ferrous salts, and yields picoline when heated with lime.

When α-γ-lutidine is heated at about 225° with benzaldehyde (2 mols.) and anhydrous zinc chloride, an oily, seemingly neutral compound is obtained. F. S. K.

β-Ethyl-α-stilbazole and its Derivatives. By G. PLATH (*Ber.*, **21**, 3086—3099).—*β-Ethyl-α-stilbazole*, $C_5NH_3Et{\cdot}CH{:}CHPh$ [= 3 : 6], is formed when collidine (10 grams), prepared from paraldehyde and aldehyde-ammonia (compare Dürkopf, Abstr., 1887, 499), is heated at 220—222° with benzaldehyde (9 grams) and zinc chloride. The product is acidified and distilled with superheated steam to free it from benzaldehyde and hydrocarbons. Excess of alkali is then added, the unchanged collidine distilled with steam, and, as soon as the distillate commences to become turbid, the steam is superheated, and the distillate containing the new base, which is only very slightly volatile, is collected separately. The yield is about 37 per cent. of the theoretical quantity. It crystallises from dilute alcohol in colourless plates, melts at 58·5°, boils at 344°, and is readily soluble in alcohol, ether, benzene, acetone, and chloroform, but insoluble in water. The *hydrochloride*, $C_{15}H_{15}N,HCl$, separates from hot benzene in an oily condition, but solidifies on cooling; it crystallises in needles and melts at 193°. The *platinochloride*, $(C_{15}H_{15}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in needles, melts at 188° with decomposition, and is soluble in dilute hydrochloric acid, but insoluble in cold water. The *aurochloride*, $C_{15}H_{15}N,HAuCl_4$, crystallises in long needles, melts at 168°, and is insoluble in water. The *stannochloride*, $C_{15}H_{15}N,HSnCl_3 + 3H_2O$, crystallises from hot dilute hydrochloric acid in white needles, melting at 245·5—246°. The *mecrurochloride*, $C_{15}H_{15}N,HAgCl_3$, crystallises from hot dilute hydrochloric acid in long needles melting at 196°. The *picrate*, $C_{15}H_{15}N,C_6H_3N_3O_7$, crystallises from alcohol or hot water in long, yellow needles melting at 203°. An aqueous solution of the hydrochloride gives precipitates with ammonium molybdate, potassium dichromate, and potassium cadmium iodide. The *periodide* is crystalline but unstable. The *bromide*, $C_{15}H_{15}Br_2N$, prepared by treating the base with bromine (1 mol.) in carbon bisulphide solution, crystallises from alcohol in small needles, melts at 127·5—128°, and is very readily soluble in chloroform, carbon bisulphide, benzene, alcohol, and ether, but insoluble in water.

Dihydroethylstilbazole, $C_5NH_3Et\cdot CH_2\cdot CH_2Ph$ [= 3 : 6], is obtained when ethylstilbazole is heated at 160—165° with concentrated hydriodic acid. The product is treated with sulphurous anhydride, the resulting iodide dissolved in water, and the solution shaken with ether; excess of soda is then added, the base extracted with ether and distilled. It is a colourless oil, boils at 316·33° (corr.), and is readily soluble in alcohol and ether, but insoluble in water. The *aurochloride*, $C_{15}H_{17}N,HAuCl_4 + H_2O$, and the *hydrochloride*, are with difficulty obtained in a crystalline state. The *platinochloride*, $(C_{15}H_{17}N)_2,H_2PtCl_6$, crystallises from dilute hydrochloric acid in long needles melting at 168°. The *mercurochloride*, $C_{15}H_{17}N,HHgCl_3$, crystallises from very dilute hydrochloric acid in long needles, and melts at 136·5°. The *picrate* is sparingly soluble in water, from which it crystallises in yellow needles.

Octohydroethylstilbazole, $C_5NH_7Et\cdot CH_2\cdot CH_2Ph$, prepared by treating a boiling alcoholic solution of ethylstilbazole with sodium and purifying the product by means of the nitroso-derivative, is a colourless oil boiling at 303° (uncorr.). It has a strong, piperidine-like odour, an alkaline reaction, and is volatile with steam. It is soluble in chloroform, benzene, ether, and alcohol, but only sparingly in water. No crystalline salts were obtained. F. S. K.

Paraxyloquinolinesulphonic Acids. By E. NÖLTING and J. FRÜHLING (*Ber.*, **21**, 3156—3158).—*Xyloquinolinesulphonic acid*, [$Me_2 : SO_3H$ = 1 : 4 : 2] (compare Nölting and Kohn, Abstr., 1886, 355), crystallises in prisms, and is very readily soluble in hot water and dilute acetic acid, but only sparingly in cold water. The *barium* salt, $(C_{11}NH_{10}\cdot SO_3)_2Ba + H_2O$, crystallises in needles, loses its water at 150°, and is readily soluble in hot water. The *potassium* salt crystallises with 1 mol. H_2O, and is readily soluble.

Xyloquinolinesulphonic acid, [$Me_2 : SO_3H$ = 1 : 4 : 3], can be prepared from paraxylidineparasulphonic acid by Skraup's reaction, or by heating paraxyloquinoline with fuming sulphuric acid for 36 hours. It resembles the preceding compound, but is more sparingly soluble. The *barium* salt crystallises in plates with 1 or 2 mols. H_2O. The *potassium* salt crystallises in anhydrous needles or plates.

Paraxyloquinoline is obtained when either of the above acids or any of their salts is distilled with ammonium chloride, but it is more easily prepared from paraxylidine. F. S. K.

Isoquinoline. By G. GOLDSCHMIEDT (*Monatsh.*, **9**, 675—684).—The author has previously shown (Abstr., 1888, 302) that papaverine and its compounds with methyl iodide and ethyl iodide yield imides of hemipinic acid when oxidised with permanganate. This property of forming imides on oxidation with permanganate appears to be common to all isoquinoline-derivatives, the base itself giving phthalimide.

Isoquinoline ethobromide, on oxidation, appears to give ethylphthalimide, but the quantity obtained was insufficient for analysis.

Isoquinoline benzyl chloride is formed on mixing its constituents in molecular proportion. It crystallises, although not easily, in prisms, dissolves readily in water and alcohol, but is only slightly soluble in ether and benzene. When oxidised with permanganate, it gives benzylphthalimide melting at 115—116°.

Isoquinoline phenacyl bromide is most conveniently prepared by mixing molecular proportions of its constituents dissolved in benzene. It crystallises from alcohol in prisms, which melt at 205° to a golden-red liquid, and furnishes a nitro-compound which in its toxicological action resembles the corresponding quinoline-derivative. On oxidation with permanganate, a nearly pure phenacylphthalimide, melting at 156—158°, was formed. G. T. M.

Creatinines. By G. S. JOHNSON (*Proc. Roy. Soc.*, **43**, 493—534).—Normal urine when boiled with picric acid in alkaline solution causes a reduction to picramate. About one-fourth of the cupric oxide reducing power of normal urine is due to uric acid, whilst the remaining three-fourths has been variously accounted for. The author finds that it is due to a creatinine which can be best precipitated by adding sodium acetate and mercuric chloride to normal urine. A flocculent precipitate is first produced, which is succeeded by one which is apparently crystalline, but which under the microscope is found to consist of globules. It has a constitution $4(C_4H_5HgN_3O,HCl),3HgCl_2 + 2H_2O$. The hydrochloride of the base, $C_4H_7N_3O,HCl$, is prepared by decomposing the mercury salt with hydrogen sulphide. It is soluble in water and alcohol. No precipitate is produced with mercuric chloride until sodium acetate has been added. With platinum chloride in alcoholic solution it gives an anhydrous salt, $(C_4H_7N_3O)_2,H_2PtCl_6$; in aqueous solution a salt, $(C_4H_7N_3O)_2,H_2PtCl_6 + 2H_2O$, is formed. The free base is obtained by treating the hydrochloride with lead hydroxide; it can be obtained in three forms, according to the temperature at which the solution is evaporated. If the crystals are dissolved in a small quantity of cold water and evaporated in a vacuum, efflorescent creatinine is obtained in square prisms, which acquire a porcelain-like appearance as the water of crystallisation evaporates. But if the evaporation is conducted at 60°, anhydrous crystals of tabular β-creatinine of urine are obtained, which when dissolved and again evaporated in the cold give efflorescent creatinine. Finally if effloresced creatinine is dissolved at 100°, tabular α-creatinine of urine is obtained, and this when dissolved and evaporated in the cold recrystallises unchanged; 2 mols of creatinine of urine are equivalent in reducing power to 1 mol. of glucose, whilst

3 mols. of flesh creatinine are required to effect the same amount of reduction. The efflorescent creatinine has the same solubility in water as the tabular α-salt. Urine creatinine differs from flesh creatinine in its power of reduction, in the composition of its platinochloride, and in its solubility in water and alcohol. Boiled with water, the creatinine is converted into urinary creatine, $C_4H_9N_3O + H_2O$. It can be converted by Liebig's process into a creatinine hydrochloride, which is identical with that obtained from flesh creatine by the same process. From this hydrochloride four different creatinines are obtained, which are not identical with the above creatinines directly prepared. Crystallographic measurements of the natural creatinines are given. The creatinines from urinary creatine have less reducing powers than the natural creatinines, but greater than that of creatinine from flesh creatine.

Measurements by Hartley of the absorption-spectra of creatinine from flesh creatine (Liebig's process), and of the new base from urine, are given. The spectra are similar, the bands being caused by condensation of numerous oxygen- and nitrogen-atoms, as in uric acid. The actinic absorption is greater for the urine creatinine than for creatinine from flesh. H. K. T.

Bases formed by the Action of Potash on Additive Products of Papaverine. By A. STRANSKY (*Monatsh.*, 9, 751—761; compare Claus and Ritzfeld, Abstr., 1886, 996).—On boiling papaverine ethobromide with aqueous potash for several hours, a brown, resinous substance is formed. It may be crystallised from water and alcohol, and forms prismatic plates, which have the formula $O(C_{20}H_{21}NO_4Et)_2$, and melt at 72°. From this oxide, the following compounds may be obtained:—The chloride, $C_{20}H_{21}NO_4EtCl$, which crystallises from alcohol in rhombic needles melting at 80°; the platinochloride, $(C_{20}H_{21}NO_4EtCl)_2,PtCl_4$; the picrate, crystallising in light yellow plates; and the chromate, $(C_{20}H_{21}NO_4Et)_2Cr_2O_7$, crystallising in yellow needles or plates and melting at 78°.

Papaverine benzyl chloride under the same conditions gives the oxide, $(C_{20}H_{21}NO_4C_7H_7)_2O$, which crystallises in needles melting at 165°. The chromate, $(C_{20}H_{21}NO_4C_7H_7)_2Cr_2O_7$, forms yellow plates, which melt with decomposition at 85°, and the picrate,

$$(C_{20}H_{21}NO_4C_7H_7)C_6H_2N_3O_7,$$

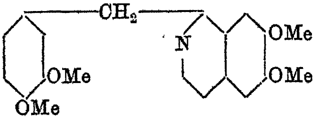
crystallises in plates melting at 185°.

Pavaverine methiodide (30 grams), potash (60 grams), and water (300 grams) when boiled together for 20 minutes give a product crystallising in greenish-yellow needles melting at 215°, efflorescing on exposure to air, and giving the hydroxide $C_{20}H_{21}NO_4Me{\cdot}OH$ when heated at 100°. The corresponding picrate crystallises in plates melting at 205°, and the chromate in small needles melting at 85°. G. T. M.

Papaverine-derivatives. By G. GOLDSCHMIEDT and C. OSTERSETZER (*Monatsh.*, 9, 762—777; compare Abstr., 1886, 83, 478; 1887, 163; 1888, 302, 1116, 1118).—The authors find that the two acids of the formula $C_{10}H_{10}O_6$, obtained by the oxidation of narcotine and papaverine respectively, are not identical, as was previously supposed. The acid from narcotine (hemipinic acid) forms crystals belonging to the monoclinic system, commences to fuse in open tubes at 160—161°, in closed tubes at 156—158°, and gives an orange-red precipitate with ferric chloride, but no precipitate with silver nitrate. The corresponding anhydride melts at 166—167°, the ethylimide at 96°. The acid from papaverine (*metahemipinic acid*) crystallises in the rhombic system, commences to fuse in open tubes at 174—175°, in closed tubes at 172—173°, gives a deep orange-red precipitate with ferric chloride, and a crystalline precipitate (needles) with silver nitrate. The corresponding *anhydride* melts at 175°, the *ethylimide* at 230°.

G. T. M.

Constitution of Papaverine. By G. GOLDSCHMIEDT (*Monatsh.*, 9, 778—781; compare preceding Abstracts).—Metahemipinic acid obtained by the oxidation of papaverine is dimethoxy-orthophthalic acid, $C_6H_2(OMe)_2(COOH)_2$ $[(OMe)_2 : (COOH)_2 = 1 : 2 : 4 : 5]$, and differs from hemipinic acid by giving protocatechuic acid $[COOH : (OH)_2 = 1 : 3 : 4]$ on fusion with potash. The constitution of papaverine must therefore be represented by the formula—



G. T. M.

Strychnine. By W. F. LOEBISCH and H. MALFATTI (*Monatsh.*, 9, 626—633; compare Abstr., 1887, 282).—Stoehr, on distilling strychnine with quicklime, obtained a mixture of scatole, and β-methylpyridine. The authors find that when the alkaloïd is distilled with soda-lime, in addition to the above-mentioned compounds, carbazole is formed, in quantity equal to 0·5 per cent. of the strychnine used.

G. T. M.

Relations between Atropine and Hyoscyamine. By A. LADENBURG (*Ber.*, 21, 3065—3070).—The author is of the opinion that atropine is an inactive base, and that it stands in the same relation to hyoscyamine as racemic acid to lævotartaric acid; moreover, that the supposed conversion of atropine into hyoscyamine, although possible, has not hitherto been accomplished, and that all observations to the contrary result from the employment of impure atropine. (Compare Will and Bredig, Abstr., 1888, 1316.) This view is supported by the following experiments:—20 grams of atropine aurochloride, prepared from "pure" atropine, was recrystallised 14 times, and yielded 1 gram of hyoscyamine aurochloride. Another sample of atropine aurochloride, prepared from the purest commercial atropine, which had been further purified by recrystallising many times, and then melted at 114°, was recrystallised 14 times. 1 gram of atropine aurochloride was obtained; it melted at about 140°, and an 18 per cent. solution of the free base prepared from this sample of salt was optically inactive.

Atropine cadmioiodide crystallises from alcohol in needles, and is almost insoluble in water. F. S. K.

Constitution of Berberine. By S. HOOGEWERFF and W. A. VAN DORP (*Rec. Trav. Chim.*, **7**, 206—209).—The view is expressed that berberine is a derivative of isoquinoline, and the authors are engaged on experiments with the object of proving this.

Commercial Preparation and Partial Synthesis of Cocaïne. By C. LIEBERMANN and F. GIESEL (*Ber.*, **21**, 3196—3202).—Most of the amorphous alkaloïds, obtained in the preparation of cocaïne, yield ecgonine when boiled for about an hour with hydrochloric acid (compare Liebermann, Abstr., 1888, 1210). The ecgonine can be isolated by evaporating the filtered solution to dryness, boiling the residue with a small quantity of alcohol to remove impurities, decomposing the salt with sodium carbonate, and recrystallising the base from alcohol.

Benzoylecgonine can be easily obtained by treating ecgonine with benzoic chloride or benzoic anhydride, but the yield is not good in either case. The following method, however, gives very good results:—Benzoic anhydride (a little more than 1 mol.) is gradually added to a hot, saturated, aqueous solution of ecgonine (1 mol.), and the mixture is heated on the water-bath for about an hour. The cold product is shaken with ether to remove benzoic acid and anhydride, and the residue is rubbed and washed with a small quantity of water on the filter-pump. The yield is about 80 per cent. of the ecgonine employed. Small quantities of benzoylecgonine can be obtained by evaporating the mother-liquor, and if the filtrate is again treated with benzoic anhydride, the greater part of the unchanged ecgonine is converted into the benzoyl-derivative. The whole of the excess of benzoic acid (anhydride) employed can be obtained from the ethereal extract.

Anhydroecgonine melts at 235°, is far less readily soluble in alcohol than ecgonine, and the crystals effloresce when kept in a partial vacuum. The hydrochloride is, however, far more readily soluble in alcohol than ecgonine hydrochloride.

Cocaïne was prepared by Einhorn's method from the benzoylecgonine obtained as described above, and the preparation was found to be identical with the natural alkaloïd in every respect.

It has been observed by Lossen that, when a solution of cocaïne hydrochloride is precipitated with ammonia, the precipitate is redissolved on adding more ammonia. The authors find that this phenomenon is simply due to the additional quantity of water, and not to any solvent action of the alkali. F. S. K.

Cocaïne. By A. EINHORN (*Ber.*, **21**, 3029—3044).—*Cocaylbenzoylhydroxyacetic acid*, $C_5NH_7Me\cdot CBz(OH)\cdot COOH$, is obtained when a 3 per cent. solution of potassium permanganate (230 c.c.) is gradually added, with constant stirring, to an aqueous (1 litre of water) solution of benzoylecgonine (5 grams) and sodium carbonate. The excess of potassium permanganate is reduced with alcohol in the cold, the filtered solution carefully acidified with hydrochloric acid and evaporated; the crystalline residue is extracted with and recrystallised from alcohol, and the resulting hydrochloride decomposed by boiling with ammonia. The acid which separates from the ammoniacal solution crystallises from alcohol or hot water in large prisms, melts at 230° with decomposition, and yields benzoic acid and cocaylhydroxyacetic acid (see below) when heated with concentrated hydrochloric acid. The *hydrochloride*, $C_{15}H_{17}NO_4,HCl$, crystallises from alcohol in plates with 2 mols. H_2O, and melts at 217—218°. The *aurochloride*, $C_{15}H_{17}NO_4,HAuCl_4$, crystallises from dilute hydrochloric acid in yellow needles, melting at 228° with decomposition. The *platinochloride*, $C_{15}H_{17}NO_4,H_2PtCl_6$, separates from water in yellowish-red, nodular crystals, containing water and melting at 233°. The *methyl* salt, prepared by passing hydrogen chloride into a methyl alcohol solution of the acid, was obtained in an oily condition; it is readily soluble in water, and the solution in hydrochloric acid yields an *aurochloride*, $C_{16}H_{19}NO_4,HAuCl_4$, which crystallises in long needles, melts at 181—182°, and is sparingly soluble in water. The *ethyl* salt, prepared in like manner, is also an oil; the *aurochloride*,

$$C_{17}H_{21}NO_4,HAuCl_4,$$

separates from acidified alcohol in yellow crystals, melts at 160·5°, and is very sparingly soluble in water.

Cocaylhydroxyacetic acid, $C_5NH_7Me{\cdot}CH(OH){\cdot}COOH$, is formed in the preparation of the benzoyl-derivative, when the oxidation product is evaporated in an acid solution. It can be obtained by gradually adding a 3 per cent. solution of potassium permanganate (900 c.c.) to an aqueous ($1\frac{1}{2}$ litres of water) solution of ecgonine hydrochloride (6 grams) and sodium carbonate. The *hydrochloride*, $C_8H_{13}NO_3,HCl + H_2O$, is isolated as described above. The free *base* is obtained in the pure state by decomposing the aurochloride with hydrogen sulphide, evaporating the filtrate, recrystallising the residue from a mixture of methyl alcohol and ether, and decomposing an aqueous solution of the resulting hydrochloride with silver oxide. It separates in long needles, or in thick prisms, when ether is added to an aqueous methyl or ethyl alcohol solution, and melts at 233°. The *aurochloride*, $C_8H_{13}NO_3,HAuCl_4$, crystallises from dilute hydrochloric acid in yellow needles containing 2 mols. H_2O, and melts at 211°. It crystallises from alcohol in short, thick, well-defined prisms containing alcohol.

Anhydroecgonine can be prepared by heating cocaïne for four hours at 140° with glacial acetic acid saturated with hydrochloric acid. When anhydroecgonine is oxidised with dilute potassium permanganate, as described above, small quantities of ecgonine or cocaylhydroxyacetic acid are formed according to the conditions of the experiment. A hydrocarbon, ammonium chloride, methyl chloride, very small quantities of a secondary base, and resinous products are formed when anhydroecgonine hydrochloride is heated at 230° for a long time with glacial acetic acid saturated at 0° with hydrogen chloride. When anhydroecgonine is heated with water at 150°, it is partially decomposed into an acid and methylamine, but all attempts to prepare a simple pyridine-derivative from the base were unsuccessful.

Cocaïne methiodide, $C_{17}H_{21}NO_4,MeI$, prepared by heating cocaïne (1 mol.) with methyl iodide (1 mol.) at 100°, crystallises from absolute alcohol in shining plates, melts at 164°, and is sparingly soluble in alcohol.

Cocaïne methochloride, $C_{17}H_{21}NO_4,MeCl$, prepared by treating the preceding compound with silver chloride, crystallises from a mixture of alcohol and ether in small needles or plates, melts at 152·5°, and is very readily soluble in water.

Methylanhydroecgonine methiodide, $C_{10}H_{15}NO_2,MeI$, is formed, together with benzoic acid, when an aqueous solution of cocaïne methiodide is heated at 100°. It crystallises from alcohol in slender, yellowish needles, or in well-defined prisms, and melts at 195—196°.

When cocaïne methiodide is heated at 140° with glacial acetic acid, previously saturated with hydrogen chloride, benzoic acid and a compound containing both iodine and chlorine are produced. When the last-named substance is treated with silver oxide, a crystalline, hygroscopic base is obtained.

Anhydroecgonine methiodide, $C_{10}H_{16}NO_2I$, is formed when an aqueous solution of the base just described is treated with hydriodic acid. It crystallises from alcohol or water in long prisms, containing 1 mol. H_2O, and melts at 207—208°. The constitution of cocaïne is probably

$$CH{<}\begin{matrix}CH_2\cdot CH_2\\ CH\cdot NMe\end{matrix}{>}CH\cdot CBz(OH)\cdot CH_2\cdot COOMe.$$

F. S. K.

An Acid from Cod-liver Oil. By A. GAUTIER and L. MOURGUES (*Compt. rend.*, **107**, 740—743).—Cod-liver oil contains an acid in the form of an unstable compound resembling the lecithins, which decomposes in contact with acids or alkalis, and yields glycerol, phosphoric acid, and the new complex acid. Lecithins themselves are present in the oil, and add to its value by presenting phosphorus in a readily assimilable form.

The oil is systematically extracted with alcohol of 35 per cent. containing 3 per cent. of hydrochloric acid, and the solution is saturated with potassium carbonate and distilled in a vacuum at 45°. The residue is acidified, heated for a moment at 100°, and extracted with alcohol at 85°. The latter dissolves the acid, which separates as a viscid, colourless substance on cooling or on adding water. The crude product is dissolved in potash, neutralised with nitric acid, and lead acetate added so long as the precipitate is not discoloured. The lead precipitate is washed with water, decomposed by hydrogen sulphide, and the solution filtered whilst hot. The lead sulphide is washed with hot alcohol, and the washings and the original filtrate are evaporated in a vacuum. The new acid, *morrhuic acid*, crystallises in soft, yellowish, square plates of the composition $C_9H_{13}NO_3$, which differs from tyrosine by H_2 only.

Morrhuic acid has a disagreeable odour recalling that of kelp; when freshly precipitated it is oily and viscid, but it gradually solidifies. It dissolves in hot water, but separates on cooling, and is soluble in alcohol, but only slightly soluble in ether. It reddens litmus, decomposes carbonates, and forms crystallisable salts with the alkalis; its solutions give precipitates with lead and silver, but not with copper salts. Morrhuic acid also combines with acids and forms a crystalline hydrochloride, which is decomposed by water, morrhuic acid separating in the form of an emulsion; the platinochloride is soluble and crystallises in very small prisms; the aurochloride forms an amorphous precipitate which readily alters when heated.

When distilled with lime, morrhuic acid yields a base which gives with methyl iodide and potash the reaction characteristic of the pyridines. When oxidised with potassium permanganate, it yields a monobasic pyridinecarboxylic acid, which crystallises in prisms and rhomboidal lamellæ, and forms a platinochloride and an aurochloride.

The silver salt of morrhuic acid contains 2 atoms of the metal, and hence it is bibasic. The fact that it gives no precipitate with copper acetate indicates that the carboxyl is not in direct union with the pyridine-ring, and it probably has the constitution

$$\mathrm{CH}\Big\langle\begin{matrix}\mathrm{CH\cdot C(OH)}\\ \mathrm{CH_2\cdot NH}\end{matrix}\Big\rangle\mathrm{C\cdot C_3H_6\cdot COOH}.$$

This formula explains the ready reduction of the silver salt even in the cold.

De Jongh's *gaduine* is probably identical with morrhuic acid.

C. H. B.

Action of Phosphorus Oxychloride on Cholic Acid. By R. CAMPANI (*Gazzetta*, **18**, 88—89).—The cholic acid employed was prepared from ox-bile by boiling it with dilute hydrochloric acid for 24 hours, and then isolating the acid in the usual way. The phosphorus oxychloride (12 grams) is added drop by drop to the cholic acid (5 grams) in fine powder; a powerful reaction takes place, and as soon as it has subsided, the product is thoroughly washed with boiling water, and allowed to dry at the ordinary temperature. It is a greenish-yellow powder, very sparingly soluble in alcohol, but easily in ether; this, on evaporation, leaves it as a brown, amorphous, vitreous residue. On analysis, it gave numbers corresponding with the formula $C_{24}H_{36}O_3$. It is insoluble in aqueous alkaline solutions, but on long boiling with alcoholic potash it dissolves and is reconverted into cholic acid, which is precipitated from the solution on adding hydrochloric acid. The compound, therefore, is the anhydride of cholic acid.

C. E. G.

Gelatinous State of Albuminoïd Substances. By V. MICHAILOFF (*J. Russ. Chem. Soc.*, 1887, **19**, 666—690; 1888, **20**, 35—72, 159—179, 274—360, 380—388).—After giving the history of this and similar subjects (colloïdal matters in general), the author shows the conditions under which white of egg from different sources exists in various solutions, precipitates, and gelatinous coagulates, and in coagulates obtained by heat, how these different modifications are formed and transformed, and describes at some length their properties (chemical and physical), especially those of Tarchanoff's "tata-albumin" and its behaviour towards solutions of different salts at different temperatures, as well as the results obtained on dialysis (see Abstr., 1887, 856). The mutual actions of different kinds of albuminoïd substances are also studied, and it is shown that albumins are acid, and globulins basic compounds. Gelatinisation of albumin in the first phase is due to hydration; in its subsequent phases to dehydration, which is more or less complete according to the conditions. B. B.

Physiological Chemistry.

Primary and Secondary Oxidation. By O. NASSE (*Pflüger's Archiv*, **41**, 378—389).—A distinction is drawn between direct oxidation (oxidation occurring at the body temperature in the blood and fluids of the body by neutral oxygen combining with some readily oxidisable matter), primary oxidation (such as occurs in the body chiefly; the complex molecules are first altered by some ferment action in order to render them readily oxidisable), and secondary oxidation (oxidation of products of metabolism which have been formed by other processes than oxidation). The influence of readily oxidisable substances, such as fat and phenol, given in the food, on secondary oxidation was investigated, the urine being examined for ethereal hydrogen sulphates and glycuronic acid; it was found that the burning of fat in the organism furthers secondary oxidation processes, as is shown by the rise in the amount of ethereal hydrogen sulphates and fall in the glycuronic acid on the days on which fat was given with the food. W. D. H.

The Influence of Light on Oxidation in Animals. By J. LOEB (*Pflüger's Archiv*, **42**, 393—407).—The comparison of plants with animals has suggested the question whether light influences the chemical processes in animals as, according to several experimenters, it does in those plants which contain chlorophyll. Moleschott (*Wien. med. Wochensch.*, 1885) found in frogs that more carbonic anhydride was produced in the light than in the dark. But here no observations were made as to whether the animals moved much or little during the experiments. In the light, animals are more stimulated to movement, and muscular activity alone might thus explain the increased production of carbonic anhydride. v. Platen (*Pflüger's Archiv*, **11**, 272) observed also an increase in gaseous metabolism, and found, moreover, that the illumination of the retina by light also produced, apparently reflexly through the central nervous system, a similar effect. Speck (*Arch. f. exp. Path. u. Pharmak.*, **12**), however, arrived at the conclusion that in the human subject, light of itself produces no increase in oxidation processes. On the local action of light on tissues removed from the body, but still retaining some vitality, the experiments recorded by Fabini and others are unsatisfactory and inconclusive, very little care having been taken to avoid putrefaction, and even if this had not occurred the tissues were dying, and not living healthily. Moreover, the influence of changing atmospheric temperature seems also to have been neglected.

In the present research, these sources of error were avoided by taking lepidopterous larvæ in the chrysalis stage when movements are practically absent. A number of these were weighed and placed in a closed glass vessel within a beaker of water, and exposed to diffused daylight. Others were exactly similarly treated, except that instead of water, a solution of nigrosine of the same temperature was used, so that they were in darkness. At the end of the experiment, they were again weighed; those which had lost most weight would be those which had undergone most active oxidation; but in case some individual peculiarities of the pupæ themselves might have produced these effects, a control experiment was performed by reversing the conditions; those which before were in the light were now put in the dark, and *vice versâ*.

From a number of experiments the conclusion was finally drawn that light produces in these animals no increase of oxidation processes; that light has in fact no influence at all on these processes. These simple experiments were fully confirmed by more complex ones in which analyses of the oxygen used and carbonic anhydride produced were measured.

This negatives the idea that light has any local action on animal tissues, although it does not at all contradict the conclusion that light may have an indirect effect on animals with intact central nervous system and active muscles, probably in this case a reflex effect through the optic nerves or sensory nerves of the cutaneous surface.

W. D. H.

The Melting Point and Chemical Composition of Butter as Effected by Nutrition. By A. MAYER (*Landw. Versuchs-Stat.*, 1888, 261—282).—The examination of butter produced by cows under various conditions was undertaken to explain if possible why Danish butter has a better sale than Dutch in the English markets. All that was known on the subject was that the Danish is harder and of a better colour. Inquiries showed that whereas in Holland the cows were fed on pasture and calved in spring, in Denmark they, for the most part, drop their calves late on in the year, and are house fed. The cows under examination were fed at various periods on roots, hay, grass, clover, and silage, and the analysis of the butter produced showed that the percentage of volatile acids varies as the specific gravity; that the melting point does not march parallel with specific gravity, but is dependent on the percentage of the oleïns, butyrin, capronin, &c., present; the percentage of volatile acids and the specific gravity of the butter produced by any one cow varies more considerably than is generally supposed when the experimental conditions are changed: the percentage of volatile fatty acids is dependent on the period of lactation, rising as the period progresses, but it is also dependent on the feeding, being highest when roots, meadow-grass, and clover are given, and lowest with ensilage: on the contrary, ensilage and hay produced a butter of high melting point, whilst grass or clover, whether as pasture or given out in the house, lowers the melting point: the solidifying point follows the melting point, rising and falling with it. E. W. P.

Proteïd Metabolism in Man. By F. Hirschfeld (*Pflüger's Archiv*, **41**, 533—565).—The following are the final conclusions drawn by the author from his research. It is possible for a healthy man (in one case for 15 days, in another for 10 days) to maintain a nitrogenous balance and equal body weight on from 5—8 grams of nitrogen daily: this corresponds to 30—35 grams of proteïd; or if one excepts the days on which very little nitrogen (5 grams) was taken, the conclusion that 35—40 grams of proteïd *per diem* is sufficient can certainly be drawn. Whether this would be possible for periods longer than those mentioned cannot be stated.

This is contrary to the generally received opinion that an adult man requires 100—120 grams of proteïd daily, and that it is dangerous to ingest less, or else the tissue-proteïds will be disintegrated. On the contrary, so much proteïd as this increases the tissue-proteïd (unless great activity compensates for this hypertrophy), and the fat of the organism also increases. W. D. H.

Glycogen. By E. Neisser (*Chem. Centr.*, 1888, 1083, from *Centr. Physiol.*, 1888, 141—142).—The author conducted experiments with mice fed with about 80 different sorts of food in order to determine the extent to which the glycogen of the liver is affected by them. Morphine, amygdalin, and mytilotoxin appear to cause an accumulation of glycogen. The health of the animals was no doubt of considerable influence on the amount of glycogen, although in one case, that of a mouse fed on mytilotoxin, and seriously ill, the liver contained a considerable quantity of glycogen, whilst, on the other hand, with several animals fed on papaïn, asparagine, coniferin, coumarin, and in perfect health, the liver contained no glycogen.

J. W. L.

Synthetical Processes in the Animal Organism. By E. Pflüger (*Pflüger's Archiv*, **42**, 144—154).—A living liver free from glycogen will again form that substance, not only from carbohydrates but from glycerol, gelatin, or proteïd. v. Mering fed dogs on phloridzin, whereby they became diabetic, and in a few days all carbohydrate material in the body had been discharged in the urine as sugar. If now the same drug was given to the same animals after a few days' interval, during which they had no food, they once more became intensely diabetic, and the quantity of sugar passed was so enormous that it cannot be supposed to have come from the drug itself (*Verhandl. VI Congresses inneres Med. Wiesbaden*, 1887). One explanation of the way in which glycogen is formed after the administration of glycerol, is the well-known "economy theory," another is that glycerol and like substances act as stimuli to liver activity. It certainly cannot be supposed that glycogen is directly formed from the substance administered—or at least not in all cases; for instance, from ammonium carbonate. The question then arises as to the genetic relationship existing between glycogen and albumin. Experiments on the decomposition products of proteïds have in no case yielded a carbohydrate; and not only that, but proteïds never yield any of the decomposition products of carbohydrates (lactic acid, mucic acid, tartaric acid, &c.). Still, we have the formation of glycogen taking place in the liver when no food but albuminous food is taken.

The following general considerations will, however, lead to a better understanding of the subject. The chemical differences between animal and vegetable cells are not so great as was at one time supposed. Their chemical composition, so far as it is known, is the same; all living cells breathe oxygen, and produce carbonic anhydride, water, and amido-compounds. If the synthetic processes are more highly developed in chlorophyll-holding plants, that does not mean that synthetic processes are absent from animal cells. As instances of synthetic processes in animal cells, the formation of hippuric acid from glycocine and benzoic acid, or of ethereal hydrogen sulphates from phenol and sulphuric acid, may be taken. A special kind of synthesis must, moreover, occur in the retrogressive metamorphoses of proteïds which lead to the formation of uric acid and members of the same group. In albumin itself, and in the products of albumin obtained outside the body, the number of carbon-atoms is much greater than that of nitrogen-atoms (indole, leucine, tyrosine, &c.); but in these products of metamorphoses in the body, the nitrogen and carbon-atoms are nearly equal in number, or, as in the cases of urea and guanidine, the nitrogen-atoms are the more numerous. The importance of such synthesis occurring in living cells, resulting in the formation of cyanogen containing molecules, has been before insisted on by the author.

Researches on the formation of fat within the body show that here again there are undoubtedly syntheses occurring as the result of the activity of living cells: in fact, reactions occur which cannot be repeated in the laboratory or explained by any known chemical laws; they are probably, therefore, the result of a breaking down of molecules in the first place, and the living cells then building up entirely new materials of a complicated nature from the simple carbon compounds so liberated.

The carbohydrates, for example, are derivatives of the hexatomic alcohol $C_6H_8(OH)_6$. But by feeding an animal on starch, the fat of the body is increased, and substances containing chains of 16 to 18 atoms of carbon linked one to another are formed; and in the case of stearic acid at least, we have a number (16) which is not a multiple of 6. By this synthesis, too, we have substances which possess the property of circular polarisation changed into those which are optically inactive. The first change must, however, be a process of reduction; metabolic changes must occur, and no nutrient material stimulates metabolism like proteïd; this explains why feeding on starch mixed with a small amount of proteïd produces fat, and without it will not. The proteïd admixture is, however, so small that it alone will not explain the great increase in fat. In other parts of the animal kingdom, there are similar occurrences; for instance, the formation of beeswax from honey. Another sample of the same kind is the formation of fat from proteïd, although this is not so well proved as the foregoing cases. In the synthesis of fat from carbohydrate, the group $CH{\cdot}OH$ must be changed into CH_2; and in the formation of carbohydrate (glycogen) from proteïd, the group CH_2 must be changed into CH·OH; in both cases, numbers of these groups become linked together.

The close resemblance between animal and vegetable cells is further shown by the fact that many lower plants (bacteria, moulds, &c.) not only flourish in solutions of albumin and sugar, but actually shed out ferments to convert proteïd into peptone, and starch into sugar, and thus aid absorption. They breathe oxygen, produce carbonic anhydride, amido-derivatives, and, without the aid of sunlight, fat, carbohydrate, and proteïd. Nägeli (*Sitzber. Bair. Akad. Wissensch.*, 1879) has, however, shown that these fungi will assimilate carbon from compounds in which it is combined with hydrogen (amines, &c.), but not from those where it is combined with nitrogen (cyanogen).

W. D. H.

The Sugar-contents of the Horse's Stomach. By ELLENBERGER and HOFMEISTER (*Pflüger's Archiv*, **41**, 484—489).—Seegen (Abstr., 1888, 171) has commented on the small quantities of sugar found in the stomach and intestines, and considers that this may be explained by its rapid absorption immediately it is formed.

The authors state that although a similar state of things may occur with peptone formed from albuminous food, it is certainly not the case in horses and pigs fed on starchy food. The quantity of sugar in the alimentary tract of these animals varies, but they have found from 1 to 3·5 per cent. of sugar (30—150 grams) in the stomach of the horse, and from 0·6 to 0·8 in the stomach of the pig.

The conditions on which the varying amount of sugar depends are:—(1) Length of time after meal: the highest amount is present 1 to 1½ hours after a meal; (2) abundance or otherwise of hydrochloric acid in the gastric juice, which stops the conversion of starch into sugar; (3) condition of the starch in the food, whether cooked or uncooked, corn or potatoes, &c.; (4) another condition which must not be overlooked is the difference of secretion in different parts of the stomach, and if the contents are not properly mixed, more sugar will be found in one part than another (Abstr., 1886, 952; 1887, 743, 744). Seegen appears to have killed his animals too late, 3½—13 hours after a meal.

W. D. H.

Post-mortem Formation of Sugar in the Liver. By H. GIRARD (*Pflüger's Archiv*, **41**, 294—302).—The table (p. 177) gives the results of estimations of the percentage of sugar and glycogen in pieces of the liver, at varying periods after death.

These figures show that the increase in sugar corresponds with the decrease in glycogen; and the conclusion drawn is that the sugar is formed from the glycogen. This conclusion is contrary, however, to the belief of Seegen, who considers that sugar is formed from peptone.

In addition to this, the following facts were also made out:—That the power of liver cells to change a solution of glycogen into sugar is not destroyed after death, even though disease may, during life, have deprived the liver of all its glycogen. The presence of blood in the liver assists in the process. Other tissues, such as muscles which

Animal.	10 minutes after death.		24 hours after death.		48 hours after death.

contain glycogen, have a similar property, namely, their glycogen is transformed after death into sugar; a solution of glycogen placed in contact with the muscle, especially when blood is present also, is similarly acted on.

If the liver is deprived of glycogen by disease, no sugar is formed in it after death. The liver, after death, moreover, does not possess the property of changing peptone into sugar. W. D. H.

Aqueous Humour. By Kuhn (*Pflüger's Archiv*, **41**, 200—202). —Contradictory statements have been made as to the presence or absence of grape-sugar in the aqueous humour. In the present experiments, the aqueous humour of the rabbit and ox was used; the humour was withdrawn from the anterior chamber of the eye by a Pravaz syringe, and the amount drawn from a single eye was sufficient to show, with Trommer's test, that a substance is always present which reduces copper oxide. This cannot be alcaptone (catechol), as it is not precipitated by lead acetate. It also reduces mercury. Two quantitative estimations were made with large quantities of the fluid, by means of the saccharimeter; the result in one case gave a percentage of 0·044 sugar, in the other 0·033. W. D. H.

Lactic Acid in Pale and Red Muscles. By W. Gleiss (*Pflüger's Archiv*, **41**, 69—75).—Pale muscles from the frog and the red muscles from the tortoise were tetanised to equal extents; their acidity was then tested with litmus, the intensity of the change in colour being taken as a measure of the amount of acid present. In some cases the degree of the yellow tint, produced by lactic acid in dilute solutions of ferric chloride, was used as the test. It was found that the quickly contracting muscles of the frog became acid much sooner, and to a greater extent, than the slowly-contracting muscles of the tortoise. This was found to be a general rule throughout the animal kingdom; if such a muscle as the *gastrocnemius* (pale) of a rabbit and the *soleus* (red) of the same animal were compared in the same way again, the more active muscle was the more acid.

With regard to the formation of sarcolactic acid during *rigor mortis*, no difference between the two sets of muscles could be made out.

W. D. H.

Citric Acid in Cow's Milk. By SOXHLET (*Chem. Centr.*, 1888, 1067—1068; see also *Landw. Versuchs-Stat.*, **35**, 351—436).—Henkel has estimated the amount of citric acid in cow's milk in the author's laboratory, and finds it contains 0·9 to 1·1 gram per litre. This quantity is by no means a small one, being equal in amount per day per cow to that contained by 2 to 3 lemons. The author calculates that the cow's milk of Bavaria annually contains 40,000 centner (= cwt. approx.) of citric acid. Condensed milk frequently contains crystals of calcium citrate.

J. W. L.

Glycollic Acid and Pyrotartaric Acid from Suint. By A. BUISINE and F. BUISINE (*Compt. rend.*, **107**, 789—791).—Glycollic and pyrotartaric acids exist in suint in the form of potassium salts, and are separated from that portion of the suint acids which dissolves in water, alcohol, and ether. After separation of barium malate and the removal of the excess of barium, the solution of the free acid is agitated with washed lead hydroxide, which precipitates basic lead glycollate, whilst pyrotartaric and lactic acids remain in solution.

Glycollic acid constitutes about 1 per cent. and pyrotartaric acid about 0·2 per cent. of the dry residue from suint.

C. H. B.

Fate of certain Ferments in the Organism. By H. HOFFMAN (*Pflüger's Archiv*, **41**, 148—176).—The result of this investigation are as follows:—

1. In normal human urine, there are varying quantities of pepsin and diastatic ferments present. The amount of these ferments in the urine is related to the intake of food. This point is thoroughly worked out, and tables and curves are given of the relative amount of pepsin in the urine in connection with the time of day and times of meals.

2. Urine has no power, or hardly any, to destroy pepsin or diastatic ferments.

3. Normal human urine contains no trypsin.

4. Normal human urine easily destroys small quantities of trypsin.

5. Very large quantities of trypsin are not destroyed by urine.

6. If the flow of the pancreatic secretion into the intestine be hindered or prevented, trypsin appears abundantly in the urine.

7. Trypsin is found in the liver, spleen, and kidneys of various animals. This will perhaps explain Herzen's observation, that a mixture of spleen and pancreas undergoes self-digestion more quickly than the pancreas alone; the action is a cumulative one.

W. D. H.

Composition of Pearls. By J. HARLEY and H. S. HARLEY (*Proc. Roy. Soc.*, **43**, 461—465).—A quantitative analysis of oyster pearls gave the following results:—Calcium carbonate, 91·72 per cent.; organic matter (animal) 5·94 per cent.; water 2·23 per cent. The proportions are quite different from those in mother-of-pearl. Pearls are not soluble in vinegar unless pulverised. A cocoanut pearl gave on analysis the same constituents as oyster pearls, but its origin was doubtful. Human pearls gave water 2·05 per cent., solids 97·95 per cent.; the solids containing cholesterin, 98·63 per cent., animal matter 1·37 per cent. Hence they appear to be pure cholesterin biliary concretions.

H. K. T.

Myxœdema. (*Clinical Soc. Trans.*, Supp. to vol. xxi.)—This volume is a report of a Committee appointed to investigate the disease known as myxœdema. The section relating to the chemical investigation of the tissues and organs from cases of the disease in human beings, as well as that produced artificially in animals by the removal of the thyroid body, contains analyses by Drs. Stevenson, Bernays, and Halliburton. The other sections of the report are of clinical interest.

Charles (*Medico-Chirurg. Trans.*, **61**, 62) stated that in the case examined by him, the skin yielded 50 times more mucin than normal skin does; hence the name myxœdema given to the disease.

Subsequent investigations have not confirmed this. The method consisted in extracting the tissue with lime-water (or diluted baryta-water), and then precipitating the mucin dissolved out by this reagent with excess of acetic acid. This precipitate was collected, washed, dried, and weighed. It is not a method which is absolutely accurate, but it gives fairly good comparative results. The following were the average percentages obtained with normal tissues:—

Skin (children)	0·766
Skin (adults)	0·385
Connective tissues	0·521
Parotid	traces.
Heart tendons	

In cases of human myxœdema, although there were instances of increase in the amount of mucin in the skin, the average of 10 analyses gives a number (0·374 per cent.) which is approximately the same as in normal adult skin. With regard to other organs, there was also noted a slight occasional increase; the most marked, however, was in the case of the tendons, especially the heart tendons, the average of five analyses giving a percentage of 1·5.

Mucin is not only, however, a constituent of the ground substance of connective tissue, but it also results from the degeneration of protoplasm as in the goblet cells of mucous membranes, and the acini of the mucous glands. In one case, the parotid gland was found to contain a large increase of mucin; it normally secretes a clear saliva containing no mucin. This is the only case in which the secreting glands were examined, and the result is interesting, as it coincides with what is seen in the disease produced in monkeys artificially. Monkeys show the disease very typically, and the increase of mucin can also be demonstrated better than in the human subject; for in late stages of the disease in man when white fibres or fat cells have permeated the new connective tissue, the increase of mucin is not at all marked; in early stages, it appears to exhibit a percentage of mucin like that found in the not fully developed tissues of very young children. Certain classes of animals do not show the typical characteristics of the disease.

The following table illustrates the quantitative results as obtained in monkeys :—

Animal.	Mucin in parts per 1000.

Chemistry of Vegetable Physiology and Agriculture.

Bacterio-purpurin. By T. W. ENGELMANN (*Pflüger's Archiv*, **42**, 183—186).—In *Pflüger's Archiv* (**30**, 95) the author has previously described a bacterium producing a red pigment, to which he gave the name *B. photometricum*, as light by varying the amount of red pigment influences its movements. Since then he has made a number of observations on different varieties of bacteria which produce a red colour. All belong to the class of sulphur-bacteria (Winogradsky, *Botan. Zeit.*, 1887, No. 31—37); that is, bacteria which in the presence of free hydrogen sulphide, oxidise sulphur, forming sulphuric acid; all these bacteria are moreover coloured by a purplish-red pigment diffused through their protoplasm—bacterio-purpurin (Ray-Lankester); they are all also influenced by light like the *B. photometricum*. This last point distinguishes them from certain colourless sulphur-bacteria.

Different coloured lights affect the bacteria differently; the most powerful being the ultra-red, the yellow, and part of the green. These are the places in the absorption-spectrum of bacterio-purpurin where the greatest absorption of light occurs. A table is given of the amount of absorption of light of bacterio-purpurin measured by the spectrophotometer for the different part of the spectrum. Absorption and physiological effects are thus closely related to one another.

This fact suggested a comparison between this pigment and chlorophyll; and it was then found that bacterio-purpurin is a chromophyll, absorbing carbonic anhydride, and giving out oxygen in the light; sunlight produces this most readily, but the ultra-red works only a little less efficiently than mixed light. W. D. H.

Beer Yeast. By MARTINAND (*Compt. rend.*, **107**, 745—748).—Observations of the time required to form acrospores do not yield results sufficiently precise to distinguish between different species of *saccharomyces*. Experiments in which various species of *saccharomyces* were allowed to act on sterilised solutions of maltose for several days, show that *S. cerevisiæ* from beer yeast acts more rapidly and completely than *S. ellipsoideus*, *S. pastorianus*, and *S. apiculatus*. The times required for the formation of acrospores were somewhat variable.

With a solution of saccharose inverted by hydrochloric acid, *S. cerevisiæ* and *S. pastorianus* were found to act less completely than *S. ellipsoideus*.

Further experiments are required before these observations can be utilised for the practical analysis of yeast. C. H. B.

Yeast-poisons. By H. SCHULZ (*Pflüger's Archiv*, **42**, 517—541).—Previous researches by the author (*Virchow's Arch.*, **108**, 427) have led him to the conclusion that drugs produce their effect by raising or lowering the physiological processes in animal cells; and that small and large doses of any one drug may produce opposite effects of this kind.

The same thing occurs with vegetable cells, the various substances that, in large amount, produce stoppage of fermentations, produce, when excessively dilute, an increase of the activity of the yeast organisms as measured by the amount and pressure of carbonic anhydride produced.

The apparatus used for the investigation is fully described, and the results set out in detail, the pressure of carbonic anhydride being represented graphically in the form of curves.

The results, however, may be briefly summarised in the following way for each of the various drugs used:—

Mercuric Chloride.—The increase of activity of the yeast showed itself most when the amount of dilution was about 1 : 500,000.

Iodine.—Here the optimum was reached when the dilution was 1 : 600,000 in one series of experiments; 1 : 100,000 in another.

Bromine.—Here two sets of experiments both yielded the dilution 1 : 300,000 as the most favourable for ferment activity.

Arsenious Acid.—The relation found here as the best was somewhat less than in the foregoing cases; the proportion of 1 : 40,000 gave the most vigorous production of carbonic anhydride: a dilution less than this, 1 : 50,000, produced no effect whatever.

Chromic Acid.—This had to be used still more concentrated; a dilution 1 : 8000 producing the most marked stimulating effect on the micro-organisms.

Salicylic Acid.—The optimum of dilution was here 1 : 4000; and in the case of *formic acid* 1 : 10,000. W. D. H.

Blood Pigment as a Gauge of Gaseous Exchanges in Plants. By T. W. ENGELMANN (*Pflüger's Archiv*, **42**, 186—188).—The principle of this method is not new, as Hoppe-Seyler showed (*Zeit. physiol. Chem.*, **2**, 425) that a piece of living *Elodea canadensis* in diluted decomposing blood will in direct sunlight cause the venous colour to become arterial, while in the dark the venous colour returns. But this same fact may also be used for microscopical investigations of living cells or small particles of living plant tissues, and as a test for chromophylls. A small spray of spirogyra was mounted on a drop of diluted defibrinated ox blood, which had been rendered venous by a stream of hydrogen or carbonic anhydride. In 10—15 minutes in diffuse daylight, in one minute in direct sunlight, the blood in the neighbourhood of the green fragment had become arterial, while in the dark it once more returned to its venous tint. The same change may be watched with a spectral ocular, or better a microspectrophotometer; the one band of hæmoglobin giving place to the two of oxyhæmoglobin, or the reverse.

The change occurs at different rates under the influence of light from different parts of the spectrum:—A spectrum was projected under the preparation; the change to the arterial tint occurred in that part of the spray of the spirogyra which was lying over the outermost part of the visible red, reaching its height, however, about the C line, and then sank until the beginning of the green was reached. Sometimes a second effect was seen in the blue-green, and a slighter one in the violet. Other chromophylls (for instance, bacterio-purpurin, see p. 180) act *mutatis mutandis* similarly to chlorophyll.
W. D. H.

A Plant which Destroys the Sense of Taste for Sweets and Bitters. By B. BERTHOLD (*Chem. Centr.*, 1888, 1071, from *Centr. Med. Wiss.*, 1888, 460—461).—This drug comes from an Asclepiadea, *Gymnema sylvestre*, found in Assam, on the Coromandel coast, and on the African continent, and is a strong woody shrub with long thin branches. The Hindoos have used the pulverised bark for a long time as an antidote against snake bites. When chewed, the leaves possess at first a bitter astringent, later a slightly acid taste. Directly after chewing, one loses the power of taste for sweet and bitter principles, but only for these two effects on the sense of taste. Sugar tastes like sand and quinine sulphate like chalk. At the end of 1—2 hours, the normal sense of taste is recovered. The author has commenced the chemical investigation, and has succeeded in separating three substances, but these are not yet sufficiently characterised.
J. W. L.

Occurrence of Aluminium in Vascular Cryptogams. By A. H. CHURCH (*Proc. Roy. Soc.*, **44**, 121—129).—More recent analyses generally recognise the presence of alumina in plants as adventitious. The author has, however, found it to be an important constituent of many Lycopodiæ, for instance, *L. alpinum*, *L. clavatum*, *L. selago*, and *L. cernuum*, whilst in *Selaginella spinulosa* it is absent. The earth is also absent in *L. phlegmaria* and *L. billardieri*, but these were afterwards found to be epiphytic. Plants closely related to the

Lycopodiæ, namely, *Equisetum*, *Ophioglossum*, *Salvinia*, *Marsilea*, *Psilotum*, and *Selaginella*, gave negative results. Of tree ferns, *Cyathea serra* gave negative results, whilst the ash of an unknown tree fern from New Zealand contained 19·65 per cent., *Cyathea medullaris* from the same source examined qualitatively gave abundance of alumina, as also did *Alsophila australis* and to a less extent *Dicksonia squarrosa*. Alumina is also an important constituent of the water-moss, *Fontinalis antipyretica*. The alumina in the Lycopodiæ occurs in combination with organic acids. It may serve to neutralise the acids produced in the plant. It is noticeable that the essential inorganic constituents of plants have low atomic weights, and fall within series 1, 2, 3, and 4 of the periodic arrangement. H. K. T.

Formation of Nitric and Nitrous Acids by the Evaporation of Water in Presence of Alkalis and Soil. By A. BAUMANN (*Landw. Versuchs-Stat.*, 1888, 217—264).—Schönbein (*Annalen*, **124**, 4) and others have stated that when water is evaporated, ammonium nitrate and nitrite are produced. They also stated that calcium carbonate as well as hydrated oxides absorb ammonia and convert it into nitrates. The author has made numerous experiments, all of which he here details, and brings forward conclusive evidence that all these experiments made by Schönbein are incorrect. He firstly attributes the false results to the absence of the delicate reagents now at hand, whereby ammonia, nitrates, nitrites, and ozone, and hydrogen peroxide may be detected. Secondly, he shows that the source of nitrates is the gas flames used for evaporation, and for heating water-baths, &c., and that when evaporation is conducted without the direct aid of gas flames, for instance, by sun heat, or previously heated sand-baths, no trace of nitrates is found, if the evaporation is conducted in a room where no gas flames have been burning. He further shows that most of the chemical preparations which are sold as pure contain nitric acid, and he instances a case in which to prepare pure calcium carbonate by precipitation, one portion of the product was dried in a water-bath, the other portion by filter-paper, the former product contained nitrate, the latter none. This holds good for all reagents similarly prepared. It is also shown that even the very tests employed to detect nitric acid, such as brucine, may and frequently do contain a trace of nitrate.

Passing on to Franks' experiments on the disappearance of the ammonia when ammonium chloride is mixed with soil, he points out that Frank seems to have forgotten the action of alkalis on compounds of ammonia, and shows that in forest soils nitrates are not found, nor are they produced from added ammonia. Finally, he warns all who are experimenting on nitrification to beware lest they introduce nitric acid by heating their solutions over gas flames, or ignite solids in open crucibles, &c., also that chemicals or samples must not be kept in rooms where gas is burning, or they will be more or less contaminated. E. W. P.

Composition of Spring Wheats grown in 1887. By M. MÄRCKER (*Bied. Centr.*, 1888, 708—715).—This is a similar paper to the following, in which the compositions of varieties of foreign wheats are compared. It appears that, generally, the highest percentage of albuminoïds and gluten is to be found in those wheats which come quickest to maturity (under 130 days), when there would be, of albuminoïds, 13·17 per cent., and of dry gluten, 18·08, whereas when the period of growth exceeds 130 days, the albuminoïds amount to only 12·47, and gluten to 9·22 per cent.; the smaller the grain, the higher the percentage of gluten, whilst a large grain is indicative of a high percentage of starch; the wheats richest in gluten produce a more bulky dough than other kinds, and the early ripened wheat and the largest grains are most suitable for baking purposes. The greater the percentage of gluten, the higher will the dough made from the flour rise in the aleurometer. E. W. P.

Composition of East Indian Wheat. By T. DIETRICH (*Landw. Versuchs-Stat.*, 1888, 309—318).—Several varieties of Indian wheat are fully described, both physically and chemically. On comparing the percentage of albuminoïds, it is found that the mean of 937 analyses of English, Russian, &c., wheats gives 13·90 of crude albuminoïds in the dry substance, whilst the Indian wheats contain only 12·66 per cent. as a mean. E. W. P.

Composition and Nutritive Value of Oats. By M. MÄRCKER (*Bied. Centr.*, 1888, 697—704).—From a number of analyses and experiments on several varieties of oats, the details of which are given, the following conclusions are drawn:—The heavier-yielding sort is poorer in albuminoïds than the lighter-yielding; there is no definite ratio between the percentages of fat and albuminoïds; that sort which comes quickest to maturity is richest in albuminoïds; the grain poorest in albuminoïds has the lowest bushel-weight, and the largest individual grains are also the poorest in nitrogen; the coefficient of digestion does not seem to be influenced by the composition. Those grains which are smallest in size and richest in nitrogen have most hull, and generally this hull is poorer in albuminoïds than that of other grains. The thickness of the skin surrounding the seed, measured immediately above the embryo, is not invariable—in one year it may be thickest in the large grains, whilst in other years it is thinnest. A table is also given representing the germinative power and total yield of nutrients per acre, but with one or two exceptions the oats are of foreign kinds and not grown in England. E. W. P.

Calcium Sulphite as a Preventative of Loss of Nitrogen in Manure Heaps. By E. JENSCH (*Chem. Zeit.*, 12, 354—355).—The author draws attention to the enormous losses of nitrogen inherent to the present system of storing farmyard manure. These losses can be reduced by spreading gypsum, superphosphate and gypsum, and kainite on the manure; but such additions are superfluous from a manurial point of view in many districts, therefore those means have not met with extensive application. Calcium sulphite is now recommended for the purpose; it is inexpensive, can be applied everywhere, and not only retains ammonia, but also acts as a disinfectant. It is obtained as a bye-product from the gases evolved from the roasting of zinc-blende, and is specially prepared for the present purpose free from lime and calcium carbonate, and with an ammonia-absorbing efficiency of 85 per cent. as compared with 68 per cent. in the best commercial unburnt gypsum. Its action as a manure on vegetation has yet to be tested. D. A. L.

Analytical Chemistry.

Gas Analysis. By H. DREHSCHMIDT (*Ber.*, **21**, 3242—3251).—The author describes a new apparatus for gas analysis similar to Hempel's (Abstr., 1887, 1062) but somewhat improved. A sketch of the apparatus is given and also examples of the results obtained by it.

N. H. M.

Estimation of Iodine. By W. STORTENBEKER (*Rec. Trav. Chim.*, **7**, 141—151).—The estimation of iodine in its compounds with chlorine may readily be effected, according to Bornemann, by decomposing the solution with potassium iodide and estimating the liberated iodine: $ICl_x + xKI = xKCl + (1 + x)I$. The author does not, however, find this method satisfactory, especially in cases where the value of x is high. This is also the case with the method proposed by Duflos of distilling with an oxidising agent (in this case a ferric salt and potassium iodide), when the whole of the iodine should pass over into the distillate. The author, therefore, proposes the reaction $2xFeSO_4 + xH_2SO_4 + 2ICl_x = xFe_2(SO_4)_3 + I_2 + 2xHCl$, which is complete as long as excess of the ferrous salt is carefully avoided or if a mixture of both a ferrous and a ferric salt is used. All that is necessary is distillation and determination of the iodine in the distillate.

The same method may also be used in estimating iodic acid, since $2HIO_3 + 10FeSO_4 + 5H_2SO_4 = I_2 + 6H_2O + 5Fe_2(SO_4)_3$, but in this case also, excess of ferrous salt must be most carefully avoided.

H. C.

Estimation of Nitrogen in Nitrate-superphosphate and in Chili Saltpetre. By P. ZIPPERER (*Chem. Zeit.*, **12**, 955 and 987—988).—The author confirms what has been advanced by others, namely that carefully prepared nitrate-superphosphate, containing no free sulphuric acid, suffers no loss of nitrogen even at 100°. But in the manufacture of nitrate-superphosphate, it is found advantageous to use a slight excess of sulphuric acid, and such superphosphates lose nitrogen on heating, in amounts varying with the quantity of free acid, the bulk of solution heated, and the duration and degree of heating. Hence Grandeau's method of evaporating a measured quantity of the solution gives low results, and to avoid this source of error the following plan is suggested:—If the substance contains 2 to 4 per cent. of nitrogen, take 20 grams, if 6 per cent. 14 grams, and if 8 per cent. 10 grams, treat in the usual way for dissolving in water, and make up to 1 litre; neutralise 500 c.c. with sodium hydroxide (free from nitrate), and make up this solution to 1 litre. 50 c.c., or in case of a superphosphate containing only 2 per cent. of nitrogen, 100 c.c., of the neutralised solution is evaporated to dryness and then examined by the Schloesing-Grandeau method or with the nitrometer. The latter plan the author finds as accurate as the former, and describes a slightly modified apparatus and the mode of using it. For the analysis of nitrate, the author takes a measured quantity of a dilute solution, in preference to a weighed quantity of a concentrated solution, and determines in the nitrometer. D. A. L.

Estimation of Phosphoric Acid. By A. STUTZER (*Chem. Zeit.*, **12**, 492).—The drawbacks to the method of estimating phosphoric acid in manures, &c., by direct precipitation with magnesia mixture in presence of ammonium citrate, are the length of time required for the complete precipitation, the inconvenience of the prolonged stirring, and the danger of scratching the sides of the vessel so that the ammonium magnesium phosphate becomes firmly attached to the glass. To avoid these difficulties the author adds a small quantity of ashless filter-paper, pulped to a thick magma in ammonia, previous to stirring for five minutes with a mechanical stirrer; the ammonium magnesium phosphate may then be at once collected. In addition to the great saving of time, 10 beakers may be stirred at once.

D. A. L.

Wiborg's Gasometric Method for estimating Carbon in Iron and Steel. By H. v. JÜPTNER (*Chem. Centr.*, 1241—1242, from *Österr. Zeit. Berg. Hüttenwesen*, **34**, 67—68).—0·2 gram of iron or steel, or 0·1 gram of pig-iron, so finely pulverised that it passes through a 1·5 mm. sieve, is brought into the carefully dried reaction-tube of the apparatus. 4 c.c. of a saturated solution of cupric sulphate is added and allowed to react for 16 minutes, or, if a smell of hydrocarbon is detected, only three to four minutes. This reaction-tube is 140 mm. long, and 20 mm. wide, and is closed at the top by a doubly bored india-rubber stopper. Through one of the holes passes a funnel with stopcock; the other is connected with a burette. This has an india-rubber stopper at its upper end, through which passes a funnel with stopcock; the lower end is connected with a water-flask for regulating the pressure. The burette is surrounded by a tube, through which water may be passed for regulating the temperature. After the cupric sulphate has acted on the iron, 1·2 grams of chromic acid is added to the mixture, stirred up well with a glass rod, and allowed to react for three to 10 minutes. The tube and contents are next cooled, the burette is filled with water and connected with the reaction-tube, and 8 c.c. of pure sulphuric acid passed gradually into the latter by means of the funnel with stopcock.

The tube is warmed gently up to the boiling point for 10 minutes, then cooled down, and finally all air and carbonic anhydride expelled out of the reaction-tube into the burette by passing in water through the funnel. The volume of gas in the burette having been read off, aqueous potash is passed in through the funnel, the gas shaken with it, and, after adjusting the level of the water, the volume again read off, when from the difference between the two readings the percentage of carbon in the iron may be calculated. J. W. L.

Absorption of Carbonic Oxide by Cuprous Chloride Solutions. By T. LONATSCHEFFSKY-PETRUNIAKA (*J. Russ. Chem. Soc.*, 1888, **20**, 108—123).—The author has analysed mixtures of gases (especially wood-petroleum gas) containing carbonic oxide by Bunsen's method, that is, absorption of that constituent by cuprous chloride. Clay balls were soaked with a solution of cuprous chloride in hydrochloric acid and introduced into the gaseous mixture to be analysed, but constant results could not be obtained. It was shown that such balls, saturated with carbonic oxide, lose some of this gas in pure hydrogen, whereas incompletely saturated balls either lose none or absorb more carbonic oxide when introduced into mixtures of hydrogen with little or much carbonic oxide. It is shown in a series of tables that the phenomena of absorption depend on the partial pressure of carbonic oxide in mixtures with other gases. The author's results were obtained independently of Drehschmidt's. B. B.

Action of Sulphuric and Hydrochloric Acids on Wood-Petroleum Gas. By T. LONATSCHEFFSKY-PETRUNIAKA (*J. Russ. Chem. Soc.*, 1888, **20**, 123—124).—By passing the gas into a hydrochloric solution of cuprous chloride, a solid substance and a volatile liquid of an aromatic character, and containing chlorine, are formed. Dilute sulphuric acid gives nothing but resinous compounds. These facts are of importance in connection with gas analysis. B. B.

Precipitation of Barium Sulphate in the Presence of Bromine. By M. LUCION (*Chem. Zeit.*, **12**, 427) and G. TAUBER (*ibid.*, 477).—Both authors independently have observed that bromine does not interfere with the accurate precipitation of barium sulphate; and, therefore, when it has been used for oxidising sulphur compounds, the removal of any excess, as generally recommended, is superfluous. D. A. L.

Analysis of Lead Peroxide. By L. OPIFICIUS (*Chem. Zeit.*, **12**, 477).—For this purpose the peroxide or red lead may be readily dissolved without the application of heat by treatment with nitric acid, sp. gr. 1·20, and chemically pure copper. In the case of red lead, especially, this method is very useful in detecting admixtures, as adulterants are left that would be dissolved by treatment with hot solvents; these can, therefore, be readily detected and estimated; further, if it is desired to determine copper also, it is only necessary to use a weighed quantity of that metal in the first instance. D. A. L.

Electrolytic Estimation of Copper. By F. Rüdorff (*Ber.*, **21**, 3050—3051).—In estimating copper electrolytically, it is advantageous to mix the solution with 2 to 3 grams of potassium or ammonium nitrate, and then to add about 10 c.c. of ammonia for every 100 c.c. of the solution containing from 0·1—0·3 gram of copper. The condition of the precipitated metal is very satisfactory, and the strength of the current employed may vary within tolerably wide limits.

F. S. K.

Estimation of Manganese in Foods. By G. Stein (*Chem. Zeit.*, **12**, 446).—The ash is boiled with nitric and sulphuric acids and lead peroxide, the resulting permanganate being determined by titration. In this way, by using 5 grams of ash, American coffee beans gave 0·0279 per cent. of manganese in the ash.

D. A. L.

Estimation of Iron and Alumina in the Presence of Calcium and Phosphoric Acid. By G. Kennepohl (*Chem. Zeit.*, **12**, 923—924).—The unsatisfactory results obtained in the estimation of iron and alumina in natural and artificial phosphates led the author to investigate the methods employed. These are numerous, but may be classified under three heads: those depending on (1) the precipitation and estimation as double phosphate of iron and aluminium; (2) precipitation by means of ammonium acetate and estimation of the calcium and phosphoric acids; and (3) separation of iron and aluminium. The latter is much too tedious for general application, and numerous quantitative experiments with mixtures of solutions of ferric chloride, aluminium sulphate, and calcium phosphate, dissolved in nitric acid, in some cases with ammonium phosphate and calcium, in other cases without one or the other, or both, lead the author to conclude that methods 1 and 2 are far too inconvenient when accurate results are required, owing to the difficulty of separating calcium compounds and phosphoric acid. The following method is, therefore, recommended:—The solution is neutralised, or made slightly ammoniacal with ammonia, in a 100 or 200 c.c. flask; it is then treated with slight excess of oxalic acid, heated at 80° for some time, filled to the mark, and filtered. A measured quantity of the clear filtrate is evaporated to dryness, and gently ignited in a platinum dish. The residue is moistened with concentrated ammonia, dried, and dissolved in concentrated hydrochloric acid. The solution is precipitated by means of ammonia and acetic acid, the iron and alumina being weighed as double phosphate, in which the iron may, if desired, be estimated in the usual way. The method also serves for the estimation of calcium, and may be made volumetric by employing standard oxalic acid. Another method, in which phosphoric acid was first eliminated by magnesia mixture in the presence of citric acid, did not prove satisfactory.

D. A. L.

Separation of Nickel and Cobalt in the Form of Nitrites. By Baubigny (*Compt. rend.*, **107**, 685—686).—Lang showed that barium nitrite forms an insoluble triple compound with potassium and nickel nitrites, and thus prevents the accurate separation of nickel and cobalt by this method. The author finds that lead nitrite also forms an insoluble triple compound with the nickel and potassium, which separates as an orange-yellow precipitate only slightly soluble in acetic acid. The composition of the precipitate varies with the proportions of the three salts in the solution, but it is evident that it interferes with the separation of nickel from cobalt.

C. H. B.

Volumetric Estimation of Stannous Chloride. By A. JOLLES (*Chem. Zeit.*, **12**, 597).—The following method is found satisfactory for the estimation of stannous chloride:—4 or 5 grams of potassium manganate dissolved in 8 or 10 grams of potassium hydroxide, and made up to a litre, is standardised by means of potassium antimony tartrate. 0·2 or 0·4 gram of the stannous chloride, or metallic tin, is dissolved in hydrochloric acid in a current of carbonic anhydride, and made up to 250 c.c. This solution is then run from a burette into 5 or 10 c.c. of the manganate solution, until the green colour is replaced by a yellowish-brown, the volume is read off and calculated as usual; the reaction is represented by the equation:—$SnCl_2 + 2KOH + K_2MnO_4 = 2KCl + SnO_2 + 2KOH + MnO_2$. When the stannous chloride is much contaminated, it is advisable to precipitate the tin by means of zinc, and then proceed as above. D. A. L.

Estimation of Titanium and Phosphorus in Iron Ores. By JENNINGS (*Chem. Centr.*, 1888, 1234, from *Berg. Hütt. Zeit.*, **47**, 294). —1 to 5 grams of the ore is digested with hydrochloric acid, the solution neutralised with sodium carbonate, reduced with sulphurous acid, 50 c.c. of acetic acid added, and diluted to 500 c.c. By boiling for one hour, the titanic acid is precipitated, a part of the phosphoric acid and iron accompanying it. The precipitate, with the insoluble portion of the ore (the latter is purposely allowed to remain in the solution, as it assists in the filtration of the titanic acid), is brought on to a filter and washed with dilute acetic acid, dried, ignited, fused with 10 times its weight of sodium carbonate, and the silicate and phosphate of soda dissolved out of the flux. The insoluble sodium and iron titanate is dissolved in dilute sulphuric acid, neutralised with sodium carbonate, reduced with sulphurous acid, and the titanic acid precipitated pure with 25 c.c. acetic acid. The first two filtrates are mixed together, oxidised with nitric acid, and the phosphoric acid, as well as some silicic acid, precipitated with ammonia; the precipitate is dissolved and evaporated to dryness, in order to render the silicic acid insoluble, and the phosphoric acid determined with molybdate solution. J. W. L.

Estimation of Noble Metals in Potassium Cyanide Solutions containing them. By L. OPIFICIUS (*Chem. Zeit.*, **12**, 525). —The solution is treated with hydrochloric acid to destroy the cyanides, warmed, sulphuric acid added, and the gold and silver precipitated by means of zinc, their complete precipitation being indicated by the appearance of a deposit of metallic copper, which is generally present in such solutions. The metallic precipitate is washed, mixed with lead, cupelled, parted, &c., in the usual manner. The method is both rapid and accurate. D. A. L.

Modifications in the Methods of Organic Analysis. By W. L. Dudley (*Ber.*, **21**, 3172—3177).—The author recommends the employment of a platinum combustion-tube and manganese sesquioxide, instead of copper oxide, and states that with such an apparatus a combustion can be made every hour with very satisfactory results. In the analysis of volatile liquids, the substance is weighed in a small bulb-tube, the two ends of which are bent upwards. When the combustion-tube is sufficiently hot, the bulb is interposed between the drying apparatus and the tube, and a stream of nitrogen passed; as soon as the air in the combustion-tube is expelled, an iron plate placed a few inches underneath the bulb is heated, so that the liquid quickly volatilises into the combustion-tube without condensing in its passage there. When the liquid has all volatilised, air or oxygen is passed, and the process completed as usual. F. S. K.

Source of Error in the Estimation of Benzene in Coal-gas. By F. P. Treadwell and H. N. Stokes (*Ber.*, **21**, 3131—3133).—In Berthelot's method for the analysis of coal-gas, fuming nitric acid is used to absorb the benzene, and bromine-water to absorb the hydrocarbons C_nH_{2n} and C_nH_{2n-2}. It is shown by the author that fuming nitric acid absorbs carbonic oxide completely (compare Hasenbach, *J. pr. Chem.* [2], **50**, 1), and that bromine-water absorbs benzene, as well as the hydrocarbons mentioned (compare also Drehschmidt, *Post's Chem. Techn. Anal.*, 1888, 108). N. H. M.

The Amount and Estimation of Fusel Oil in Spirits. By F. L. Ekman (*Chem. Zeit.*, **12**, 564—565).—According to the results of the author's investigations, brandies prepared from potatoes or cereals, with the exception of normal propyl and isobutyl alcohols, contain no other alcohols with boiling points between ethyl and amyl alcohols; this is at variance with the statements of some previous observers. The fusel oils from such spirits contain from 3—12 per cent. by weight of propyl alcohol, 15—47 of butyl alcohol, 44—71 of amyl alcohol, with 5—7 per cent. of high-boiling residue. The largest proportion of butyl alcohol was found in spirit from cereals. The various constituents were separated by fractionation, using a Le Bel tube; the corn spirits required 20—25 fractionations to get the propyl alcohol sufficiently pure. The sp. grs. at 15° were propyl alcohol 0·8085, isobutyl alcohol 0·8064, amyl alcohol 0·8157. The amount of these oils was estimated colorimetrically by means of sulphuric acid. The types were strong solutions containing hydrochloric acid and known quantities of cobaltous chloride for red, ferric chloride for yellow, and copper chloride for blue. 200 c.c. of spirit and 25 c.c. of water are rapidly distilled from a brass retort until 185 c.c. have passed over. The distillate is diluted to 200 c.c., and 25 c.c. is steadily run into 15 c.c. of sulphuric acid, sp. gr. 1·8436, during about five minutes, with brisk stirring; they are compared with the types after a lapse of at least three hours. Propyl alcohol is not coloured by sulphuric acid. Aldehyde to the extent of 0·02 per cent. in 46 per cent. alcohol gives no noteworthy reaction with sulphuric acid, but, nevertheless, is objectionable, as it has the property of intensifying the colour reaction of amyl alcohol, and may lead to considerable error. D. A. L.

Estimation of Sugar in Molasses by Clerget's Inversion Method. By F. Herles (*Chem. Centr.*, 1888, 1136—1137, from *Zeit. Zuckerind Böhmen*, **12**, 381—387).—Owing to the presence of raffinose in molasses, the determination of the sugar is not made by directly polarising, but, according to Clerget's method, after inversion. As the raffinose is fermentable, the author considers that it should not be omitted from the percentage of sugar, and he proposes the following method and formula. The molasses is clarified with plumbic acetate in a 100 c.c. flask, 50 c.c. is inverted with 5 c.c. concentrated hydrochloric acid, by heating at 70° for 15 minutes. After cooling, the degree of rotation is noted as well as the temperature. Then the difference between the two readings of the polariscope, before and after inversion, is multiplied by 0·42, and added to the determination according to Clerget. For temperatures approaching 20°, the author recommends the calculation of the sugar contents from the reduction of the rotation (S) on account of inversion:—

$$C = \frac{100S}{142 - t/2}, \text{ where } t = {}^\circ\text{C}.$$

J. W. L.

Estimation of Saccharose as well as Invert-sugar or Raffinose and on the Quantitative Estimation of Glucose with Levulose. By J. Dammüller (*Chem. Centr.*, 1888, 1248, from *Zeit. Ver. Rüb. Zuck. Ind.*, **25**, 742—755).—The author prefers weighing half the normal weight of sugar for inversion (namely, 13·024 grams) dissolving in 75 c.c. of water and inverting with 5 c.c. of concentrated hydrochloric acid by heating at 70° for $7\frac{1}{2}$ minutes. The resulting solution is then diluted to 100 c.c. and polarised. Then, since 26·048 grams cane-sugar cause a deviation of +100°, and further, the same weight of cane-sugar after inversion causes a deviation of −32·66°, then for each +1° (=1 per cent.) rotation before inversion, the same amount of cane-sugar causes a rotation of −0·3266° after inversion. Under the same conditions of inversion, 16·576 grams of raffinose ($C_{18}H_{32}O_{16} + 5H_2O$), causes before inversion a rotation of +100°, after inversion of +51·82°; before inversion, therefore, it rotates the ray 1·852 times more strongly than cane-sugar. 26·048 grams of anhydrous raffinose, after inversion, would rotate the ray +95·98°. If now P = the reading in degrees of deviation caused by 26·048 grams sugar before inversion; J = the reading after inversion; Z = the percentage of cane-sugar; and R = the percentage of anhydrous raffinose;

then (1) $P = Z + 1{\cdot}85\,R.$
(2) $J = -0{\cdot}3266\,Z + 0{\cdot}9598\,R,$

from which we obtain—

$$Z = 0\cdot5188\,P - J/0\cdot8454 = \text{per cent. cane-sugar},$$
$$R = P - Z/1\cdot85 = \text{per cent. raffinose.}$$

The author has experimented with Sieben's method for destroying levulose, but the results obtained were not altogether satisfactory, especially when the proportions of levulose and glucose varied.

J. W. L.

Estimation of Raffinose in Beet-sugar. By G. LOTMAN (*Chem. Zeit.*, **12**, 391—392).—Simple examination of the methyl alcohol extract of sugar gives too high a percentage of raffinose. The following method gives accurate results with even 0·1 per cent. of raffinose. 50 grams of the sugar is perfectly dried at 60° with the aid of a water-air-pump, allowed to cool in the drying chamber, and treated with 100 c.c. of methyl alcohol and polarised. 50 c.c. of the solution is then mixed with 2 c.c. of a solution of lead acetate (sp. gr. 1·4, which precipitates all the raffinose), made up to 55 c.c., and again polarised. This reading +10 per cent. gives the rotation due to cane-sugar, and by deduction from the first reading, the rotation due to raffinose is found, and the percentage calculated as usual. One part of raffinose prevents the crystallisation of at least five parts of sugar.

D. A. L.

Detection of Foreign Starches in Chocolate. By C. HARTWICH (*Chem. Zeit.*, **12**, 375).—Owing to the variable amount of starch in cocoa-beans, chemical examination of chocolate cannot be taken as decisive, as regards admixture of foreign starches, unless the percentage is above 10 per cent. Therefore, microscopical examination is resorted to, and for this purpose the chocolate is best deprived of its fat and sugar before being placed under the microscope. The starch granules are counted in different parts of the object, and a mean taken; a pure chocolate is then mixed with a corresponding amount of the supposed foreign starch, and examined in the same manner; in this way, the quantity of starch may be estimated with sufficient accuracy.

When small-grained starches are present, it is not advisable to treat with iodine in potassium iodide beforehand. D. A. L.

Butter Analysis. By PAGNOUL and GRENET (*J. Pharm.* [5], **18**, 353—360).—The present rapid method of analysis is based on a determination of both the volatile and fixed acids in the butter. 10 grams of butter is just melted and transferred to a burette graduated to 70 c.c., into which a few drops of warm water and a little light petroleum have been previously placed. The capsule in which the butter has been melted is washed alternately with petroleum and a few drops of water, and the burette is filled up with petroleum to a point below the 70 c.c. mark. The burette is closed above with the moistened hand, and strongly shaken, after which it is allowed to remain five or six minutes. Then the water level is brought up to 10 c.c., and the petroleum level up to 70 c.c., and after shaking again the tube is closed and allowed to remain for 10 minutes. If the temperature is low, it may be necessary to warm the burette a little. The aqueous portion is carefully drawn off into a tared platinum dish, a little water being added several times, to remove all that is soluble in water. This solution serves to determine the foreign matters—ash and sodium chloride. 10 c.c. is now run out of the burette and thrown away, then 20 c.c. is run into a flask for the estimation of the fatty acids, and 20 c.c. more is run into a tared capsule for estimation of the total fat. The flask just mentioned is heated on the water-bath for 5 to 10 minutes to expel the petroleum; then for saponification there is added 50 c.c. of a solution prepared as follows:—60 grams of potash-lime is placed in a flask with 800 c.c. of alcohol of 95°, and agitated from time to time during several days; this is then filtered and made up to a litre. The flask containing the fatty matter and alkaline solution is heated at 100° and agitated from time to time, but more actively towards the end of the operation; in 30 to 40 minutes the saponification is complete. 50 c.c. of water is now added, and warmed a little to dissolve the soap, three or four bits of pumice and 12 c.c. of phosphoric acid of 45° are then added. The flask is shaken and closed with a stopper carrying a funnel with stopcock and a tube with two bulbs in the vertical portion and then bent slightly downwards and leading to a vertical worm condenser. When 45 c.c. has been distilled over, 50 c.c. of water is passed into the flask; when 95 c.c. has passed over, a second 50 c.c. of water is added, and the distillation is continued until 145 c.c. has passed over. Phenolphthaleïn is added to the distillate and decinormal soda solution. The volatile fatty acids expressed as butyric acid, per 100 of butter, equals 0·264 time the number of c.c. of soda solution used. With margarin, only 1 or 2 c.c. is required, whilst pure butter requires about 20 c.c. The presence of sodium chloride in the flask would give rise to hydrochloric acid, which would be estimated as so much fatty acid. If present, the titrated liquid may be acidified with a few drops of nitric acid, and neutralised with calcium carbonate in excess, then potassium chromate and standard silver nitrate solution will indicate the amount of hydrochloric acid which is to be deducted. 20 to 25 c.c. of light petroleum is added to the warm residue in the flask, and the contents are transferred to the burette, the flask is then washed alternately with petroleum and warm water to collect the whole of the residue. On running off the water from the burette, the phosphoric acid and glycerol are removed; three or four washings give a water which is quite neutral. The solution of fatty acids thus completely washed is evaporated on the water-bath, the capsule being sunk in the boiling water, so that the outside level is 2 or 3 cm. higher than that of the inside; the residue is dried at 105° or 110°, and weighed. The platinum capsule containing the other 20 c.c. of petroleum solution is evaporated, dried at 105° to 110°, and weighed. From these figures the amount of fixed and volatile fatty acids per cent. of fatty matter are deduced. The platinum capsule containing the original 10 c.c. of aqueous solution is evaporated, dried, and weighed; then gently heated to dull redness and weighed again. The ash is dissolved in a little water, filtered, and the liquid is made up to

100 c.c. In 20 c.c., the chlorine is titrated with silver nitrate solution and potassium chromate. Finally, the moisture is determined on 5 grams of butter mixed with 8 or 10 little balls of paper, made from one of two dried and balanced filters. By turning over the paper balls two or three times, the drying is completed at 105° to 110° in about three hours. If boric or salicylic acid is suspected, special methods then become necessary. J. T.

Detection of Cotton-seed Oil in Lard. By W. Bishop and L. Ingé (*J. Pharm.* [5], 18, 348—353).—American lard imported into France is frequently adulterated with 50 to 60 per cent. of other fats; cotton-seed oil is often used, and the desired consistence is given to the mixture by the addition of pressed tallow. Bechi has shown that cotton-seed oil, to the exclusion of other fats, reduces silver nitrate. (Compare, however, Bizio, this vol., p. 86.) Labiche has remarked the production of a special coloration when this oil is treated with lead acetate and ammonia. Finally, the rise in temperature produced by mixing this oil with sulphuric acid is relatively considerable. These three characteristics are sufficient to detect the oil, when mixed with lard, as follows:—100 to 150 grams of the lard is heated at 80—100° until it becomes perfectly clear. 5 grams of this limpid material is treated with 20 c.c. of absolute alcohol and 3 c.c. of a solution containing 2 grams of silver nitrate to 250 c.c. of absolute alcohol. The mixture is heated at 100° during 10 minutes, and stirred from time to time. In presence of cotton-seed oil, a more or less accentuated coloration is produced, and a coloured cake is formed on cooling; on decanting the alcohol and dissolving the cake in ether or light petroleum, a cold solution is obtained, having the same colour. Again, 25 grams of the limpid fat is treated with 25 c.c. of a solution, cooled to about 35°, made up of crystallised lead acetate 500 grams, and water 1000 c.c., 5 c.c. of pure ammonia of 22° B. is then added, and the mixture is vigorously stirred for some minutes to form a homogeneous emulsion. After 24 hours the colour is observed. Finally, 25 grams of the melted fat is cooled to about 30°, the temperature is taken, and 20 grams of sulphuric acid, of sp. gr. at least 1·836, is added. The mass is strongly agitated, and the point of maximum temperature observed. By operating always in the same way, duplicate experiments will give readings not differing by more than two degrees. Comparative experiments are made at the same time with pure materials. The authors have not succeeded in devising a quantitative method.

J. T.

Estimation of Fatty Acids in Soap. By Samelson (*Chem. Zeit.*, 12, 355).—The fatty acids are precipitated by means of sulphuric acid, and are collected and washed on a tared filter. The filter and precipitates are then transferred to a weighed weighing bottle, treated first with absolute alcohol, which is driven off on a water-bath, then with ether in a similar manner. After this treatment, the tube and contents are placed in a water-oven, and are dry in an hour. The method is speedy, and avoids both loss and decomposition of the fatty acids. D. A. L.

Detection and Estimation of Salicylic Acid, chiefly in Beer. By H. Elion (*Rec. Trav. Chim.*, **7**, 211—219).—The acid is extracted from the solution containing it, by shaking it with two or three times its volume of ether; the ethereal solution, after separation, is then shaken up with a small quantity of a dilute solution of soda or potash, which takes up the whole of the acid. In a very small portion of the solution, after acidification with hydrochloric acid, the salicylic acid can usually be detected by means of the ferric chloride test.

If the acid is extracted as above from beer, the impurities which accompany it prevent its direct estimation by evaporating the ethereal solution and weighing the residue. Direct titration by means of dilute alkali also gives unsatisfactory results. Excess of bromine converts salicylic acid into the compound $C_6H_2Br_3{\cdot}OBr$, and this, by the action of potassium iodide, is converted into potassium tribromophenoxide, $C_6H_2Br_3{\cdot}OBr + 2KI = C_6H_2Br_3{\cdot}OK + I_2 + KBr$. The author attempted, by determining the iodine liberated in the latter reaction, to estimate the salicylic acid by this means, but found that the action of the potassium iodide was far from complete at the ordinary temperature and with moderately dilute solutions. Estimation of the hydrobromic acid formed when salicylic acid is converted into tribromophenol by excess of bromine, also gave discordant results in the case of beer, owing to the presence of foreign organic matter. It was finally decided to determine the salicylic acid by separating and weighing the tribromophenol itself. This can be done by steam distilling the solution, after removing the excess of bromine by means of potassium iodide and sodium thiosulphate, extracting the distillate with ether, and evaporating the ethereal solution. This last method was found to yield satisfactory results. H. C.

Detection of Salicylic Acid in Beer. By A. J. C. Snyders (*Chem. Centr.*, 1888, 1186, from *Rev. internat. fabricat. aliment*, **1**, 166—170).—25 c.c. of beer, with a few drops of sulphuric acid, is shaken up with 40 c.c. of ether, and the ether extract is tested with very dilute ferric chloride. By this means, 0·004 gram of salicylic acid per litre of beer may be detected. For the quantitative estimation, 250 c.c. is distilled and the first 130 c.c. of the distillate is taken.

J. W. L.

The Simand-Kohnstein Method of Estimating the Acids in Tanning Liquors. By R. Koch (*Dingl. polyt. J.*, **269**, 168—182).—In a recent communication (*Gerber*, **323** and **324**), Simand, in defending the gravimetric method of estimating the free acid in tannins (Abstr., 1885, 935), refers to the author's criticisms, and asserts that Koch wrongly condemns the method owing to the fact that, through the formation of sparingly soluble magnesium salts, a considerable error arises in the estimation of free acids by the Simand-Kohnstein method.

The author in reply states, that although, from a scientific point of view, he quite agrees with this contention, having recently carried out a further series of experiments to prove the correctness of the supposed formation of sparingly soluble magnesium salts, he condemned the method as being useless for practical purposes on account of its extreme tediousness and complexity, and, therefore, advocates the estimation of the free acids in tanning liquors by his titration method. (Compare Abstrs., 1887, 871, 1144; and 1888, 1138.) D. B.

Testing Peru Balsam. By C. DENNER (*J. Pharm.* [5], **18**, 259—260, from *Gehe's Handelsber.*, 1888).—To detect gum benzoïn or storax in Peru balsam, 5 grams of the balsam is treated with 5 grams of sodium hydroxide solution (Ph. Germ., II) and 10 grams of water. The whole is well shaken twice with 15 grams of ether, each time decanting the ether layers as completely as possible. The residue is boiled, and acidified with hydrochloric acid; on adding cold water, a resin separates which is dissolved in sodium hydroxide solution. The solution thus obtained is diluted with 20 grams of water, boiled, and precipitated with barium chloride; the precipitate thus formed is collected on a filter, dried on the water-bath, and extracted with alcohol. The residue is treated with concentrated sulphuric acid, and the liquid stirred up with chloroform. The chloroform becomes violet or blue if gum benzoïn or storax is present. This method is capable of detecting the presence of minute quantities. J. T.

General and Physical Chemistry.

Refractive Indices of Turbid Media. By A. Haschek (*Monatsh.*, 9, 900—902).—Solutions were made in alcohol of shellac, mastic and guaiacum, 8·9, 10·01, and 12·83 grams of each being taken to 100 grams of alcohol. 20 grams of each solution was added to 100 grams of water, and the refractive index then measured. These were for the sodium and lithium lines, mastic 1·3454 and 1·3341, guaiacum 1·3429 and 1·3401, shellac 1·3461 and 1·3410. A solution of water and alcohol alone, in the proportions in which each was present in the above liquids, gave 1·3365 and 1 3341.

Nine square centimetres of filter-paper were boiled in 100 c.c. sulphuric acid for half an hour, and the refractive index of the solution found to be 1·4320 and 1·4313, that of the acid alone being 1·4317 and 1·4310. On again boiling for half an hour the solution gave 1·4328 and 1·4320, and the acid 1·4318 and 1·4311.

Since in each solution there has been an increase in the refractive index, due to the suspended particles, it must be assumed that these particles cause a retardation in the velocity of light, the more so as this retardation appears to increase as the size of the particles decreases. H. C.

Refraction of Liquids within wide Limits of Temperature. By E. Ketteler (*Ann. Phys. Chem.* [2], **35**, 662—699).—In former papers (Abstr., 1888, 541), the author established, in the case of water and alcohol, the two formulæ $(n^2 - 1)(v - \beta) = \text{M}$, and $\text{M} = \text{C}(1 + ae^{-kt})$. Of the four constants, β, C, a, k, occurring in these formulæ, β, a, and k have to be determined by refraction observations, whilst C may be assumed to be known independently.

In the present paper, the author describes an elaborate series of experiments on the refraction of carbon bisulphide, from the results of which he deduces the following conclusions:—

(1.) The coefficient β can be determined most accurately from the results of Zehnder's and Quincke's pressure researches.

(2.) The refraction of carbon bisulphide within the limits of temperature of the observations $-20°$ to $160°$, is approximately given by the formula $(n^2 - 1)(v - \beta) = \text{constant}$.

(3.) The dispersion, given by the expression $(n^2_a - 1)/(n^2_0 - 1) - 1$, diminishes with the density, the decrease being such as would be accounted for by a change in the maximum absorption, proportional to the change of density.

(4.) Assuming these relations, the temperature-coefficient can be determined for all temperatures and wave-lengths.

Tables are given showing the indices of refraction for wave-lengths corresponding with the lines A, C, D, F, G, and H of the solar spectrum for different temperatures, with the corresponding values of the temperature-coefficient, and the incorrectness of the principal older formulæ. G. W. T.

Molecular Refraction of Fumaric, Maleïc, Mesaconic, Citraconic, and Itaconic Acids, and of Thiophen. By C. Knops (*Annalen*, **248**, 175—231).—The author has determined the index of refraction of the methyl, ethyl, and propyl salts of fumaric, maleïc, mesaconic, citraconic, and itaconic acids. A comparison of the molecular refraction of these acids and their ethereal salts, leads the author to the conclusion that fumaric and maleïc acids contain only one double-linked carbon-atom, and that fumaric acid stands in the same relation to maleïc acid that mesaconic acid does to citraconic acid (Abstr., 1888, 938). Brühl's theory is at present incapable of indicating in what points the constitution of fumaric and mesaconic acids differ respectively from the isomeric maleïc and citraconic acids. According to Anschütz (Abstr., 1887, 916; 1888, 448), ethyl fumarate and mesaconate contain two double-linked oxygen-atoms, but the isomeric maleate and citraconate only contain one double-linked oxygen-atom.

The molecular refraction of thiophen indicates that this compound contains only one double-linked carbon-atom. Further investigation is required in order to decide whether the formula  correctly represents the constitution of thiophen. W. C. W.

Preparation of Phosphorescent Calcium and Strontium Sulphides. By E. Becquerel (*Compt. rend.*, **107**, 892—894).—When calcium carbonate, as pure as possible, is calcined with sulphur, it yields calcium sulphide which is only feebly phosphorescent. If, however, traces of a sodium compound are added before calcination, the product shows a brilliant and persistent green phosphorescence. Manganese or bismuth alone has very little influence on the result, but in presence of traces of sodium, the former produces a brilliant yellow and the latter a brilliant blue phosphorescence. Lithium is even more active than sodium, and the phosphorescence is green. Potassium, on the contrary, has very little effect. From these results, it follows that the simultaneous presence of an alkali is essential to the production of any phosphorescence by manganese or bismuth.

Oyster shells and other shells, and aragonite and gypsum from some localities, contain sodium, and hence the phosphorescent properties of the calcium sulphide prepared from these substances.

If 0·1 part of rubidium carbonate is added to calcium carbonate which also contains a small quantity of sodium, and the mixture is heated with sulphur to a moderate temperature, the middle of the mass has a red colour, whilst the outer parts in contact with the crucible show a green phosphorescence. When the product is recalcined, the red disappears and only the green remains.

Strontium sulphide shows similar phenomena, which, however, are less strongly marked; if free from sodium, it shows a feeble, greenish-blue phosphorescence. In presence of lithium, the phosphorescence is yellow. With rubidium, no red colour is observed. Pure strontium oxide and pure sulphur yield a sulphide with a violet-blue phosphorescence, which, in presence of sodium or lithium, becomes greenish or yellowish in parts. C. H. B.

Decomposition of the Haloïd Salts of Silver by the Action of Light. By F. GRIVEAUX (*Compt. rend.*, **107**, 837—839).—The author's experiments lead him to the conclusion that the decomposition of the haloïd salts of silver by the action of light is a phenomenon of dissociation similar to the decomposition of the same compounds when heated. This view is supported by the following phenomena which are especially well marked in the case of silver iodide. When a beam of light is allowed to fall on one of two silver plates coated with silver iodide and immersed in a cell filled with liquid, an electromotive force is developed, and attains a maximum after a certain time. If iodine solutions of different concentrations are allowed to circulate in the cell, the plates coated with silver iodide remaining the same, the electromotive force diminishes as the concentration of the iodine increases, and at a particular concentration it becomes *nil.* If the distance between the cell and the source of light is gradually increased, the concentration of the iodine solution required to produce zero E.M.F. gradually diminishes, and *vice versâ.* If the cell is gradually moved to or from the light, and finally placed at a distance *d*, the E.M.F. developed is the same as if the cell had been placed at *d* at the beginning. When the concentration of the iodine solution in the cell gradually varies, the E.M.F. also varies gradually, but in the inverse direction. If when the E.M.F. has reached its maximum value the circulation of the iodine solution is stopped, the E.M.F. increases gradually and regularly, but when the circulation is restored the E.M.F. gradually sinks to its normal value for the particular degree of concentration. This result may be ascribed to the decrease in the concentration of the solution, due to the action of the iodine on water under the influence of light, a decomposition which is rendered evident by the decolorisation of the solution.

Similar phenomena are observed with silver bromide and silver chloride, but the concentration of the solution required to produce zero E.M.F. varies with the nature of the haloïd. C. H. B.

Decoloration and Recoloration of Litmus Solution by Light. By F. BELLAMY (*J. Pharm.* [5], **18**, 433—435).—That litmus solution loses its colour when kept in a closed vessel, and regains it on exposure to air, is well known. The author boiled 50 grams of litmus three times with three successive litres of water. Four flasks were filled with the last solution and hermetically sealed, so as to include only a small bubble of air. The flasks were placed on a table near to a window where, as a rule, only diffused light fell on them. Between August 24 and October 2 the four liquids became quite colourless. On October 15, one of the flasks had become somewhat coloured, and this grew in intensity until November 12, when it had reached its original intensity; the other three remained colourless. The coloured flask, placed alternately in darkness and light, became colourless, and coloured four and three times respectively, finally the flask was broken by expansion of the liquid caused by the direct action of sunlight.

The author has only been able to repeat the experiment once, and that less satisfactorily; he has not yet made out the cause of the changes of colour, but is working at the question. J. T.

Minimum-point of Change of Potential of a Voltaic Couple. By G. GORE (*Proc. Roy. Soc.*, **44**, 294—296).—The effect of dissolved substances on the electromotive force of a magnesium-platinum couple in distilled water (this vol., p. 90) can be easily shown by balancing one couple against another through a galvanometer, the salts experimented with being added to one of the couples. The plates must be cut from the same piece of metal, and immersed at the same time in separate quantities of the same water. The results are compared with those obtained by means of a thermopile. The minimum-point of change depends on the couple and liquid used, temperature, and particular galvanometer. The latter effect is probably dependent on the inertia of the needle. The minimum-point is dependent on the free chemical energy, and, with certain exceptions, on the chemical heat of the substance dissolved. H. K. T.

Change of Potential of a Voltaic Couple. By G. GORE (*Proc. Roy. Soc.*, **44**, 296—300).—The effect of potassium chlorate and chloride, hydrochloric acid, and bromine at different temperatures in increasing the voltaic potential of a zinc-platinum couple is examined (see preceding Abstract). The electromotive force increases more or less regularly with increase of the strength of the solution; in some cases (potassium chlorate and chloride) it reaches a maximum before the saturation point is reached; in others (potassium chloride and bromine) a momentary decrease is observed; in others the electromotive force becomes constant for a time, and then again increases. The amount of salt required for minimum change is greatest with potassium chlorate, least with bromine. The total increase in electromotive force is given. H. K. T.

Influence of the Chemical Energy of Electrolytes on the Minimum-point and Change of Potential of a Voltaic Couple. By G. GORE (*Proc. Roy. Soc.*, **44**, 300—308).—A continuation of experiments on the "minimum-point" (see preceding Abstracts). The quantities of dissolved salt required for the minimum-point of change for the oxyhalogen salts of potassium are in the order chlorate, bromate, iodate, beginning with the greatest; hence the more feebly united the negative constituent, the smaller the proportion of salt required to disturb the voltaic balance. With the haloïd salts, the minimum quantity was much smaller and in the order iodide, bromide, chloride; hence the action is more powerful, and the order of activity reversed. With the halogens themselves, the quantity required is still less, the order remaining the same; hence the effect is greater the greater the chemical energy of the substance and the greater the freedom of that energy. At low potentials the rate of increase of the electromotive force per unit weight of substance is larger the greater the effect of the substance. The curve of variation of potential is characteristic for each substance. H. K. T.

Effects of different Positive Metals on the Change of Potential of a Voltaic Couple. By G. GORE (*Proc. Roy. Soc.*, **44**, 368—377).—A continuation of the above experiments, in which the metals and form of galvanometer are varied. The more easily the positive plate, or the less easily the negative plate is corroded, the smaller the quantity of dissolved substance required to disturb the balance. With chlorine and bromine, the quantities vary directly as the atomic weights of the positive metals in the couples magnesium-platinum, zinc-platinum, cadmium-platinum. As the smallness of the quantity of substance required to disturb the balance depends both on the sensitiveness of the galvanometer and on the chemical energy of the substance, it is probable that the effect really begins with the first addition of substance, but is too small to detect. H. K. T.

Certain Generic Electrical Relations of the Alloys of Platinum. By C. BARUS (*Amer. J. Sci.*, **36**, 427—442).—Measurements of the conductivity of a large number of alloys of platinum with other metals are given, and also the observed temperature-coefficient for each alloy. Plotting the temperature-coefficients against the specific resistance, it appears that the effect of alloying platinum with less than 10 per cent. of any other metal is to produce a variation in the temperature-coefficient which is quite independent of the special ingredients, and depends only on the resistance of the alloy. Also, although the resistance of the alloys examined varied from 10 to 65 microhms. per c.c., throughout the whole of this enormous variation the temperature-coefficient was found to vary as a linear function of the conductivity. The author shows that a similar relation holds good in the case of alloys of other metals. H. C.

Electrical Resistance of Mercury. By F. KOHLRAUSCH (*Ann. Phys. Chem.* [2], **35**, 700—764).—This paper contains a very full account of a determination of the absolute resistance of mercury carried out by Weber's method of damping with some modifications of Dorn's. The result of the determination gives 94060 centimetre-seconds as the resistance of a cubic centimetre of mercury at 0°. Glazebrook has compared one of the author's mercury standards with the B.A. unit in the Cavendish Laboratory, and the result of the comparison gives one B.A. unit = 0·9866 ohm.

It will be remembered that at the Paris Conference it was determined that the legal ohm should be the resistance of a column of mercury 1 square centimetre in sectional area, and 106 centimetres in length at 0°. It was considered practically certain at the time that this length was a little too short, but as the amount of the excess was doubtful it was considered advisable to adopt the whole number. According to the author the true value lies between 106·2 and 106·3 centimetres. G. W. T.

Influence of the State of Aggregation of various Substances on their Electrical Resistance. By L. GRUNMACH (*Ann. Phys. Chem.* [2], **35**, 764—772).—Clausius has pointed out (*Ann. Phys. Chem.*, **104**, 650) that from Arndtsen's researches on the electrical resistance of metals, it follows that in the case of simple metals in the solid state, the resistance varies directly as the absolute temperature. Werner Siemens (*ibid.*, **113**, 91) has confirmed this conclusion, subject to the condition that it only holds when the metal is not near the melting point.

In the present paper, the author describes some observations of the resistance of mercury at temperatures ranging from −90° to + 20°. He obtains the value 0·00086 for the temperature-coefficient of liquid mercury, which agrees fairly well on the one hand with the value 0·00095 given by Werner Siemens, and on the other hand with the value 0·000882 given by Mascart, Nerville, and Benoît. During liquefaction he finds that the resistance undergoes a rapid increase up to about 1·5 times its original value, a much smaller increase than that given by Cailletet and Bouty, and by C. L. Weber. He finds, moreover, that the temperature-coefficient does not remain constant between the temperatures −40° and −90°, but steadily diminishes with the temperature, as shown briefly in the table below:—

Temperature.	Temperature-coefficient.
−40° to −50°	0·00226
−50 „ −60	0·00134
−60 „ −70	0·00111
−70 „ −80	0·00078
−80 „ −90	0·00037

These results show that pure mercury, with regard to its resistance, behaves differently from other simple metals, not only in the liquid state but even when solid, and at temperatures much below the melting point. G. W. T.

Electromotive Force of Selenium. By W. v. Uljanin (*Ann. Phys. Chem.* [2], **35**, 836).—Kalischer (this vol., p. 3) laid claim to a prior use of the method of preparing sensitive selenium at a temperature of 195°. While quite willing to grant this, the author points out that in his paper (Abstr., 1883, 883) he had expressly stated that the method he had employed was that originally described by Siemens in 1877, which he had found much better than the one claimed by Kalischer. The writer quite agrees with Kalischer that Fritts's results have nothing to do with the E.M.F. of selenium.

G. W. T.

Theory of the Dissociation of Electrolytes. By J. H. van't Hoff and L. T. Reicher (*Zeit. physikal. Chem.*, **2**, 777—781).—The relation which Ostwald has deduced (Abstr., 1887, 1020, 1142) as expressing the behaviour of electrolytes on dilution, $m^2/(1-m)v = C$, has been tested with a number of acids, and found to hold good with remarkable accuracy. The acids examined were acetic, butyric, benzoic, formic, and chloracetic. H. C.

Electrochemical Studies. By W. Ostwald (*Zeit. physikal. Chem.*, **2**, 840—851).—The conductivity of electrolytes may according to Kohlrausch be represented by $\mu = a + s$, where a and s are the ionic velocities, but since in electrolysis only the dissociated portion of the electrolyte is active, the proportion K of the electrolyte in the dissociated condition must be taken into account, and we get $\mu = K(u + v)$. Since u/v is known from Hittorf's measurements, and μ may be observed with certain salts at maximum dilution, we have all the elements for calculating the values of u and v.

The calculation of the velocities of a number of negative ions from observations of their sodium salts shows that for these velocities certain definite relations exist. Isomeric ions have the same velocity within very narrow limits. The examination of homologous series of acids shows very distinctly that as the number of atoms in the ion increases its velocity decreases. The nature of the elements of which the ions are composed influences the velocity, but this is more marked in the case of simple than in that of complex ions. Thus the difference between acetic acid and each of its chlorinated derivatives is very marked, whereas between benzoic and chloro- or bromo-benzoic acids it is hardly perceptible.

If the number of atoms in the anion is greater than 12, the velocity depends almost solely on this number, the differences, as before observed, being smaller and smaller the greater this number is. Hence if the number of atoms, as abscissæ, be plotted against the velocities as ordinates, a curve is obtained having its convex side towards the axis of abscissæ, which it approaches asymptotically, from which the velocity of any ion containing more than 12 atoms may be read off with an error of not more than 1 to 2 units.

Specific Heat of Tellurium. By FABRE (*Ann. Chim. Phys.* [6], **14**, 101—103. Compare Regnault, *Ann. Chim. Phys.* [3], **46**, 280).—The specific heat of a sample of tellurium, precipitated by sulphurous acid, washed with water saturated with nitrogen, and dried in a stream of this gas, was found to be 0·05243 as the average of three experiments at temperatures ranging from 98·01° to 98·39°. The specific heat of the same sample, after having been distilled in a stream of sulphurous anhydride, was found to be 0·05177 as the average of three experiments at 97·62°, 97·7°, and 97·9° respectively. The element as thus obtained differed in appearance from tellurium which has been distilled in hydrogen, and it did not clearly show a crystalline fracture. Crystalline tellurium, prepared by decomposing alkaline tellurides, was washed with water saturated with nitrogen, distilled in an atmosphere of hydrogen, and then melted and cooled very slowly. Its specific heat was found to be 0·048265 as a mean of two experiments at 98·22° and 98·13°.

F. S. K.

Estimation of the Value of a Degree in Thermometers of Short Range. By L. CALDERON (*Ber.*, **21**, 3303—3315).—The method described below was employed for ascertaining very accurately the value of the graduations of a thermometer of short range by direct comparison with a standard thermometer. It is also suitable for determining the exact value of the graduations of thermometers, endiometers, &c., or for accurately measuring the height of the barometer, coefficients of expansion, &c.

If the distance a between two consecutive graduations n^1 and n^2 of a thermometer, between which the end of the mercury column stands, is measured in units sufficiently small, and if the distance p between the lower graduation n^1 and the end of the mercury column is also ascertained, the quotient p/a gives the fraction of the interval a occupied by the column of mercury. If q is the distance between the higher graduation n^2 and the end of the column of mercury, then $q = a - p$, and whatever the value of a, $p + q = a$. The two expressions p/a and q/a, either of which can be employed to control the other, will then give the distances of the mercury column from the two consecutive graduations n^1 and n^2 respectively in fractions of the unit employed.

The instrument employed for making the necessary measurements is a sort of cathetometer, a full description of which is given with the aid of a diagram. The author also describes in detail the *modus operandi*, and gives examples showing with what accuracy the graduations can be controlled. In one experiment with a standard thermometer registering from —0·5° to 100·5°, and divided into tenths of a degree, the distance between the graduations corresponding with 97·8° and 97·9°, was equal to 96 divisions on the micrometer scale of the cathetometer. The thermometer being placed in the vapour of boiling water, the distance from the end of the mercury column to the graduation 97·8° was 75 divisions on the scale; the exact temperature shown by the thermometer was therefore 97·87812°. In a second experiment, the thermometer being placed in melting ice, the distance between 0° and —0·1° was 102 divisions, and that between the end of the column of mercury and the zero point 28 divisions; so that the exact temperature registered was —0·02745°. The value of 1° of this thermometer, all corrections having been made, is therefore 0·999644°. The following day a change of more than 6 mm. having taken place in the height of the barometer, the temperatures registered by the same thermometer under the same conditions were 98·1632° and 0·06061°. The value of 1° after making all necessary corrections was therefore 0·999635°. A series of 16 observations was made in which the thermometer referred to above was compared with an instrument graduated from —0·3° to 14°, and divided into fifteenths of a degree; the mean error of observation was only ±0·004°. F. S. K.

Dilatation of Salt Solutions by Heat. By N. TSCHERNAY (*J. Russ. Chem. Soc.*, 1888, **20**, 430—442).—The author has determined the dilatation of several salt solutions by Marignac's method, using dilatometers the constants of which had been accurately determined previously. The following nitrates were investigated, V_t being volume at t° :—

(1.) $HNO_3 + 50H_2O$ $Vt = 1 + 0{\cdot}0001595t + 0{\cdot}000003699t^2$.
(2.) $LiNO_3 + 50H_2O$ $1 + 0{\cdot}0001471t + 0{\cdot}000003673t^2$.
(3.) $NaNO_3 + 50H_2O$ $1 + 0{\cdot}0002144t + 0{\cdot}000003194t^2$.
(4.) $KNO_3 + 50H_2O$ $1 + 0{\cdot}0001746t + 0{\cdot}000003575t^2$.
(5.) $AgNO_3 + 50H_2O$ $1 + 0{\cdot}0001593t + 0{\cdot}000003587t^2$.
(6.) $Ca(NO_3)_2 + 50H_2O$ $1 + 0{\cdot}0001719t + 0{\cdot}000003531t^2$.

He gives also the coefficients of dilatation dv/dt, the equations for the change of molecular volume with the temperature and the corresponding dilatation coefficients, &c. From a comparison of the different values, it is seen that the above solutions of nitrates have approximately the same dilatation coefficient at temperatures higher than 30°. The dilatation coefficients of molecular volumes are found not to agree when the temperature rises to 50°, and the difference between the numbers corresponding with different salts diminishes very slowly with falling temperature. B. B.

Table of Vapour-tensions of Solutions of Potassium Hydroxide. By G. ERRERA (*Gazzetta*, **18**, 225—231).—This is an elaborate table of vapour-tensions of solutions of potassium hydroxide of various strengths, containing from 1 to 49 parts of the hydroxide to 100 of water. It is an extension of Wüllner's table (*Ann. Phys. Chem.*, **110**, 564) in which the values for the various lacunæ in it are calculated and inserted: the formulæ used for temperatures below 52·84° being $D = 0·003320T - 0·00000432T^2$, and for 52·84° to 100° $D = 0·002863$; in which D indicates the diminution of tension produced by 1 part of the hydrate $KHO,2H_2O$ dissolved in 100 of water, and T the tension of water-vapour at the given temperature.

C. E. G.

Dissociation of Carbonic Anhydride. By H. LE CHATELIER (*Zeit. physikal. Chem.* **2**, 782—786).—The author shows that by aid of the formula $\log P + \log \frac{x^3}{(2+x)(1-x)^2} - 500 \int \frac{2L}{T^2}\, dT = \text{const.}$, the dissociation coefficient x of carbonic anhydride at the temperature T and pressure P may be calculated, L being the molecular heat of formation of carbonic anhydride. The results agree very well with the experiments of the author, Mallard, Crafts, and Deville.

The value of L decreases with rising temperature, and at length becomes equal to zero, when the dissociation coefficient reaches a maximum. This maximum will be smaller the greater the pressure, a result which is in contradiction to the ordinary idea that at a sufficiently high temperature all substances undergo complete dissociation.

H. C.

Rise of Salt Solutions in Capillary Tubes. By M. GOLDSTEIN (*J. Russ. Chem. Soc.*, 1888, **20**, 408—415).—The author has found, as Valson did, that the heights of liquids in capillary tubes are inversely proportional to their densities, so that hd = const. This rule, however, holds good only in the case of very dilute solutions, the value hd growing with increasing concentration. In such a case, the capillary rise of the solution is found to be a function not only of the density, but also of the molecular weight of the salt dissolved. In concentrated solutions containing one and the same percentage of different salts, the height of the column increases with a decreasing molecular weight of the salt dissolved. Inversely, when two different solutions give columns of the same height, that salt, which is in smaller quantity, is sure to have a larger atomic weight. The difference in the height of the column corresponding with an equal difference of

percentages in solution will be nearly the same with salts of the same molecular weight, but larger with increasing molecular weight of the salt in solution. For example, with change of percentage of sodium chloride from 23·4 to 5·8 there is a difference of 2·6 mm. in the height of the column of liquid, whereas for the same change in a solution of potassium chloride the difference in the height of the column is 6·9 mm. The author proposes to investigate in the same way solutions of carbon compounds, and especially solutions of salts containing water of crystallisation.
B. B.

Catalytic Action of Metals on Oxyhydrogen Gas and the Occlusion of Hydrogen. By A. Berliner (*Ann. Phys. Chem.* [2], **35**, 791—810).—The term catalysis was first applied by Berzelius (*Ann. Chim. Phys.*, **37**, 66) to the power shown by certain substances of causing decomposition or other chemical changes in other substances without being themselves affected.

Dulong and Thénard have shown (*Ann. Phys Chem.*, **76**, 81) that all metals and some earths can determine chemical union between oxygen and hydrogen at temperatures below the boiling point of mercury, and in the case of platinum, palladium, rhodium, and iridium, at ordinary temperatures. Faraday has shown (*Ann. Phys. Chem.*, **33**, 149) that the action of platinum on oxyhydrogen gas occurs at ordinary temperatures, only when the surface of the metal is perfectly clean.

Henry (*Phil. Mag.* [3], **6**, 354) and Turner (*Annalen*, **2**, 210) have shown that copper and iron turnings, zinc-foil and wood-carbon have the same effect on oxyhydrogen gas, but only at temperatures not far below the boiling point of mercury, and Loew (*J. pr. Chem.* [2], **11**, 372) has shown that glass begins to act in the same way at about the same temperature.

Berthelot (Abstr., 1882, 1022) pointed out the connection existing between catalytic action and occlusion of hydrogen, and the present paper contains an account of an extensive series of experiments directed to the further elucidation of the subject. The author arrives at the conclusion that these catalytic actions are invariably due to the occlusion of hydrogen, which when occluded always seems to act in the same way as when in the nascent state, as Graham (*Phil. Mag.* [4], **32**, 503) showed conclusively in the case of palladium. The fact that when the metallic surface is not clean catalysis still takes place at high temperatures is attributed by the author to the partial removal of the film of impurity when the temperature is sufficiently increased; this is in accordance with Graham's observation that the largest amount of gas was occluded when the metal was first strongly heated and then allowed to cool in the gas forming the subject of experiment.
G. W. T.

Metallic Lustre. By W. Spring (*Bull. Soc. Chim.*, **50**, 218—221).—When finely powdered bismuth sulphide, copper sulphide, or manganese peroxide are compressed in cylinders, they acquire a metallic lustre, whilst zinc sulphide, mercury oxide, and copper carbonate acquire a vitreous lustre. A microscopic examination showed that the substances which take a metallic lustre form, without exception, opaque powders, and that the compounds which have glazed surfaces are more or less transparent when finely powdered. Between metallic and vitreous lustre there are all degrees corresponding with the various degrees of transparency and opaqueness. The metallic lustre, therefore, does not depend on the chemical but on the physical state of a substance (compare Dove, *Ann. Phys. Chem.*, **83**, 169; Brewster, *Fortschritte d. Phys.*, **8**, 331; and Brücke, *ibid.*, **17**, 313).

N. H. M.

Apparatus for Fractional Distillation in a Vacuum. By J. W. BRÜHL (*Ber.*, **21**, 3339—3342).—The apparatus consists of a cylindrical vessel, closed at the bottom and provided at the top with a ground flange, on to which fits a lid provided with a corresponding flange and two tubulures, one of which is placed in the centre of the lid. Through the centre tubulure, closed by an india-rubber cork, passes a rod by means of which a circular rack containing test-tubes can be rotated in order to bring the tubes in turn immediately under the condenser-tube which passes through the second tubulure, also closed by an india-rubber cork. The cylindrical vessel is provided with a tubulure for connection to a pump.

W. P. W.

Ether Levels. By R. WEBER (*Ber.*, **21**, 3448—3451).—The crystalline figures frequently observed in the ether levels attached to levelling instruments or physical apparatus, are caused by the use of wet ether, and of glass which is readily attacked by water. Three kinds of glass having the composition—

	SiO_2.	Al_2O_3.	CaO.	K_2O.	Na_2O.	Total.
Relatively hard ...	69·00	0·89	12·21	18·52	—	100·62
Relatively soft	65·42	0·93	13·67	19·76	—	99·78
Bonsack glass	69·93	0·94	4·56	7·27	17·30	100·00

were experimented with, and it was found that tubes of Bonsack glass were attacked both by wet and dry ether, and gave crystalline figures within a month of being filled; that tubes of the softer potash glass were also readily attacked by wet ether, but showed only slight indications of crystals after two years when filled with dry ether, whilst tubes of the harder potash glass were also attacked, although more slowly, by wet ether, but remained clear after the lapse of two years when filled with dry ether.

Inorganic Chemistry.

Oxidation of Hydrogen Iodide by Oxy-acids. By O. BURCHARD (*Zeit. physikal. Chem.*, **2**, 796—839).—This paper contains the details of a large number of experiments on the action of chloric, bromic, and iodic acids on hydrogen iodide, with varying concentrations of the solutions, and also in the presence of other acids. Of the above three acids, iodic acid is the one which acts most readily on hydrogen iodide and chloric acid the least. With dilute solutions of iodic acid and hydrogen iodide, a certain period elapses before the reaction sets in, this period increasing, of course, with the dilution and also with the temperature.

It was necessary in studying the reaction, as a time reaction, to neutralise the mixture of both acids at a given moment, without affecting in any way the liberated iodine. This it was found could be done by the addition of acid sodium carbonate to the solution. The carbonate, which is thus introduced in excess, interferes, however, with the estimation of the iodine by means of thiosulphate, but for the latter, sodium hydrogen sulphite may be substituted, the action of which on iodine in solution is represented by $NaHSO_3 + H_2O + I_2 = NaHSO_4 + 2HI$, and is not affected by the presence of the carbonate.

The action of iodic acid on hydrogen iodide is represented by $5HI + HIO_3 = 3H_2O + 3I_2$. For the action of bromic acid, solutions of at least $\frac{1}{1000}$ normal concentration are required, and the action takes place in three stages: (1) $HBrO_3 + 5HI = 3H_2O + Br + 5I$; (2) $Br + HI = HBr + I$; (3) $HBrO_3 + 5HBr = 3H_2O + 3Br_2$. Hence, if there are less than six equivalents of hydrogen iodide to each equivalent of bromic acid present, bromine will be found in the solution at the end of the reaction. For the action of chloric acid, the solutions must be so concentrated, and the time required is so long, that a decomposition of the hydrogen iodide itself occurs, and thus the exact nature of the reaction cannot be ascertained.

None of the ordinary equations satisfy the conditions of the above changes studied as time reactions. The author finds, however, that the time required for the oxidation of a given quantity of hydrogen iodide depends in a similar manner on the concentration, as the action of sulphurous on iodic acid studied by Landolt (Abstr., 1886, 658). An excess of either acid above the equivalent quantities produces an acceleration of the reaction. The presence of other acids, both those which take part in the reaction and those which do not, also causes an acceleration, which in the case of the latter is in proportion to their avidities.

H. C.

Action of Incandescent Platinum on Gases and Vapours.

By W. R. HODGKINSON and F. K. S. LOWNDES (*Chem. News*, **58**, 223—224; compare Abstr., 1889, 20).—It is now shown that iodine monochloride or trichloride, or chlorine in the presence of iodine or iodine bromides, when vaporised and submitted to the action of incandescent platinum wire, in the manner already described, give rise to flames, to mixtures of platinous chloride or bromide and iodide, and in the presence of chlorine to the deposition of crystals of platinum on the hottest part of the wire. In similar experiments with carbon tetrachloride, there is no flame, chlorine is liberated and carbon and carbon sesquichloride are deposited; with phosphorus pentachloride there is flame, but the wire soon becomes alloyed with liberated phosphorus, and, consequently, melts; with hydrochloric acid, platinous chloride is formed; hydrogen fluoride yields a soluble platinum salt; mercurous chloride gives platinous chloride and mercury; phosphorus or arsenic vapour destroys the wire at once, whilst there is no apparent action with mercury, sulphur, nitrogen oxides, or sulphurous anhydride.

D. A. L.

Analysis of Atmospheric Air. By UFFELMANN (*Chem. Centr.*, 1888, 1324—1325, from *Archiv. f. Hygiene*, 8, 262—350).—The carbonic anhydride was determined in a flask of about 2½ to 4 litres capacity. After filling with water, the flask was completely filled with the air under investigation, by running out the water again and allowing it to drain for 10 minutes. 50 c.c. of baryta-water (7 : 1000) was next added, the flask closed with a tight stopper with india-rubber cap, and after shaking for one minute, allowed to remain by itself for 24 hours. The stopper was now replaced by a double-bored one, 60 c.c. of freshly boiled water added to wash down the sides of the flask, and the excess of baryta titrated with oxalic acid from a burette with a very long nozzle, reaching through the stopper down to the liquid at the bottom of the flask. (The oxalic acid = 2·8636 grams per litre.)

The determination of the organic matters of the atmosphere was made by passing a definite quantity of the air through a solution of potassium permanganate, of which 1 c.c. = 0·395 gram $KMnO_4$ (= 0·1 mgrm. = 0·07 c.c. O = 0·7875 mgrm. oxalic acid) and the excess of permanganate determined by oxalic acid. The dust was collected on an asbestos filter and titrated with permanganate according to the method above mentioned. The micro-organisms were determined, after collecting in sterilised water, according to Esmarch's method.

The ammonia was determined by projecting a spray of water against a slanting glass plate at the distance of 1 metre, and titrating with Nessler's reagent.

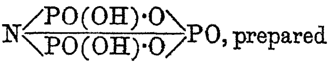
The principal results of a long series of examinations of the atmosphere in the neighbourhood of Rostock are as follows :—(1.) The carbonic anhydride amounted to 3·18 in 10,000 in the open field; the amount increased with land-winds or fog. (2.) The organic matters were equivalent to 2·71 c.c. oxygen per 1,000,000 vols. of air in the open field; this amount varied very greatly, it being decidedly less after continued rain. (3.) The amount of organic matter in the air at the sea-coast was found to be but one-third of that found 12 kilometres inland. (4.) The air of the Rostock University yard contained one-tenth more carbonic anhydride and one-third more organic matter than the air of the open fields. (5.) The air in the open fields near Rostock contained, on the average, 250 micro-organisms per cubic metre, that of the university yard 450, whilst the air on the sea-coast contained but 100 per cubic metre; these quantities being less after continued rain and greater during fog. (6.) The amount of carbonic anhydride in cellars depends greatly on the barometric pressure, and varies inversely as the height of the barometer. (7.) The air of cellars contained spores of fungi. (8.) The air of house sewers was found to be but little richer in organic matter than that of well ventilated rooms, and contained but few germs. (9.) Atmospheric air may be considered impure when it contains so much oxidisable organic matters that in 1,000,000 vols. 12 or more vols. of oxygen are required in the permanganate test. J. W. L.

Hydrogen Telluride. By BERTHELOT and FABRE (*Ann. Chim. Phys.* [6], **14**, 103—106).—Pure hydrogen telluride (compare Bineau, *Ann. Chim. Phys.* [2], **47**, 232) can be prepared by treating magnesium telluride with very dilute hydrochloric acid in an atmosphere of nitrogen. The gas thus obtained is completely and rapidly absorbed by alkalis, yielding white or colourless, crystalline tellurides which dissolve in pure water, forming colourless solutions; if, however, a trace of oxygen is present, violet or purple solutions are produced, and, with a large excess of oxygen, metallic tellurium is immediately precipitated. It is very unstable; when kept over dry mercury, it decomposes in a few hours, even in the dark, but in presence of moist air decomposition is instantaneous. The smell of hydrogen telluride differs considerably from that of hydrogen sulphide or selenide, and when the gas is inhaled the effects produced are far less disagreeable than in the case of the latter. The magnesium telluride referred to above is prepared by the action of excess of tellurium vapour on heated magnesium in an atmosphere of pure, dry hydrogen. It is a white substance, which quickly darkens on exposure to the air, and dissolves in water, forming a blackish-purple solution, owing to the presence of oxygen; it dissolves in water saturated with nitrogen, yielding an almost colourless solution. F. S. K.

Amides of Phosphorus and Sulphur. By A. MENTE (*Annalen*, **248**, 232—269).—Gladstone (this Journal, 1864, 225; 1866, 1 and 290; 1868, 64 and 261, and 1869, 55) obtained a series of compounds by the action of gaseous ammonia on phosphorus oxychloride, which he regarded as amic acids of pyrophosphoric or tetraphosphoric acid. The author considers that these compounds are *imido*-acids. *Imidodiphosphoric acid*, $NH<\substack{PO(OH)\\PO(OH)}>O$ (Gladstone's pyrophosphamic acid), can be prepared by the action of ammonium carbamate on phosphorus oxychloride. The product is dissolved in water containing hydrochloric acid, and the acid is precipitated in the form of the barium or iron salt by the addition of barium or ferric chloride. The *barium* salt contains 1 mol. H_2O.

Di-imidodiphosphoric acid, $NH<\substack{PO(OH)\\PO(OH)}>NH$, is best prepared by adding phosphorus oxychloride diluted with 10 times its volume of benzene to excess of ammonium carbamate. The barium salt is sparingly soluble in water and is anhydrous. A basic sodium salt, $NaN{:}P_2O_2(ONa)_2{:}NH$, is known.

Di-imidodiphosphormonamic acid (pyrophosphotriamic acid), $NH<\substack{PO(NH_2)\\PO(OH)}>NH$, is an insoluble, white powder, obtained by saturating phosphorus oxychloride with ammonia at 100°, and washing the product with water. The acid is decomposed by boiling with sodium hydroxide, yielding the basic sodium salt of di-imidodiphosphoric acid. Silver nitrate gives. with neutral solutions of the acid, the monobasic silver salt, $P_2O_2(NH)_2(NH_2)\cdot OAg$, with ammoniacal solutions a salt of the formula $NAg{:}P_2O_2(NAg)_2(NH_2)\cdot OAg$. The salts of this acid have already been described by Gladstone (*loc. cit.*).



Nitroltrimetaphosphoric acid, $N\begin{matrix}\diagup PO(OH)\cdot O \diagdown \\ \diagdown PO(OH)\cdot O \diagup\end{matrix}PO$, prepared by heating imidodiphosphoric chloride, $NH(POCl_2)_2$, at 290°, yields an insoluble *barium* salt, $NP_3O_7Ba + H_2O$. The *calcium* and ferric salts are insoluble, even in strong acid. Most of the metallic salts are insoluble in water but dissolve in acids. Neither the acid itself nor the salts of the alkali metals have been obtained in a crystalline form.

Ammonium imidosulphonate, $NH(SO_2\cdot ONH_4)_2$, is formed by the action of ammonium carbamate on sulphuryl chloride, pyrosulphuryl chloride, or sulphuric monochlorhydrin. Ammonium chloride is removed by digesting with alcohol, and the residue is recrystallised from water. The compound crystallises in the monoclinic system, and its sp. gr. is 1·965. *Imidosulphurylamide*, $NH(SO_2NH_2)_2$, is the first product of the action of ammonium carbamate on pyrosulphuryl chloride. It is decomposed by water, yielding ammonium imidosulphonate. The amide forms beautiful crystals, and is freely soluble in water. W. C. W.

Allotropic Arsenic. Reply to Geuther. By Engel (*Bull. Soc. Chim.*, **50**, 194—197).—Several new determinations of the specific gravity of allotropic arsenic gave the mean 4·6, which is the same number as that previously obtained (compare Geuther, Abstr., 1887, 888). The ratio of the densities of crystalline and allotropic arsenic is 1·245, and is practically the same as the ratio of white and red phosphorus = 1·244. The molecular constitution of the two modifications of arsenic seems to be the same as that of the corresponding modifications of phosphorus. N. H. M.

Action of Ammonia and Amines on Arsenious Bromide. By W. Landau (*Chem. Centr.*, 1888, 1354—1355).—By passing dry ammonia into a solution of arsenious bromide and benzene, the compound $2AsBr_3,7NH_3$ was formed. *Ethylamine* forms the compound $AsBr_3,4NH_2Et + H_2O$, melting at 152°. *Dipropylamine* forms with it the compound $AsBr_3,4NHPr_2 + H_2O$, melting at 258°. The *trimethylamine*-derivative, $AsBr_3,3NMe_3$, melts at 235°. The compound from *triethylamine*, $AsBr_3,3NEt_3$, melts at 242°. The *aniline* compound, $AsBr_3,3NH_2Ph + H_2O$, becomes changed into $AsBr_3,4NH_2Ph + H_2O$, by treatment with absolute alcohol or glacial acetic acid. *Diphenylamine arsenious bromide*, $AsBr_3,3NHPh_2 + H_2O$, melts at 140°, and becomes changed, like the aniline compound, by the action of alcohol or acetic acid into a compound melting at 230°. The *quinoline* compound, $AsBr_3,C_9NH_7,HBr$, melts at 137°. The *triethylphosphine*-derivative, $AsBr_3,PEt_3,HBr$, melts at 65°. J. W. L.

Preparation of Boron and Silicon. By S. G. Rawson (*Chem. News*, 58, 283).—A mixture of 3·5 grams of boric anhydride and

11 grams of calcium fluoride, is gently heated with concentrated sulphuric acid; the boron fluoride evolved is passed over heated potassium contained in a series of bulbs. Potassium fluoride and boron are formed, and are easily separated by washing with water. Amorphous silicon may be prepared in a similar manner. D. A. L.

Preparation of Silicon. By H. N. WARREN (*Chem. News*, **58**, 215—216).—The author prepares amorphous silicon by passing silicon fluoride over metallic magnesium heated in a combustion tube. Among the other products of the reaction is a magnesium silicide, and by the action of concentrated acids on this, a gas is evolved, which takes fire spontaneously in the air with explosive violence; with feeble acids the gas is not spontaneously inflammable. Owing to the difficulty of eliminating free hydrogen from this gas, its exact composition could not be ascertained; it, however, appears to be a mixture of solid, liquid, and gaseous silicon hydride. D. A. L.

Effect of High Temperature and Pressure on Carbon. By C. A. PARSONS (*Proc. Roy. Soc.*, **44**, 320—323).—Carbon rods were surrounded by benzene, paraffin, treacle, chloride or bisulphide of carbon, and submitted to great pressure in a hydraulic press, the rods being meantime heated by passing an electric current through them. In some cases a considerable amount of gas was evolved, and a soft friable deposit of carbon produced. In no case was the density of the carbon increased. When the rod was surrounded with silica, the latter fused, and the rod was largely converted into graphite; the same occurred with hydrated alumina in lime or magnesia, the rod being rapidly destroyed with evolution of gas. With layers of coke, lime, and silica, the rod was rapidly corroded, and was found after the experiment to be coated with a coke-like layer of great hardness, sufficient to scratch rock-crystal and ruby, and to wear down the cut facets of a diamond. It resists the action of a mixture of hydrofluoric and nitric acids. The conditions of temperature and pressure with presence of moisture, lime, and silica, resemble those which appear to have existed in the craters of the Cape diamond mines. The part played by the lime and silica is not clear. H. K. T.

Formation of Carbon Oxysulphide by the Action of Carbon Bisulphide on Clay. By A. GAUTIER (*Compt. rend.*, **107**, 911—913).—Kaolin previously heated to incipient redness is packed into a large porcelain tube, which is then heated to bright redness, whilst carbon bisulphide vapour is passed through it. The gas which issues from the tube contains 60—64 per cent. of carbon oxysulphide, 35—39 per cent. of carbonic oxide, about 1 per cent. of carbonic anhydride, and traces of hydrogen sulphide, mixed of course with excess of carbon bisulphide vapour. The proportion of carbonic oxide is lower, and the proportion of oxysulphide higher the higher the temperature. The products are passed into a flask half filled with ice-cold water, which condenses the greater part of the bisulphide; then through potassium hydroxide, which absorbs hydrogen sulphide and carbonic anhydride; then through acidified cuprous chloride, which absorbs carbonic oxide, and finally through a 12 per cent. solution of aniline in alcohol, and over pumice and sulphuric acid. Alcoholic aniline has no action on carbon oxysulphide, but readily absorbs carbon bisulphide.

The properties of pure carbon oxysulphide agree mainly with the ordinary description. It has a very faint, somewhat ethereal alliaceous odour. Carbon oxysulphide, as Berthelot observed, combines slowly with ammonia, forming yellow crystals of ammonium oxythiocarbamate, which is decomposed by water. Sodium hydroxide slowly absorbs the gas, and a 35 per cent. solution in contact with excess of the gas yields pale-yellow tabular and acicular crystals of a thiocarbonate, which is decomposed by water, as indicated by the equation $2NaHCSO_2 + H_2O = NaHCO_3 + NaHS + CO_2 + H_2S$.

When carbon oxysulphide is prepared by the action of carbon bisulphide on an oxide, alumina gives the best results, but it becomes too finely divided, and is difficult to manage. It must be heated to a white heat, since even at a cherry-red heat the yield is small. If, however, sulphur vapour is passed over a mixture of alumina and carbon heated to bright redness, almost pure carbon oxysulphide is obtained. Frémy observed that when carbon bisulphide is passed over heated oxides of lead, zinc, iron, and copper, crystalline sulphides are formed. The author finds that only in the case of zinc oxide is any notable quantity of carbon oxysulphide obtained.

After carbon bisulphide has been passed over kaolin, the tube contains brilliant, acicular crystals of silicon sulphide, and somewhat large, hard, lozenge-shaped crystals, which evolve hydrogen sulphide when moistened, and are slowly decomposed by water into alumina and gelatinous silica. They consist of a kind of thiosilicate, some of the oxygen in the kaolin having been replaced by sulphur, whilst some of the silicon has been removed in the form of sulphide.

C. H. B.

Alkaline Aluminates. By K. J. Bayer (*Chem. Zeit.*, **12**, 1209—1210).—When the product of the ignition of alumina and soda in the molecular proportions 1 : 1 is treated with water, pure hydrated alumina, $Al_2O_3,3H_2O$, is spontaneously and continuously deposited until the solution contains alumina and sodium hydroxide in the proportions of 1 mol. of the former to 6 mols. of the latter; the decomposition then proceeds no further, and the solution remains clear. If instead of water a solution of sodium hydroxide, containing as much sodium as is already present in the ignited mixture is employed, then the solution remains quite clear, whether warm or cold, or at rest or in motion, provided it is protected from carbonic anhydride; but in the presence of this gas, or of spontaneously deposited hydrated alumina, this solution behaves in the manner already described. Neither pulverised glass, nor sand, nor granite powder, nor even ordinary gelatinous alumina can initiate this decomposition. If the solutions contain sodium salts with alkaline reaction, the sodium determined by titration is somewhat higher, but the precipitated alumina is always pure. Potassium aluminate behaves in a similar manner. In explanation of these results, the author suggests that the $Al_2O_3,2Na_2O$ and $Al_2O_3,6Na_2O$ are really chemical compounds.

and therefore with the compounds Al_2O_3,Na_2O and $Al_2O_3,3Na_2O$ would indicate the existence of four different alkaline aluminates.

D. A. L.

Porcelain Glazes. By C. Lauth and G. Dutailly (*Bull. Soc. Chim.*, **50**, 221—251).—The first part of the paper contains the results of experiments made with colourless glazes, which are divided into three classes:—(1.) Silicates of a single base associated with silica and alumina. (2.) Silicates of two bases, associated with silica and alumina. (3.) Silicates of several bases together, associated with silica and alumina. In the second part of the paper, experiments with various coloured glazes are described. N. H. M.

Cause of Rails Rusting less Quickly when in Use than when not. By W. Spring (*Bull. Soc. Chim.*, **50**, 215—218).—The preservation of rails, when in use, from rust is not the result of vibratory movement, or of an electric action due to the passage of trains, but is due to the superficial formation of the magnetic oxide produced by the compression of the rust on the metal.

N. H. M.

A Crystalline Subsulphide of Iron and Nickel. By J. B. Mackintosh (*Chem. News*, **58**, 200).—A compound approximating in composition to the formula Fe_4Ni_2S, has been found in fern-like aggregations of small cubical crystals in the cavities in the concretions in the hearth of a shaft furnace used for smelting roasted nickeliferous pyrrhotite. The author's analytical numbers are: Cu 2·20; Ni,Co 26·16; Fe 61·685; S 8·305; SiO_2 0·56; total, 98·91; deficiency and silica being due to adherent slag. D. A. L.

New Fluorine Compounds of Vanadium. By A. Piccini and G. Giorgis (*Gazzetta*, **18**, 186—194).—On dissolving ammonium metavanadate in aqueous hydrofluoric acid and treating the hot liquid with sulphurous anhydride, a blue liquid is obtained, which on neutralising with ammonia and adding ammonium fluoride, yields a bluish, crystalline precipitate. This is collected, washed with a little water, and recrystallised from water; at first monoclinic prisms having the composition of Baker's salt (Trans., 1879, 760) separate, and then small, blue, lustrous crystals; these are monometric octahedra, which dissolve easily in water, yielding a blue solution, from which the salt separates again on the addition of ammonium fluoride. On analysis, it gave results corresponding with the formula $VOF_2,3NH_4F$. The author calls it *octahedral ammonium hydrofluoroxyvanadate*. When dissolved in concentrated hydrofluoric acid and allowed to remain for some days, it deposits crystals of Baker's salt, $VOF_2,2NH_4F + H_2O$. The new salt is also formed at the negative pole, when a solution of ammonium metavanadate, acidified with hydrofluoric acid and mixed with ammonium fluoride, is submitted to electrolysis; or when the mixture is reduced by alcohol. In the latter case, however, the mother-liquors, if exposed to the air after the hydrofluoroxyvanadate has been deposited, yield yellow, octahedral crystals of the composition $VO_2F,3NH_4F$. These can be obtained more easily by dissolving vanadic acid in excess of hydrofluoric acid, and carefully neutralising with ammonia while the liquid is still warm. On cooling, an abundant deposit of the crystals is obtained; care must be taken not to add any great excess of ammonia, otherwise colourless crystals of ammonium vanadate alone will separate.

By adding potassium hydrogen fluoride to a solution of ammonium metavanadate reduced by sulphurous anhydride, and evaporating the blue solution, the author obtained sky-blue, crystalline crusts, of the composition $VOF_2,2KCl$.

The remainder of the paper is devoted to theoretical consideration of the crystallographic connection of various isomorphous fluorides, the author drawing especial attention to the fact that the four compounds $VO_2F,3NH_4F$, $VOF_2,3NH_4F$, $FeF_3,3NH_4F$, and $CrF_3,3NH_4F$, all crystallise in the monometric system in cubes or octahedra, and all contain the same number of atoms. C. E. G.

Mineralogical Chemistry.

A Remarkable Bed of Sulphur. By PREUSSNER (*Chem. Centr.*, 1888, 1339—1340, from *Zeit. deut. geol. Gess.*, **40**, 184—187).—In 1869, when oil was being bored for, an unusually large bed of sulphur was found in Louisiana, one mile from the South Pacific Coast, eight miles from Calcasieu River. Since 1886 four borings have been made, all close together, and with very similar results. The following structure was met with during the first of these:—

	Thickness of bed. feet.	Depth. feet.
Yellow and blue clay	160	160
Grey and yellow sand	173	233
Rock	2	235
Blue sandy limestone	48	383
White soft limestone	60	443
Pure sulphur	108	551
Sulphur accompanying gypsum	99	650
Pure sulphur	6	656
Sulphur accompanying gypsum	24	680
Gypsum rich in sulphur	440	1130
Sulphur accompanying gypsum	100	1230

J. W. L.

Arsenopyrite from Servia. By J. LOCZKA (*Zeit. Kryst. Min.*, **15**, 40—41).—The crystals analysed by the author had the following percentage composition:—

S.	Sb.	As.	Fe.	Zn.	Insoluble.	Total.
21·71	0·14	42·38	34·58	0·46	0·22	99·49

The insoluble residue consists of silica with a trace of calcium. The sp. gr. of the mineral is 6·0594. B. H. B.

Constitution of Arsenopyrite. By J. LOCZKA (*Zeit. Kryst. Min.*, **15**, 41—42).—When heated without access of air, arsenopyrite loses much of its arsenic, the loss amounting to 40·55 per cent. The author has made a series of experiments to ascertain the chemical changes that take place when arsenopyrite is heated, and concludes that in this mineral an iron sulphide must be present, which loses when heated a portion of its sulphur. The latter then renders the arsenic free by combining as iron sulphide with the iron that was present in combination with arsenic. As analysis shows the composition of arsenopyrite to correspond with the ratio 1Fe : 2S,1Fe : 2As, it must be supposed that this iron sulphide is FeS_2, and consequently that arsenopyrite consists of $FeAs_2$ and FeS_2. The decomposition brought about by the action of heat may be illustrated by the following equations:—(1.) $FeAs_2 + FeS_2 = FeS + S + FeAs_2$. (2.) $FeAs_2 + S = FeS + 2As$. (3.) $FeAs_2 + FeS_2 = 2FeS + 2As$.

B. H. B.

Periclase from Nordmarken. By A. SJÖGREN (*Zeit. Kryst. Min.*, **15**, 106, from *Geol. Fören. Förh.*, **9**, 527).—Periclase occurs with hausmannite in large and small grains in a bed of limestone in a manganese mine in Nordmarken. The mineral is colourless and transparent, but is usually coloured green by admixed minerals. Analysis gave the following results:—

MgO.	MnO.	ZnO.	FeO.	Total.
87·38	9·00	2·52	0·19	99·09

B. H. B.

Psilomelane. By G. LANGHAUS (*Jahrb. f. Min.*, i, Ref., 16—17).—The author has analysed three varieties of psilomelane with the following results:—

	BaO.	CaO.	MgO.	K_2O.	Na_2O.	H_2O.	Al_2O_3.	Fe_2O_3.
I.	0·61	1·18	0·52	2·59	0·18	3·06	1·16	0·37
II.	6·50	0·52	0·66	2·17	0·76	3·90	0·87	0·49
III.	6·43	1·33	0·21	1·89	0·69	3·10	1·10	0·50

MnO.	O.	SiO_2.	Insoluble.
74·37	15·06	0·38	0·21
69·76	13·93	2·72	0·24
67·29	12·19	3·12	2·47

Traces of CoO, NiO, CuO, PbO were also observed in each case, and of Li_2O in II and III. The varieties analysed were obtained (I) from the Volle Rose mine, Mittelberg, in the Duchy of Gotha, (II) from the Heinrichsglück mine, Rumpelsberg, Gotha, and (III) from Eisenbach, near Neustadt, in the Black Forest. Qualitative analyses of psilomelane from other mines in the Duchy of Gotha led to similar results. The author calculates the formula of psilomelane to be H_2MnO_3.

B. H. B.

Analyses of Monazite and Xenotime. By C. W. Blomstrand (*Zeit. Kryst. Min.*, 15, 99—103, from *Geol. Fören. Förh.*, 9, 160).—The author gives the results of the analyses of nine specimens of monazite from Norway. The localities from which the specimens were derived were Moss, Dillingsö, Lönneby, Arendal, Narestö, and Hvalö. The analyses show that monazites are normal salts of tribasic phosphoric acid. There is, however, an excess of bases, which appear to be in combination with silica. The general formula of these minerals is therefore $m(3RO,P_2O_5) + 2RO,SiO_2 + pH_2O$, in which m is between 5 and 20, and p usually less than 1. The author's conclusion is that monazites are normal cerium and thorium phosphates, in which a portion of the phosphoric acid is replaced by silica. This view is not in accord with that of Penfield, who regards monazites as cerium phosphates with mechanically admixed thorite. In an appendix, the author gives two analyses of xenotime from Hvalö and Narestö, and concludes that the composition of this mineral is similar to that of monazite. B. H. B.

Sulphohalite, a New Sodium Sulphato-chloride. By W. E. Hidden and J. B. Mackintosh (*Amer. J. Sci.*, 36, 463—464).—This mineral belongs to the regular system, and occurs in rhombic dodecahedra. It is transparent, with a faint yellow colour. Its sp. gr. is 2·489, and its hardness 3·5. Analysis yielded the following results:—

Cl.	SO_3.	Na_2CO_3.
13·12	42·48	1·77

The formula is $3Na_2SO_4,2NaCl$. Excepting the very rare Cornish mineral connellite, no other species is known of analogous composition. The mineral was found with hanksite at Borax Lake, San Bernardino Co., California. Only three examples are known, and two of these are in the collection of C. S. Bement, of Philadelphia. The authors propose for this new mineral the name of sulphohalite as indicating its remarkable composition.

B. H. B.

Allactite from Långban. By A. Sjögren (*Zeit. Kryst. Min.*, 15, 106—107, from *Öfvers. Vet. Akad. Förh.*, 1887, 107).—This mineral occurs, with a manganiferous barytes, calcite, and a mineral resembling aphrodite, at the Collegii mine at Långban. It resembles the allactite found at Nordmarken. On analysis, it gave the following results:—

As_2O_5.	MnO.	CaO.	MgO.	H_2O.	Total.
29·00	58·87	1·77	1·35	9·00	99·99

B. H. B.

Pyrrhoarsenite and Berzeliite. By A. G. Högbom (*Zeit. Kryst. Min.*, 15, 105—106, from *Geol. Fören. Förh.*, 9, 397).—Two specimens of pyrrhoarsenite were analysed; one being the usual orange variety (1), and the other a purer yellow, transparent variety (II) having a sp. gr. of 4·01. Both contained admixed barytes and calcite. The berzeliite (III) examined was a honey-yellow isotropic variety from Långban.

	CO_2.	$BaSO_4$.	FeO.	MnO.	CaO.	MgO.	As_2O_5.	Sb_2O_5.	Total.
I.	1·27	3·96	trace	19·18	18·35	3·50	50·92	2·60	99·78
II.	1·58	1·36	—	14·12	18·54	7·53	53·39	2·90	99·42

B. H. B.

Pyrrhoarsenite and other Swedish Antimoniates. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1888, i, Mem., 48—53).—The bright straw-yellow anhydrous arsenate from the Sjö mine, in the parish of Grthyttan, Örebro, Sweden, is undoubtedly pyrrhoarsenite, but with double the amount of antimonic acid contained in the yellow variety (Analysis II) discovered by Högbom in 1885. The analysis gave the following results (I) :—

	As_2O_5.	Sb_2O_5.	CaO.	MnO.	MgO.	Total.
I.	53·23	6·54	20·21	10·82	9·20	100·00
II.	56·40	3·07	17·50	15·03	8·00	100·00

The author considers the formulæ of the antimoniates and antimonio-arsenates hitherto found in Sweden to be as follows :—

Pyrrhoarsenite (type I, analysed by Högbom), $20(Ca,Mg,Mn)_3As_2O_8 + Ca_2Sb_2O_7$.

Pyrrhoarsenite (type II, analysed by the author), $10(Ca,Mg,Mn)_3As_2O_8 + Ca_2Sb_2O_7$.

Polyarsenite (Abstr., 1887, 347), $40H_2Mn_4As_2O_{10} + (Ca,Mg)_2Sb_2O_7$.

Xanthoarsenite (Abstr., 1886, 25), $16(Mn,Mg,Fe,Ca,H_2)_{10}As_2O_{15} + (Ca,Mg)_2Sb_2O_7$.

Manganostibiite, $2(Mn,Fe,Ca,Mg)_3As_2O_8 + 5(Mn,Fe,Mg)_{10}Sb_2O_{15}$.

Hæmatostibiite, $Mg_2Sb_2O_7 + 5(Mn,Fe)_{10}Sb_2O_{15}$.

Atopite, $(Ca,Na_2,Fe,Mn,K_2)_2Sb_2O_7$.

Monimolite, type I (Nordenskiöld), $Pb_3Sb_2O_8$; type I (Igelström), $(Pb,Fe,Ca,Mg)_4Sb_2O_9$; type II (Flink) $(Pb,Fe,Mn)_3Sb_2O_8$.

(Compare Abstr., 1888, 565.) B. H. B.

Thioantimonites from Colorado. By L. G. EAKINS (*Amer. J. Sci.*, **36**, 450—453).—The author gives the results of the analyses of two thioantimonites from Gunnison Co., Colorado. The first (Analysis I) was found in the Domingo mine, on the ridge between Dark Cañon and Baxter Basin. It consists of aggregates of small, acicular crystals, forming wool-like masses in the cavities of a highly decomposed siliceous gangue. It is dull, greyish-black in colour, and no crystalline form could be distinguished. Its formula is $3(Pb,Fe)S,2Sb_2S_3$. The second specimen was found at a mine on Augusta Mountain. It occurs in a siliceous gangue with iron pyrites and zinc blende, and forms groups of acicular crystals, which are deeply striated, elongated prisms. Its formula is $5PbS,2Sb_2S_3$. It thus appears to be a freieslebenite in which the silver has been completely replaced by lead. The analytical results were as follows :—

	Ag.	Cu.	Pb.	Fe.	Mn.	Sb.	S.	Insoluble.	Total.
I.	Trace	trace	39·33	1·77	trace	36·34	21·19	0·52	99·15
II.	Trace	—	55·52	trace	—	25·99	18·98	—	100·49

B. H. B.

Hjelmite. By M. Weibull (*Zeit. Kryst. Min.*, **15**, 104—105, from *Geol. Fören. Förh.*, **9**, 371).—This mineral crystallises in the rhombic system, the axial ratio being $a : b : c = 0·465 : 1 : 1·026$. The specimens examined were considerably altered, and were seen under the microscope to consist of an amorphous substance containing black metallic grains of unaltered hjelmite. Analysis gave results corresponding with the formula $4RO,3R_2O_5 + 2H_2O$.

B. H. B.

Eudidymite. By A. E. Nordenskiöld (*Zeit. Kryst. Min.*, **15**, 107—108, from *Geol. Fören. Förh.*, **9**, 434).—Eudidymite was discovered in 1887 in the Island of Upper Arö in the Langesundsfjörd. According to Brögger it is monoclinic, with the axial ratio of $a : b : c = 1·71069 : 1 : 1·107113$; $\beta = 86° 14' 27''$. Analysis gave the following results:—

SiO_2.	BeO.	Na_2O.	H_2O.	Total.
73·11	10·62	12·24	3·79	99·76

B. H. B.

Analysis of Natrolite. By G. Lindström (*Zeit. Kryst. Min.*, **15**, 108, from *Geol. Fören. Förh.*, **9**, 434).—This analysis was made in order to determine whether the so-called brevicite that accompanies the eudidymite of Arö (see preceding Abstract) also contained beryllium. This was, however, not the case. The analytical results were as follows:—

SiO_2.	Al_2O_3.	Na_2O.	K_2O.	H_2O.	Total.
47·92	26·80	16·25	0·26	9·51	100·74

B. H. B.

Hyalotekite from Langban. By G. Lindström (*Zeit. Kryst. Min.*, **15**, 96—97, from *Öfvers. Sv. Vet. Förh.*, 1887, 589).—The hyalotekite described by Nordenskiöld has been analysed by the author with the following results:—

SiO_2.	PbO.	BaO.	CaO.	CuO.	MnO.	BeO.	MgO.	K_2O.	Na_2O.
39·47	25·11	20·08	7·82	0·09	0·29	0·75	0·09	0·89	0·17

Al_2O_3.	Fe_2O_3.	B_2O_3.	F.	Cl.	Ignition.	Total.
0·18	0·06	3·73	0·99	0·06	0·59	100·37

The formula deduced from these results is $12(RO,2SiO_2) + 3RO,2B_2O_3 + RF$ B. H. B.

Gadolinite. By C. Rammelsberg (*Jahrb. f. Min.*, 1889, i, Ref., 25—26, from *Sitzb. preuss. Akad. Wiss.*, 1887, 553).—The author has analysed specimens of gadolinite from Hitterö (I) and from Ytterby (II) with the following results:—

	SiO_2.	Y_2O_3.	Ce_2O_3.	Fe_2O_3.	FeO.	BeO.	CaO.	Loss on ignition.	Total.
I.	24·36	45·51	7·01	2·85	11·50	8·58	0·36	0·50	100·67
II.	25·35	38·13	13·55	4·07	7·47	10·03	0·57	1·34	100·51

The gadolinite from Hitterö occurs in large, black crystals; sp. gr. 4·448 to 4·490; that from Ytterby has a vitreous or amorphous nature, and brilliant lustre; sp. gr. 4·212. The formula of both varieties is $R''_5R'''_2Si_4O_{19}$. Gadolinite thus approaches datolite and euclase in composition.

B. H. B.

Mineralogical Notes. By A. E. NORDENSKIÖLD (*Zeit. Kryst. Min.*, **15**, 97—98, from *Geol. Fören. Förh.*, **9**, 26).—1. *Alvite and Anderbergite.*—Alvite from Alve, near Arendal, gave on analysis the following results:—

SiO_2.	Metallic* acids.	PbO.	Fe_2O_3.	MnO.	Ce_2O_3.	Y_2O_3.	BeO with some Al_2O_3.
26·10	2·78	0·45	5·51	0·27	3·27	1·03	14·73

ZrO_2.	CaO.	MgO.	Loss on ignition.	Total.
32·48	2·44	1·05	8·84	98·95

This mineral is absent from the felspar mines of the pegmatite veins. It is, however, replaced by a somewhat similar mineral, which the author regarded as cyrtolite, but which Blomstrand claims to be a new species to which the name of anderbergite should be given. (See following Abstract.)

2. An analysis of monoclinic crystals of hydrargillite from Langesund in Norway, gave the following results:—

Al_2O_3.	SiO_2.	H_2O.	Total.
65·90	0·43	33·57	99·90

3. *Diaspore from Horrsjöberg in Wermland.*—An analysis of this mineral, supposed to be identical with Igelström's new mineral "empholite," gave, when corrected for admixed cyanite and pyrophyllite, 84·32 per cent. of alumina and 15·68 per cent. of water.

B. H. B.

The so-called Cyrtolite of Ytterby. By C. W. BLOMSTRAND (*Zeit. Kryst. Min.*, **15**, 83, from *Sv. Vet. Akad. Handl.*, **12**, 1—10).—Four analyses of massive somewhat impure material gave the following mean results:—

SiO_2.	ZrO_2.	Y_2O_3.	Ce_2O_3.	FeO.	CaO.	MgO.	CuO.	Na_2O.	H_2O.	Total.
26·93	41·17	10·93	trace	1·54	5·85	trace	0·17	0·89	12·55	100·03

The results were obtained after 10·51 per cent. of phosphates, &c., regarded as impurities, had been subtracted. The formula is $R_3Y_2Zr_9(SiO_4)_{12} + 18H_2O$. The analysis agrees so well with that of crystals by Nordenskiöld, that the author cannot regard the mineral merely as an altered zircon, but considers it a distinct mineral species.

---

* Metallsaüre.

and, as its composition differs considerably from that of the American cyrtolite, proposes for it the name of *Anderbergite*. B. H. B.

Swedish Minerals. By G. Flink (*Zeit. Kryst. Min.*, **15**, 88—92, from *Sv. Vet. Akad. Handl.*, **13**, 1—94).—1. The author gives the following new analysis of manganese-epidote:—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MnO.	H_2O.	Total.
36·44	24·65	12·44	19·52	4·52	3·19	100·76

The crystals of this mineral occur with titanite, barytes, and manganophyll in fissures filled with calcite, in a matrix consisting of berzeliite, calcite, and manganese-epidote. On the crystals, the author has determined the following new forms: $0P$, $\infty\bar{P}\infty$, $\frac{1}{2}\bar{P}\infty$, $\bar{P}\infty$, $-\frac{1}{2}\bar{P}\infty$, ∞P, $\infty\grave{P}2$, P, $\grave{P}\infty$. With regard to its composition and most of its optical properties, manganese-epidote forms a link between ordinary epidote and piemontite.

2. Manganophyll occurs at Långban in small copper-coloured scales intimately mixed with magnetite and iron-glance, as well as in crystals with tephroite and magnetite in fissures filled with calcite. The analysis gave the following results:—

SiO_2.	F.	MgO.	MnO.	Fe_2O_3.	Al_2O_3.	K_2O.	Na_2O.	H_2O.	Total.
41·36	0·49	13·27	5·41	4·66	16·02	11·43	2·09	4·62	99·33

Manganophyll is thus shown to differ considerably from all the micas hitherto described.

3. The author gives the following analyses of (I) hornblende and (II) grammatite from Nordmarken:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	MgO.	CaO.	Total.
I.	49·81	7·83	8·90	13·89	0·95	4·75	12·89	99·82
II.	55·77	—	—	2·95	—	24·73	15·92	99·37

The hornblende seems to contain of 50 per cent. $Ca(Fe,Mg,Mn)_3Si_4O_{12}$, 37·5 per cent. $Ca(Al,Fe)_2Si_4O_{12}$, and 12·5 per cent. $Ca(Al,Fe)_2SiO_6$. Of these compounds, the first is the ordinary actinolite-silicate, whilst the two others have not hitherto been identified in the hornblende series. The formula of the grammatite is $Ca(Mg,Fe)_3Si_4O_{12}$.

B. H. B.

Auerlite, a new Thorium Mineral. By W. E. Hidden and J. B. Mackintosh (*Amer. J. Sci.*, **36**, 461—463).—This mineral has hitherto been found at only two places in Henderson Co., North Carolina, namely, at the Freeman mine, and on the Price land, three miles to the south-west. At both places it occurs in disintegrated granitic or gneissic rock, intimately associated with zircon crystals, on which it is often seen implanted. The crystals are tetragonal, lemon-yellow to brown-red in colour, and sub-translucent to opaque. The mineral is very brittle; its hardness is 2·5 to 3, and its sp. gr. 4·422 to 4·766, the darker crystals having the greatest density. Analysis gave the following results:—

H_2O.	CO_2.	SiO_2.	P_2O_5.	ThO_2.	Fe_2O_3.	CaO.	MgO.	Al_2O_3.	Total.
10·21	1·00	7·64	7·46	70·13	1·38	0·49	0·29	1·10	99·70

The formula is $ThO_2,SiO_2,\frac{1}{3}P_2O_5,2H_2O$, or that of a thorite in which part of the silica is replaced by phosphoric acid. As this mineral was found while mining the zircons necessary to supply the demand caused by the invention of the system of incandescent gas-lighting of Carl Auer v. Welsbach, the authors propose to name it *Auerlite* in his honour. B. H. B.

Phosphatic Deposits at Montay and Forest. By J. LADRIÈRE (*Compt. rend.*, **107**, 960—961).—At Montay and Forest there is a chalky conglomerate covered by a sandstone containing glauconite. The sandstone is from 0·3 to 1·8 metre thick, and contains 15 to 17 per cent. of phosphoric anhydride. The conglomerate is less rich in phosphates. C. H. B.

Composition of Piperno of the Collina del Vomero. By G. FREDA (*Chem. Centr.*, 1888, 1340, from *Rend. R. Inst. Lombardo* [2], **2**, 177—180).—The grey porous part (I) of the rock has the same composition as the compact part (II). The composition is almost the same as that of the piperno from Pianura, but very different from the tuff of Campi Flegrei. The analytical results of the piperno of Vomero are as follows:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	Cl.
I.	62·51	18·44	3·88	0·83	0·47	4·98	7·17	0·22
II.	61·65	19·06	4·14	1·28	0·62	5·31	6·72	—

J. W. L.

Metamorphic and Plutonic Rocks at Omeo. By A. W. HOWITT (*Jahrb. f. Min.*, 1889, i, Ref., 122—125, from *Trans. R. S. Victoria*).—About a mile from the northern end of the Hinnomugie Marsh there is a small tributary of Livingstone Creek in which the contact of muscovite granite and a greyish, fine-grained mica-schist is visible. The latter is seen under the microscope to consist of muscovite, brown mica, and tourmaline, or, in other places, of these minerals and quartz. The granite contained yellow microperthite (Analysis I), and silver-white mica (Analysis II).

Several miles to the south-east of this locality, at Wilson's Creek, a series of rocks consisting of mica-schists and gneisses have been collected. They are traversed by eruptive rocks, and at the contact have been subject to various changes. An analysis (III) is given of a finely granular mica-schist, which under the microscope is seen to consist of colourless mica, yellowish magnesia-mica, a little quartz in grains, and graphite. In the author's opinion, this and similar rocks are metamorphosed Lower Silurian sedimentary rocks. An analysis (IV) is also given of a graphic granite, consisting of microcline, quartz, secondary muscovite, and albite.

	Fe.	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	Na_2O.	K_2O.

B. H. B.

Composition of some Rocks from the Shore at Nice. By C. Montemartini (*Gazzetta*, **18**, 170—179).—These rocks, which were collected soon after the earthquake of February 23rd, 1887, are 31 in number, and may be divided into seven groups, of which a minute detailed description is given.

1. *Augite-andesite.*—The 10 specimens of this rock, mostly collected at Capo d'Aglio, near Monaco, are of irregular granular structure, in the brown or grey ground-mass of which it is easy to distinguish crystals of augite and of triclinic felspar; magnetite is also present. The sp. gr. of the specimens varied from 2·64 to 2·83. The silica varied for 54·38 to 55·89 per cent.

2. *Andesites which contained both Augite and Hornblende.*—Of the 11 specimens examined, 5 came from Capo d'Aglio, and 6 from the neighbourhood of Antibo. Some of these were homogeneous and compact, of greyish-black colour, and sp. gr. 2·65 to 2·70; magnetite was present. The results of analysis gave—

SiO_2.	Fe_2O_3.	Al_2O_3.	CaO.	MgO.	Alkalis.	Loss on ignition.
55·50	7·78	19·57	7·67	2·76	4·30	2·42

The alkali was estimated by difference.

The other samples were altered and not homogeneous, and contained besides augite and felspar, crystals of hornblende, magnetite, and apatite.

3. *Andesites of Trachytic Appearance.*—These were yellowish-white, of granular structure, and contained basaltic hornblende and a large quantity of vitreous, crystalline grains of triclinic felspar. The sp. gr. of one specimen was 2·49, and it contained 2·96 per cent. of water and 53·98 of silica.

4. *Andesite-conglomerate.*—The two specimens of this rock have the appearance of a conglomerate formed from fragments of andesite, the rock is much weathered, but neither by analysis nor by microscopical examination could any cementing material be discovered.

5. *Basaltic-augite.*—This has the same composition as the augite-andesite, but differs from it in not being granular in structure, but compact.

6. *Andesite coated with Gypsum.*—This has a sp. gr. of 2·52, and contains 5·13 per cent. of water and 60·04 of silica.

7. *Compact-semiopal.*—This rock is compact, of light greenish-brown, with resinoid lustre and conchoïdal fracture, and is nearly as hard as quartz. Its sp. gr. is 2·22, and it contains 2·26 per cent. of water and 91·18 of silica. C. E. G.

Examination of the Rocks of the Vulsinian Volcanoes. By L. Ricciardi (*Gazzetta*, **18**, 268—288).—The author has analysed a large number of rocks from the extinct Vulsinian volcanoes, and gives full details of their composition and of the results of their examination both macroscopically and microscopically. From the results obtained now and in former researches, and a comparison of these Vulsinian rocks with those of other volcanic districts, the author considers that most, if not all, of the volcanoes of the Italian peninsula, in very early periods, emitted trachytic and other acid rocks which were succeeded by those of basic character. It would seem, moreover, that the volcanic rocks of the Alpi-Sila group differ in some respects in chemical composition from those of the insular volcanoes of the Pilla group. The different basic lavas of the Alpi-Silla group are almost identical in composition, so that it would seem probable that they have a common origin. The acid rocks of trachytic type of Amiata, Bolsena, and Cimini are almost identical in composition with the trachytes and tufas of Campi Flegrei. C. E. G.

Meteorite from Novo-Ureï. By M. Erofeéff and P. Latschinoff (*J. Russ. Chem. Soc.*, 1888, **20**, 185—213).—This meteorite fell on September 10, 1886, near Novo-Ureï, Penza, together with two other aerolites, the larger of which fell into water, and the smaller was powdered and devoured by the superstitious moujiks. The fragment investigated weighed 1900 grams, and its sp. gr. was found to be 3·463 at 16°. On being powdered for analysis, it was found to contain extremely hard particles which scratched the agate mortar and pestle. It does not yield anything to neutral solvents, such as water, alcohol, and ether, but partly dissolves in hydrochloric acid with liberation of hydrogen and hydrogen sulphide, owing to the presence of iron and probably of magnetic pyrites. Aqua regia dissolves only 70—75 per cent.; and even when the insoluble residue is treated with hydrofluoric and sulphuric acids from 2—2·5 per cent. of a blackish-grey powder remains undissolved. It contains graphite and another substance, which is very hard, and was found to be capable of being burned in oxygen. An elementary analysis made in this way gave its composition: carbon 89·56 per cent., ash 10·44 per cent. Another portion remaining after fusion with potassium pyrosulphate gave: carbon 95·40, ash 3·23. In order to test it for different allotropic modifications of carbon, the residue was treated with strong nitric acid and potassium chlorate, but Brodie's graphitic acid was not formed, although 40 per cent. of the residue dissolved after three treatments. The residue was now whiter, and its sp. gr. was found on an average to be 3·1, which, considering the small quantity used, agrees well with that of diamond (sp. gr. 3·5). The powder was found to be harder than corundum, as the last polished and unpolished faces) is scratched by it very perceptibly.

The meteorite contains therefore diamond (*carbonado*) together with some soft carbon. The total quantity of diamond in the meteorite is no less than 1 per cent. = 85·4 carats. Analysis of the meteorite gave—

Ni.	Fe.	FeO.	MnO.	Al_2O_3.	Cr_2O_3.	MgO.	CaO.	S.	P.
0·20	5·25	13·35	0·43	0·60	0·95	35·80	1·40	0·15	0 02

SiO_2.	C.	Soft.	Hard (carbonado).	Total.
39·51	2·26	=(1·26	1·00)	99·92

Assuming that the sulphur is present as magnetic pyrites and adding phosphorus to nickel-iron, the composition is—

Ni,Fe.	Cr_2O_3.	Fe_7S_8.	C.	Silicates.	Total.
5·47	0·95	0·43	2·26	90·76	99·87

It was shown further, that 67·48 per cent. of the meteorite consist of olivine, of the following percentage composition:—

Mg_2SiO_4.	Fe_2SiO_4.	Ca_2SiO_4.	Mn_2SiO_4.
72·93	24·48	1 89	0·70

Another constituent is augite, to the extent of 23·82 per cent. of the mass of the meteorite. Chromium is present partly in the metallic state, 0·2 per cent. being dissolved in cold hydrochloric acid; partly as chrome-iron ore, 0·65 per cent. A table shows the way in which the different constituents are distributed in the meteorite. The paper contains moreover an account of the microscopic examination of the meteorite, which shows that the mass contains among other ingredients, small, transparent octahedra, in some of which very small black grains were found. They *may* consist of diamond, but unfortunately the carbon residue obtained in the analysis of the meteorite, after treatment with Brodie's solution (see above), consists of almost black particles of an irregular form. With high magnifying power, they appear to be partly transparent and without action on polarised light, but no trace of crystalline form could be detected. In conclusion the authors discuss different cases of occurrence of carbon in meteorites. Pantsch and Haidinger (1846) found cubes of graphite in the Arva iron (Hungary), and regard them as pseudomorphs after iron pyrites, but G. Rose has shown, that this mineral is not found in meteorites, and the forms are besides quite different. Rose thought the graphite cubes may be pseudomorphs after diamond, especially as an analogous allotropic change takes place when diamond is strongly heated in absence of air. G. Rose's prediction is thus confirmed by the results of the present investigation, diamond, however, being found in meteoric stones, whereas it was sought in meteoric irons. Fletcher (see Abstr., 1887, 30) has described graphite in cubic forms as a new mineral, cliftonite, found in the Youndegin meteorite, but this is totally different in properties from the modification of carbon occurring in the Novo-Ureï meteorite. The authors find, after comparison with known classes of aerolites, that the meteorite described above differs from all of them in many points, and propose to name this form *ureïlithe*. B. B.

Black Rivers in Equatorial Regions. By A. MUNTZ and V. MARCANO (*Compt. rend.*, **107**, 908—909).—In the equatorial regions of South America, there are several rivers the water of which is black. Some of the tributaries of the Orinoco and Amazon show this peculiarity. The rocks forming the banks of these rivers remain white, whilst the banks of several ordinary rivers become dark coloured. The black rivers do not impart their colour to the waters with which they mix. They flow through a granitic district covered with a luxuriant, tropical vegetation. The water has a fresh agreeable taste, and remains perfectly limpid even after two months. It contains 0·028 gram per litre of black organic matter similar to that formed in peat bogs, and has an acid reaction which increases when the water is concentrated. It contains no calcium and no nitrates, and the inorganic matter, which consists of silica and oxides of iron, manganese, aluminium, and potassium, with traces of ammonia, does not exceed 0·016 gram per litre. The waters retain their colour for a long time, because in the absence of calcium salts there is no nitrification, and the acid reaction and high degree of aeration prevent putrefaction.

Organic Chemistry.

Mineral Matter in Natural Petroleums. By J. A. LE BEL (*Bull. Soc. Chim.*, **50**, 359—361).—Bitumen was extracted from a bituminous limestone from Lobsann in Alsace by means of light petroleum; the greater part of the light petroleum was then distilled off, and the rest treated with amyl alcohol which precipitated a black resin. This was again dissolved in light petroleum, precipitated with amyl alcohol, and the solid precipitate washed with ether which removed a reddish resin. The asphaltene so obtained contains 5·4 per cent. of ash. The latter contains 13 per cent. of silica, 17 per cent. of ferric oxide with traces of manganese, and the rest consists chiefly of lime and calcium sulphate.

Asphaltene from the natural oil of Coloméa in Galicia contains only traces of mineral matter.

N. H. M.

Oxidation of the Hydrocarbons, C_nH_{2n-2}. By G. WAGNER (*Ber.*, **21**, 3343—3346; comp. Abstr., 1888, 665).—When diallyl is oxidised with potassium permanganate in dilute aqueous solution, it yields, in addition to a trace of an aldehyde, a mixture of two *hexylerythrols*, $C_6H_{10}(OH)_4$, which can be separated by fractional crystallisation, on adding successive quantities of ether to their solution in absolute alcohol. The less soluble hexylerythrol crystallises in aggregates of colourless, lustrous, right-angled tables, melts at 95·5°, and is sparingly soluble in cold alcohol, almost insoluble in ether, and readily soluble in water; its taste is slight, but sweet and cooling. The more soluble hexylerythrol is very hygroscopic, and more soluble in alcohol and ether-alcohol than the preceding compounds; its taste is slight, but sweet and cooling.

The production of two isomeric hexylerythrols in this way renders it very probable that diallyl is not a homogeneous compound, but consists of two isomerides, $CH_2{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH{:}CH_2$ and $CHMe{:}CH{\cdot}CH{:}CHMe$, and additional evidence in favour of this view is to be found in the results obtained by Sabanéeff (Abstr., 1885, 495) in brominating, and by Sorokin (Abstr., 1878, 962; 1880, 370) in oxidising the hydrocarbon.

Neither diallyl dioxide nor its first hydrate could be detected among the oxidation products of diallyl, and inasmuch as Přibytek has shown that diallyl dioxide is not completely converted into the corresponding erythrol by heating with water at 100° for 40 hours (*Inaug. Diss., St. Petersburg*, 1887, 33), the author concludes that the hexylerythrols are obtained directly by the oxidation of diallyl without the formation of the corresponding oxides as intermediate products.

W. P. W.

Hydration of Methylamylacetylene: Ethyl Amyl Ketone. By A. Béhal (*Bull. Soc. Chim.*, **50**, 359).—*Ethyl amyl ketone*, $C_8H_{16}O$, is obtained when the product of the hydration of methylamylacetylene is treated with sodium hydrogen sulphite, and kept for 10 days. The product is then pressed in a calico filter, the liquid which runs off, consisting of an aqueous and an oily layer, separated, and the oil washed, dried, and distilled. It boils at 164—166°, has a penetrating odour, is insoluble in water, and does not combine with hydrogen sodium sulphite. Sp. gr. = 0·8502 at 0°. N. H. M.

Preparation of Ethylene Cyanide. By A. Fauconnier (*Bull. Soc. Chim.*, **50**, 214).—Ethylene bromide (300 grams) and alcohol (500 grams) are boiled in a reflux apparatus and a saturated aqueous solution of potassium cyanide (200 grams) is gradually added. The reaction is completed in less than two hours, when the product is allowed to cool, and the liquid decanted, and evaporated in a vacuum. The residue is then dissolved in absolute alcohol, and the solution distilled first from a water-bath, then in a vacuum over a flame. It boils at 147° under 10 mm. pressure, and solidifies to a colourless mass, sometimes crystalline and sometimes amorphous. The yield is 75 to 80 per cent. of the theoretical. N. H. M.

Perthiocyanic and Dithiocyanic Acids. By P. Klason (*J. pr. Chem.* [2], **38**, 366—387. Compare Abstr., 1887, 1025).—The isoperthiocyanic acid prepared by mixing a solution of ammonium thiocyanate (1 kilo. in 650 c.c.) with hydrochloric acid (1 litre of 35—40 per cent.) contains 10—15 per cent. of dithiocyanic acid, even after fractional crystallisation from 60 per cent. acetic acid. The pure acid is best obtained by decomposing the barium salt with hydrochloric acid and recrystallising from a solution in 60 per cent. acetic acid. Isoperthiocyanic acid is very sparingly soluble in water, alcohol, and ether, but crystallises from acetic acid in beautful, yellow, dichroic prisms, which are the better formed the freer they are from dithiocyanic acid; its constitutional formula, according to Glutz, is

 $<\begin{array}{l}\mathrm{CS{\cdot}NH}\\ \mathrm{NH{\cdot}CS}\end{array}>\mathrm{S}$. When treated with alkalis, it is partially decomposed into dithiocyanic acid and sulphur; but a recombination takes place between some of the dithiocyanic acid, which is converted into the normal acid by the action of the alkali, and the sulphur, giving rise to a salt of normal perthiocyanic acid; thus the final result of the action of an alkali on isoperthiocyanic acid is a mixture of the alkaline salts of dithiocyanic acid and normal perthiocyanic acid.

Normal perthiocyanic acid is best prepared as follows:—100 grams of barium hydroxide, 50 grams of crude isoperthiocyanic acid, and 300 grams of water are gently warmed together until the sulphur at first separated has mostly redissolved. The mixture is then concentrated and cooled, when the barium perthiocyanate crystallises out, and is decolorised and recrystallised. If a fairly strong solution of this salt is mixed with hydrochloric acid, the iso-acid crystallises out; but if the solution is weak and is cooled to 0° nothing crystallises; if the cooled solution is shaken with ether, the normal acid is extracted and is obtained, together with some of the iso-acid, when the ethereal solution is evaporated at a low temperature. It is colourless and easily soluble in water and in ether; it easily passes into the iso-acid, and its constitution is probably expressed by the formula  $<\begin{array}{l}\mathrm{C(SH){:}N}\\ \mathrm{N{:}C(SH)}\end{array}>\mathrm{S}$, its properties indicating the presence of two SH-groups.

When a solution of iodine is added to a solution of a perthiocyanate, the colour of the former disappears, and a white precipitate is afterwards formed, but it is too unstable for analysis. Potassium permanganate is also bleached by a perthiocyanate, 1 mol. of the acid absorbing 8 atoms of oxygen; this would account for the oxidation of two of the sulphur-atoms to sulphuric acid and the formation of an acid of the formula  $<\begin{array}{l}\mathrm{C(OH){:}N}\\ \mathrm{N{:}C(OH)}\end{array}>\mathrm{S}$; but this has not been obtained in a state fit for analysis.

A solution of potassium perthiocyanate gives a green precipitate with copper sulphate, a yellow one with lead and bismuth salts, and a white one with silver nitrate—all insoluble in excess of the perthiocyanate; the precipitates formed with cadmium, zinc, mercury, cobalt, nickel, and ferrous salts are all soluble in excess of the perthiocyanate. Ferric chloride gives a black precipitate which gradually becomes white. *Barium perthiocyanate* crystallises in slender needles containing 4 mols. H_2O, three of which are lost at 110° and the fourth at 150°; it is easily soluble, forming an alkaline solution which is converted into barium thiocyanate and sulphur when heated for 12 hours on the water-bath. The *neutral* and *acid potassium* salts, the *calcium*, *lead*, and *silver* salts are also described. The *ethyl* salt, $Et_2C_2N_2S_3$, is a strongly refractive, colourless oil of the consistency of olive oil; its sp. gr. is 1·2544 at 18°; it has a faint, sweet smell, and boils in a vacuum at about 190°. When heated with strong hydrochloric acid, in which it is soluble, in a sealed tube, it is decomposed with formation of ammonia, carbonic anhydride, hydrogen sulphide, ethyl hydrosulphide, and ethyl polysulphide. Alcoholic potassium hydrosulphide converts it into ethyl hydrosulphide and potassium perthiocyanate. The ethyl and sulphur thus appear to be directly united.

Perthiocyanoglycollic acid, $C_2N_2S(S{\cdot}CH_2{\cdot}COOH)_2$, is obtained when isoperthiocyanic acid (1 mol.) is first shaken with a solution of potassium hydroxide (2 mols.) for some time, and a solution of sodium chloracetate (2 mols.) then added. This mixture is heated on the water-bath and hydrochloric acid added, when the free acid crystallises out on cooling in long, slender, obliquely cut, colourless tables. It melts with decomposition at 177°, and is nearly insoluble in cold, but easily soluble in hot water. Its solution gives white precipitates with lead acetate and silver nitrate, and a yellow one with ferric chloride. When heated with hydrochloric acid in a sealed tube, thioglycollic acid is formed among other products. The *potassium*, *barium* (with 3 mols. H_2O), *calcium* (with 3·5 mols. H_2O), *zinc*, *cadmium*, and *copper* salts are described. The *ethyl* salt cannot be distilled; the *amide* forms slender prisms which melt at 125°.

The dithiocyanic acids were first described by Fleischer; the iso-acid is always obtained along with isoperthiocyanic acid when a thiocyanate is decomposed by an acid; but the author has never obtained it in the pure state.

The normal dithiocyanates are colourless, not yellow, as Fleischer has stated; the author has not obtained them free from perthiocyanates, from which they differ in that with ferric chloride they give a dark-red coloration which rapidly changes to yellow and finally to a greyish-white precipitate. When it is attempted to prepare the ethyl salt, ethyl thiocyanate is obtained; nor can the hydrogen in the acid be displaced by any organic radicle without decomposing the molecule with formation of a thiocyanic derivative. A. G. B.

Platinum Compounds of Methyl Sulphide. By C. ENEBUSKE (*J. pr. Chem.*, [2], **38**, 358—365).—Three isomeric chlorides, of the general formula $PtCl_2,2Me_2S$, are obtained by the action of potassium platinosochloride on methyl sulphide. The *α-platosomethylsulphine chloride*, $Pt(SMe_2)_2Cl_2$, crystallises from chloroform in citron-yellow, transparent, monosymmetrical crystals melting at 159°; after melting, it dissolves in chloroform with formation of both the α- and β-chlorides. The *β-chloride* forms quadratic tables which contain 1 mol. of chloroform; it melts at 159°, and gives both chlorides after melting. A red, pulverulent chloride is first formed when potassium platinosochloride acts on methyl sulphide, and this becomes yellow and flocculent at a temperature of 50°; both forms are insoluble in chloroform, and are stable towards reagents; the author regards this as a double chloride of the formula $Pt(SMe_2Cl{\cdot}Cl{\cdot}Pt{\cdot}SMe_2{\cdot}SMe_2Cl)_2$. *Platosomethylsulphine bromide*, $Pt(SMe_2Br)_2$, forms bright yellow, monoclinic crystals; the *iodide* forms ruby-red crystals which decompose at 172°; the *sulphate*, $Pt(SMe_2O)_2SO_2 + 2H_2O$, forms yellowish crystals, easily soluble in water and melting at 91°; the *nitrate*, *nitrite*, *chromate* and *hydroxide* are also described.

The author has obtained salts of the radicle *platosomethyldisulphine*, $Pt(SMe_2)_4$.

The platinic derivatives are obtained from the platinous derivatives by treating their chloroform solutions with the halogens. *Platinomethylsulphine chloride*, $PtCl_2(SMe_2Cl)_2$, is a yellow, crystalline powder, decomposing at 218° without melting. The *bromochloride*, *bromide*, *iodochloride*, *iodobromide*, and *iodide* are also described.

A. G. B.

Action of Hot Manganese Dioxide on Alcohol Vapour. By E. DONATH (*Chem. Zeit.*, **12**, 1191—1192).—Carbonic anhydride, acetone, and small quantities of some higher boiling products are obtained when alcohol vapour is exposed to the action of manganese dioxide heated to temperatures varying from 150° to 360°, the latter being reduced to manganese sesquioxide, Mn_2O_3. Barium is frequently present as an impurity and in combination with the manganese, and such compounds give rise mainly to barium and manganese acetates, but also to salts of these metals with the higher homologous acids in small quantities. Mixing with lime did not increase the yield of acetic acid; but soaking the dioxide with sodium hydroxide and drying well was more successful in this respect. D. A. L.

Platinum Compounds of Ethyl Sulphide. By C. W. BLOMSTRAND (*J. pr. Chem.* [2], **38**, 352—358).—*α-Platosethylsulphine chloride*, $PtCl{\cdot}SEt_2{\cdot}SEt_2Cl$, is directly obtained by the action of potassium platinosochloride on ethyl sulphide. It melts at 81°. The crystals are bright yellow and monoclinic [$a : b : c = 1·5876 : 1 : 1·2610$; $\beta = 86°\ 4'$]. The *β-chloride*, $Pt(SEt_2Cl)_2$, is formed from the α-chloride and ethyl sulphide. It crystallises in greenish, monoclinic tables melting at 106° [$a : b : c = 1·5567 : 1 : 1·2961$; $\beta = 82°\ 44'$]. The *bromide*, $Pt(SEt_2Br)_2$, forms yellowish-red, monoclinic crystals melting at 118° [$a : b : c = 1·5072 : 1 : 0·98239$; $\beta = 87°\ 2·5'$]. The *iodide*, $Pt(SEt_2I)_2$, forms large, dark red, monoclinic crystals which melt at 136° [$a : b : c = 1·4714 : 1 : 0·9885$; $\beta = 89°\ 43'$].

Platosethylsulphine platinosochloride, $Pt(SEt_2Cl)_2,PtCl_2$, is obtained by heating platinous chloride for some time with ethyl sulphide (1 mol.); it is a yellow powder insoluble in alcohol.

Platosethylmethylsulphine chloride, $SEt_2Cl{\cdot}Pt{\cdot}SMe_2Cl$, is formed when platinous chloride acts on a mixture of ethyl and methyl sulphides; it is a heavy oil with a low freezing point. *Platosethylpropylsulphine chloride*, $SEt_2Cl{\cdot}Pt{\cdot}SPr_2Cl$, is a syrup which solidifies slowly; the *iodide* is precipitated by alcohol from a chloroform solution in small, lustrous, yellowish-red crystals.

Platosethylsulphine nitrite, $Pt(SEt_2{\cdot}O{\cdot}NO)_2$, is obtained by the action of fuming nitric acid on the sulphate (see below); it crystallises from chloroform in large, rhombic, pure white crystals which are sparingly soluble in cold water. The *sulphate* is formed from the chloride and silver sulphate; it is very soluble and crystallises in large, short, and thick crystals which have the formula $Pt(SEt_2O)_2SO_2 + 7H_2O$. The *phosphate*, *nitrate*, *chromate*, and *oxalate* have been obtained, and also, by treating the sulphate with barium hydroxide, a strongly alkaline solution of the *hydroxide*.

The platinic derivatives are obtained by dissolving the platinous derivatives (preferably in chloroform) and acting on the solution with the halogen. *Platinethylsulphine chloride*, $PtCl_2(SEt_2Cl)_2$, crystallises in small, bright-yellow tables and prisms which are triclinic, and melt with decomposition at 175°; the *bromide* forms red, monoclinic prisms: $\beta = 88° 30'$; the *bromochloride* forms yellowish-red crystals, and the *iodide* crystallises from chloroform in pretty dichroic prisms melting at 104°, dark-red by transmitted, and dark-blue by reflected light. A. G. B.

Oxidation of Unsaturated Compounds. By G. WAGNER (*Ber.*, **21**, 3347—3355; compare Abstr., 1888, 665).—When ethyl vinyl carbinol (b. p. = 114—114·5°) is oxidised with a dilute aqueous solution of potassium permanganate, it is converted into a series of compounds which can be partially separated by steam distillation. The neutral products volatile with steam, in addition to unaltered ethyl vinyl carbinol, consist of propaldehyde and a small quantity of a pungent substance distilling below 110°, which yields a reddish-brown oil containing nitrogen with phenylhydrazine, and is most probably ethyl vinyl ketone. The neutral product not volatile with steam (yield, 63 per cent. of that theoretically possible) is *pentenylglycerol*, $OH{\cdot}CHEt{\cdot}CH(OH){\cdot}CH_2{\cdot}OH$, a sweet, thick, and very hygroscopic syrup, which boils at 192° under 63·3 mm. pressure, has a sp. gr. = 1·0851 at 34° (water at 0° = 1), and is soluble in all proportions in water and alcohol, and also soluble to some extent in ether. Its *triacetate* is a syrup with a faint, alliaceous odour, boils at 177° under 52 mm. pressure, and at 264—265° under the ordinary pressure, has a sp. gr. = 1·122 at 0°, and = 1·103 at 18° (water at 0° = 1), and is soluble in the ordinary solvents. The acids volatile with steam consist of a mixture of formic and propionic acids, and the non-volatile acids comprise oxalic acid and a compound which, from the analysis of its zinc salt and behaviour with phenylhydrazine, is almost certainly propionylformic acid. To only a limited extent, therefore, under these conditions, is ethyl vinyl carbinol oxidised, as a secondary alcohol, to the corresponding ketone; on the contrary, it undergoes oxidation as though it were an olefine (Abstr., 1888, 665), yielding pentenylglycerol, which by further oxidation yields on the one hand, probably, propionic and oxalic acids, on the other formic and propionylformic acids, the last by its decomposition forming carbonic anhydride and propaldehyde.

Methyl allyl carbinol, when oxidised in like manner, yields as chief product (82 per cent. of that theoretically possible) *pentenylglycerol*, $OH{\cdot}CMeH{\cdot}CH_2{\cdot}CH(OH){\cdot}CH_2{\cdot}OH$, which boils at 180° under 27 mm. pressure, has a sp. gr. = 1·135 at 0°, and = 1·120 at 22° (water at 0° = 1), is somewhat more mobile than its isomeride, and has a sweet but burning taste. Its *triacetate* has a cucumber-like odour, and a sp. gr. = 1·120 at 0°, and = 1·101 at 20° (water at 0° = 1). The neutral product volatile with steam is acetaldehyde, and the acids volatile with steam are formic and acetic acids, traces only of non-volatile acids being present. Inasmuch as no trace of a ketone could be found, methyl allyl carbinol under these conditions seems to be oxidised exclusively as an olefine.

Allyl alcohol, under like conditions, yields glycerol, acraldehyde and formic acid, and therefore forms oxidation products characteristic both of an olefine and of a primary alcohol.

Unsaturated aldehydes are known to yield the corresponding acids on oxidation, and hence behave like the saturated compounds. Unsaturated ketones, however, probably yield the corresponding hydroxyketones; thus, the production of hydroxyisobutyric and acetic acids by the oxidation of mesityl oxide (Pinner, Abstr., 1882, 941) is most probably preceded by the formation of the dihydroxyketone.

In the author's view, hydroxy-compounds are the primary oxidation-products of unsaturated hydrocarbons, alcohols and ketones when the oxidation is effected not only by dilute aqueous potassium permanganate but also by any substance which exerts a purely oxidising action, these primary products subsequently undergoing various further changes under the different conditions obtaining in each oxidation. The view hitherto generally accepted, that unsaturated compounds on oxidation break up at the point of the "double bonds," is no longer tenable even in those cases where decomposition is effected by fusion with potassium hydroxide, since this reaction finds its most probable explanation in the view that, for example, an acid, $CHR{:}CR'{\cdot}COOH$ (where $R = C_nH_{2n+1}$ and $R' = H$ or C_nH_{2n+1}) is first oxidised to the compound $CHR(OH){\cdot}CR'(OH){\cdot}COOH$, which then undergoes reduction to the β-ketonic acid $R{\cdot}CO{\cdot}CHR'{\cdot}COOH$, which in the presence of the alkali hydrolyses in the usual way into the acids $R{\cdot}COOH$ and $CH_2R'{\cdot}COOH$. W. P. W.

The Part played by Water in the Oxidation of Unsaturated Compounds. By G. WAGNER (*Ber.*, **21**, 3356—3360).—The author's experiments (Abstr., 1888, 665; preceding Abstract) show that unsaturated compounds when oxidised in the presence of water cannot combine directly either with oxygen or water, but invariably yield compounds formed by direct union with hydroxyl. Water, therefore, plays a very important part in the oxidation, and the reaction is probably represented, in the case of ethylene, by the equation $C_2H_4 + O + H_2O = C_2H_4(OH)_2$. Thermochemical data show that the formation of glycol by the oxidation of ethylene, according to this equation, involves the liberation of 58·4 cal., whereas the production of acetaldehyde by the action of oxygen on the hydrocarbon would require an absorption of 33 cal. W. P. W.

Preparation of Epichlorhydrin. By A. FAUCONNIER (*Bull. Soc. Chim.*, **50**, 212—214).—Dichlorhydrin is best obtained by the action of hydrogen chloride on glycerol at 120—130° (Abstr., 1888, 244). Water and acid with traces of the symmetrical dichlorhydrin (b. p. 176°) distil over. The product is distilled in a vacuum. The fraction boiling at 50—120° contains the two dichlorhydrins, and the fraction boiling at 120—150° the two monochlorhydrins. The monochlorhydrins with the addition of more glycerol, are again treated with hydrogen chloride. With 3 or 4 kilos. of glycerol, the operation takes 30 to 40 hours.

Epichlorhydrin is prepared by treating the crude dichlorhydrin with very strong potash or soda, following Reboul's method. The product is decanted and distilled in a vacuum; the epichlorhydrin distils over below 75°; the fraction boiling at 75—120° is unchanged dichlorhydrin. The crude epichlorhydrin is washed with water, and distilled without previously drying it; the fraction boiling at 116—118° is redistilled in a vacuum. The yield is very good, and with little trouble 1500 to 2000 grams can be prepared in a week. N. H. M.

Benzoic Acetals of Mannitol. By J. Meunier (*Compt. rend.*, **107**, 910—911; compare Abstr., 1888, 950).—The benzoic acetal of mannitol is very readily obtained by dissolving mannitol in sulphuric or hydrochloric acid, adding the requisite quantity of benzaldehyde, and agitating, when the mixture becomes completely solid. Pure mannitol is not necessary. The acetal is insoluble in water, acids, alkalis, and cold alcohol, &c., and hence is easily purified by washing. It is readily reconverted into mannitol and benzaldehyde, and hence may be utilised to separate mannitol from mixtures, such as plant juices, in which it occurs along with albuminoïds, glucose, &c.

When the benzoic acetal is perfectly free from benzaldehyde it resists the action of acids as well as alkalis, and is not decomposed even by prolonged boiling with acidified water. If, however, a small quantity of the aldehyde is present, the acetal is readily decomposed, the rate of decomposition increasing with the quantity of aldehyde. In fact, decomposition will take place when it is treated with sulphuric acid of only 1 per cent. C. H. B.

Sugar obtained from Plantago Psyllium. By R. W. Bauer (*Annalen*, **248**, 140—144).—The carbohydrate obtained from the epidermis of *Psyllium gallicum*, by boiling the aqueous extract with dilute sulphuric acid, is xylose. It was identified by its melting point, rotatory power, and by its compound with phenylhydrazine. W. C. W.

Amylene Nitrosate and its Derivatives. By O. Wallach (*Annalen*, **248**, 161–175).—Amylene nitrosate, $NO_2\cdot O\cdot CMe_2\cdot CMe{:}NOH$, is prepared by the action of nitric acid (sp. gr. 1·385) on a mixture of amyl nitrite, amylene, and glacial acetic acid. The best yield is obtained with an amylene boiling at 36—38°. The crude product decomposes in closed vessels, but is tolerably stable when exposed to the air. It is purified by recrystallisation from warm benzene, and afterwards from ethyl acetate; if the solvent is rapidly evaporated, the nitrosate is deposited in needles, but on slow evaporation fine monoclinic crystals resembling cubes in appearance are deposited; axial ratios, $a : b : c = 0·977 : 1 : 1·4485$; $\beta = 83° 32'$. By the action of potassium cyanide on amylene nitrosate (Abstr., 1888, 38), the nitrile, $CN\cdot CMe_2\cdot CMe{:}NOH$, is formed. This substance melts at 99—100°, and boils at 280° with partial decomposition. It is freely soluble in water, alcohol, ether, and benzene. On saponification, it yields an amide, $CONH_2\cdot CMe\cdot CMe{:}NOH$, and the hydroxylamine-derivative of dimethylacetic acid or *ketoximedimethylacetic acid*, $OH\cdot N{:}CMe\cdot CMe_2\cdot COOH$. The acid is freely soluble in alcohol, benzene, and water. The silver salt is deposited from aqueous or alcoholic solutions in needles. The acid melts at 96—97° with decomposition, yielding carbonic anhydride and the ketoxime of methyl isopropyl ketone, $CHMe_2{\cdot}CMe{:}NOH$. The synthesis of ketoximedimethylacetic acid from amylene nitrosate shows that this compound is derived from trimethylethylene.

Amylenenitrolpiperidide, $C_5NH_{10}{\cdot}CMe_2{\cdot}CMe{:}NOH$, is best prepared by the action of amylene nitrosate on an alcoholic solution of piperidine. It is deposited from alcohol in glistening prisms. By the action of boiling dilute sulphuric acid, it is converted into the *keto-base*, $C_5NH_{10}{\cdot}CMe_2{\cdot}COMe$, a colourless liquid boiling at 219—220°, sp. gr. 0·934. The hydrochloride is very hygroscopic, but the platinochloride, $(C_{10}H_{19}NO)_2,H_2PtCl_6$, forms fine crystals. W. C. W.

Aldehyde and Acetone Sulphites of Organic Bases. By H. Schiff (*Annalen*, **248**, 144—146).—Not only primary monamines but also secondary and tertiary amines and diamines have the power of uniting with aldehydosulphites to form crystalline compounds. W. C. W.

Sulphines. By G. Patein (*Bull. Soc. Chim.*, **50**, 201—206; compare Abstr., 1888, 664).—When the compound SEt_2Br_2, prepared by Cahours by the action of bromine on methyl sulphide, is dissolved in water (8 mols.), it is decomposed with liberation of hydrogen bromide. When the alcoholic solution is treated with zinc, the solution evaporated, and the viscous product dissolved in water and treated with mercuric chloride, the *compound* $SMe_2,HgCl_2 + SMe_2,ZnBr_2$ is obtained as a white precipitate.

The *iodide*, SMe_2I_2, prepared by the action of iodine on the sulphide, is crystalline and resembles iodine in appearance; it dissolves in alcohol, ether, and benzene, but not in water, and has an unpleasant odour. It is converted by anhydrous alcoholic ammonia into iodoform, and a compound of iodoform with methyl suphide. When treated with silver cyanide, silver iodide, cyanogen iodide and methyl sulphide are formed. N. H. M.

Symmetrical Dibromacetone. By E. Hjelt and V. O. Sivén (*Ber.*, **21**, 3288—3289).—Dibromacetone (symmetrical) can be prepared by oxidising dibromhydrin (50 grams) with a mixture of potassium dichromate (25 grams), sulphuric acid (40 grams), and water (40 grams), and purifying the product by means of the sodium hydrogen sulphite compound (compare Aschan, this vol., p. 31). The yield is 20—25 per cent. of the dibromhydrin employed. It is a colourless liquid with a pungent odour (compare Völker, Abstr., 1878, 781). The hydrogen sodium sulphite compound, $C_3H_4OBr_2,NaHSO_3 + 1\frac{1}{2}H_2O$, crystallises in nacreous plates and effloresces on exposure to the air. Dibromacetone yields a very unstable compound, $C_3H_4OBr_2,NH_3$, with ammonia, and it also reacts with phenylhydrazine. The *oxime* crystallises in slender needles. When the acetone is heated with Fehling's solution, the latter is reduced, and when it is dissolved in baryta-water or potassium carbonate, solutions are obtained which probably contain dehydroxyacetone, as they reduce Fehling's solution when warmed with it, and yield a syrupy liquid when evaporated and extracted with alcohol. F. S. K.

Preparation of Ketones. By J. HAMONET (*Bull. Soc. Chim.*, **50**, 355—358).—*Propione*, $COEt_2$, is prepared by digesting propionic chloride (1 mol.) with ferric chloride (1 mol.), using a reflux apparatus. The mixture is at first cooled and afterwards heated at about 60°. The product is poured into a little well-cooled water and the oil washed with water and distilled. It boils at 101—102°. The yield is about 34 per cent. of the theoretical.

Butyrone, $COPr_2$, is obtained by heating butyric chloride (4 mols.) and ferric chloride (1 mol.) at 45° or 50°; the black oil is washed with alkaline water before being distilled. It is lighter than water, and boils at 142—144°.

Œnanthylone was prepared from heptylic chloride. N. H. M.

Diethoxyacetone. By E. GRIMAUX and L. LEFÈVRE (*Compt. rend.*, **107**, 914—916).—Ethyl ethoxyaceto-ethoxyacetate is allowed to remain 48 to 72 hours at the ordinary temperature with a sufficient quantity of a 2·5 per cent. solution of potassium hydroxide to convert it into the potassium salt. The liquid is then acidified with sulphuric acid which liberates the free acid, and the latter at once decomposes with evolution of carbonic anhydride. The liquid is extracted with ether and the ethereal solution dried and distilled. The greater part of the residue boils at 193—196°, and the yield is 20—25 per cent. of the original ethereal salt.

Diethoxyacetone, $CO(CH_2{\cdot}OEt)_2$, boils at 195°, and is a colourless liquid with an aromatic odour and a sweet, burning taste; sp. gr. at 17·8° = 0·980; vapour-density 4·95. It dissolves in alcohol and ether, and is slightly soluble in water; it volatilises in steam. Diethoxyacetone combines with sodium hydrogen sulphite with great development of heat, forming a very soluble compound. Its reducing power is very much greater than that of an equal weight of glucose. It readily reduces Fehling's solution, and yields a mirror with ammoniacal silver nitrate even at the ordinary temperature.

It cannot be converted into symmetrical dichloracetone. When treated with sodium ethoxide, an energetic reaction takes place with formation of brown, resinous products, insoluble in water but soluble in alkalis.

Diethoxyacetone is remarkable in having the properties of both ketones and ethereal derivatives of glycols. C. H. B.

Action of Copper Acetylacetone on Carbonyl Chloride. By THOMAS and LEFÈVRE (*Bull. Soc. Chim.*, **50**, 193—194).—When the powdered copper-derivative is heated at 60—70° with carbonyl chloride dissolved in benzene, the product filtered and evaporated, crystals are obtained which are recrystallised from ether. The new compound melts at 120—121°. When heated, a sublimate of large, yellow needles is obtained which seems to be a different substance. It dissolves in alcohol, ether, and benzene, very readily in chloroform; warm water seems to decompose it. When heated with ammonia, it dissolves at once and yields a compound melting at 250°. The composition of the compounds has not yet been determined.

Arrangement of Atoms in Space. Geometrical Constitution of the Crotonic Acids and their Halogen Substitution Products. By J. WISLICENUS and, in part, E. TEISLER and H. LANGBEIN (*Annalen*, **248**, 281—355).—α-β-Dichlorobutyric acid and its derivatives have already been described by the author (Abstr., 1887, 655). α-β-Isodichlorobutyric acid is prepared by saturating a mixture of isocrotonic acid and carbon bisulphide with chlorine. After removing the solvent by passing a current of dry air through the product, a small quantity of α-β-dichlorobutyric acid is deposited in crystals, but the α-β-isodichlorobutyric acid remains as a non-crystallisable oil. α-β-Isodichlorobutyric acid yields α-chlorocrotonic acid when it is treated with an excess of an aqueous solution of sodium hydroxide, and an aqueous solution of its sodium salt decomposes at 80°, yielding carbonic anhydride and α-chloropropylene (b. p. 36°).

α-Isochloropropylene,  $\begin{array}{c}CH_3\cdot C\cdot H\\ \Vert\\ H\cdot C\cdot Cl\end{array}$, is easily attacked by alkalis at 100° and converted into allylene. α-Chloropropylene,  $\begin{array}{c}H\cdot C\cdot CH_3\\ \Vert\\ H\cdot C\cdot Cl\end{array}$, is less readily attacked.

In the preparation of α-β-dichlorobutyric acid by the action of chlorine on a solution of solid crotonic acid in carbon bisulphide, an oily bye-product is obtained It consists of a mixture of α-β-isodichlorobutyric acid with the normal isomeride. The amount of this bye-product is increased by raising the temperature at which the reaction takes place.

The chief product of the action of bromine on isocrotonic acid mixed with carbon bisulphide is α-β-isodibromobutyric acid. A small quantity of solid α-β-bromocrotonic acid is also formed. α-β-Isodibromobutyric acid is decomposed by an excess of alkali, yielding at the ordinary temperature α-bromocrotonic acid, but at 100° a mixture of α-isobromopropylene (b. p. 59—60°) and a new α-bromopropylene (b. p. 63—64°). The latter is more conveniently prepared by converting α-isobromopropylene (from α-β-dibromobutyric acid) into tribromopropane by the action of bromine. The ααβ-tribromopropane is mixed with alcohol and treated with zinc-dust.

α-Bromopropylene,  $\begin{array}{c}H\cdot C\cdot CH_3\\ \Vert\\ H\cdot C\cdot Br\end{array}$, is not easily attacked by alkalis, but α-isobromopropylene,  $\begin{array}{c}CH_3\cdot C\cdot H\\ \Vert\\ H\cdot C\cdot Br\end{array}$, is converted into allylene.

One part of potassium bromocrotonate dissolves in 493·4 parts of 99·5 per cent. alcohol at 21°. Under similar conditions, potassium isobromocrotonate only requires 10·8 parts of alcohol.

αβ-Dichlorobutyric acid is partly converted into αβ-isodichlorobutyric acid by exposure to a temperature of 100—185°, and chloro- and bromo-crotonic acids are always formed in small quantities when αβ-isochloro- or bromo-crotonic acids are distilled in a current of steam. Exposure to a small quantity of hydrogen chloride at 100° partially converts isocrotonic into crotonic acid.

α-Isobromocrotonic acid is completely converted into crotonic acid by the action of sodium amalgam in alkaline solution, but in an acid solution isocrotonic acid is formed as well as crotonic acid.

The author concludes by replying to the criticisms of Michael (Abstr., 1888, 1147 and 1176). W. C. W.

Action of Phosphorus Sulphides on Dibromosuccinic Acids. By I. Ossipoff (*J. Russ. Chem. Soc.*, 1880, **20**, 245—254).—If, as is generally admitted, dibromosuccinic acid is a derivative of fumaric acid and isodibromosuccinic acid of maleïc acid, the first ought to be convertible into thiophen or its derivatives. The author finds, however, that dibromosuccinic acid, when heated with phosphorus trisulphide or pentasulphide under the ordinary pressure at 140°, does not give a thiophen compound. In sealed tubes with phosphorus trisulphide, nothing but thiomalic acid was formed. No better result was obtained when the sodium salt of dibromosuccinic acid was employed or with isodibromosuccinic acid or its anhydride. These results are not in accordance with the equations Kues and Paal give (*Ber.*, **19**, 555) as representing the formation of thiophen. B. B.

The Ethereal Salts of Fumaric and Maleïc Acids. By I. Ossipoff (*J. Russ. Chem. Soc.*, 1888, **20**, 254—267).—Silver fumarate was treated with isobutyl iodide in the presence of ethyl ether, but hardly any reaction took place. Silver maleate with isobutyl or isoamyl bromide gave no better results; the same is the case with the iodides of higher alcohol radicles.

Ethyl and isopropyl maleates were found to have a normal vapour-density. The same is the case with isopropyl fumarate, but the isobutyl salt is found to decompose under these circumstances; even isopropyl fumarate, which shows the normal vapour-density at the boiling point of amyl benzoate, decomposes at the boiling point of β-naphthol (285—290°).

The mono-silver salt of maleïc acid (acid silver maleate) gave, with ethyl iodide, hydrogen ethyl maleate, and from this the sodium salt, $C_4H_2O_4EtNa$, was obtained. This, after decomposition with sulphuric acid, gives free ethylmaleïc acid, which is not identical with ethylfumaric acid.

With acetic chloride, the above sodium salt gives a compound which would seem to be the acetyl-derivative of ethylmaleïc acid, as when it is treated with ethyl alcohol at the ordinary temperature it yields ethyl acetate and ethyl maleate. When maleïc anhydride is heated in a sealed tube with benzyl alcohol, a mixture of substances is obtained consisting chiefly of sodium benzylmaleate. Phenol gives no reaction with maleïc anhydride. B. B.

Compounds of Dibromopyruvic Acid with Hydrazines. By O. Nastvogel (*Annalen*, **248**, 85—92).—*Phenylosazonglyoxalcarboxylic acid*, $N_2HPh{:}CH{:}C(N_2HPh)\cdot COOH$, is deposited in orange-coloured crystals on mixing aqueous solutions of phenylhydrazine and dibromopyruvic acid. It melts at 201—203° with decomposition, and is soluble in acetone, acetic acid, and in boiling alcohol or benzene. The sodium, potassium, and ammonium salts are crystalline, and are sparingly soluble in water.

Paratolylosazoneglyoxalcarboxylic acid, $C_{17}H_{18}N_4O_2$, melts at 186—188° with decomposition, and dissolves freely in warm alcohol, acetone, benzene, and acetic acid. The sodium, potassium, and ammonium salts are much more soluble in hot than in cold water.

α-Naphthylosazoneglyoxalcarboxylic acid forms cherry-red crystals and melts at 196°. β-Naphthylhydrazine and dibromopyruvic acid unite together, forming a hydrazide, probably

$$C_{10}H_7{\cdot}N_2H{:}CH{\cdot}CO{\cdot}C(OH){:}N_2H{\cdot}C_{10}H_7.$$

This substance is insoluble in alkalis, and is decomposed by boiling with an alcoholic solution of potassium hydroxide.

Dibromomethylhydroxytoluquinoxaline,  $C_7H_6{<}\substack{N{:}C(CHBr_2)\\ N{:}C(OH)\,—}{>}$, is formed when a mixture of orthotoluylenediamine and dibromopyruvic acid in molecular proportions is boiled. It melts with decomposition at 235°, and is reprecipitated on adding an acid to its solution in alkalis. W. C. W.

Tricarballylic Acid. By P. DÄUMICHEN (*Chem. Centr.*, 1888, 1347—1348).—In the preparation of ethyl malonate from monochloracetic acid and potassium cyanide, an oil of high boiling point (286—287°) was obtained as a bye-product. Its behaviour with barium hydroxide and hydrochloric acid, its elementary analysis and the analysis of its silver and copper salts, showed it to consist of triethyl tricarballylate.

No well-characterised substance is obtained from tricarballylic acid by subjecting it to distillation.

Benzyl tricarballylate, prepared from the sodium salt and benzyl chloride, consists of lustrous, pearly leaves, soluble in alcohol, sparingly in ether, insoluble in water. It may be prepared more readily by neutralising the alcoholic solution of tricarballylic acid with potash, distilling off the greater portion of the alcohol, and boiling with benzyl chloride in a reflux apparatus. *Acetyl tricarballylic anhydride*, $C_{18}H_{14}O_{11}$, prepared by boiling carballylic acid with excess of acetic chloride, melts at 128—129°; when exposed to moist air, it becomes hydrated, with formation of acetyl tricarballylic acid. *Tricarballylanilic acid*, $C_{12}H_{11}NO_4$, prepared by heating 1 gram of tricarballylic acid with 3·18 grams of aniline, forms lustrous, pearly scales, and melts at 137°. *Tricarballylparatoluic acid* crystallises with 1 mol. H_2O and melts at 174°. These two acids take up water when dissolved in it, and pass into the bibasic derivatives; their silver salts are amorphous, as also the copper salts of the toluyl-derivative. The *tricarballylparaditoluic acid* was also obtained; it melts at 174°, is monobasic, and, with the heavy metals, forms salts which are amorphous. *Tricarballylparatoluidide* was also found as a product of the action of toluidine on tricarballylic acid; it melts at 253°. *Tricarballylparaditoluyl* is formed by dissolving paratoluidine and tricarballylic acid in alcohol; it melts at 178°, and when boiled with alkalis passes into the paraditoluic acid.

Tricarballylamide is prepared by treating ammonium tricarballylate in ammoniacal solution in a sealed tube, or by protracted agitation of the triethyl salt with ammonia; it melts at 218° with decomposition, ammonia being evolved, and *tricarballylamideimide* remains; this melts at 172—173°. J. W. L.

Rate of Oxidation of Tartaric Acid. By J. KRUTWIG (*Zeit. physikal. Chem.*, **2**, 787—795).—The author doubts the generality of the conclusions arrived at by Dreyfus (Abstr., 1888, 24), and gives the details of an investigation on the oxidation of tartaric acid by means of potassium permanganate under different conditions. He shows that the rate of oxidation increases with the amount of tartaric acid present, and that it also proceeds more rapidly without than with the addition of sulphuric acid. The reaction takes place much more readily in sunlight than in the dark, and the addition of excess of sulphuric acid up to a certain point has an accelerating influence, as has also the presence of manganese sulphate in the solution. H. C.

Alloxan Sulphites of Organic Bases. By G. PELLIZARRI (*Annalen*, **248**, 146—152).—The following compounds were prepared by adding an aqueous solution of alloxan to solutions of organic sulphites saturated with sulphurous anhydride:—*Alloxan ethylamine sulphite*, $C_2H_7N,SO_3H_2,C_4H_2N_2O_4 + H_2O$, forms colourless, monoclinic crystals; $a : b : c = 0·8341 : 1 : 1·2462$; $\beta = 100° 40' 20''$. *Alloxan aniline sulphite*, $C_6H_7N,SO_3H_2,C_4H_2N_2O_4 + 2H_2O$, crystallises in large, quadratic plates. The methylaniline compound, $C_7H_9N,SO_3H_2,C_4H_2N_2O_4 + 2H_2O$, forms small, yellowish prisms. *Alloxan dimethylaniline sulphite*, $C_8H_{11}N,SO_3H_2,C_4H_2N_2O_4 + 4H_2O$, forms monoclinic plates; $a ; b : c = 1·3399 : 1 : 0·3394$; $\beta = 99° 22' 40''$. The benzidine compound forms triclinic prisms containing 1 mol. H_2O. Tolidine and amidobenzoic and aspartic acids yield similar compounds. *Alloxan pyridine sulphite* is triclinic. The crystals are anhydrous. Anhydrous crystalline compounds are also obtained with quinoline, picoline, morphine, and cinchonine. The strychnine compound crystallises with 1 mol. H_2O, and the brucine compound with $1\frac{1}{2}$ mol. H_2O. *Alloxan ammonium sulphite* forms triclinic crystals; $a : b : c = 0·6648 : 1 : 0·7121$; $\alpha = 71° 11' 20''$, $\beta = 99° 47' 20''$, and $\gamma = 80° 40'$. The aqueous solution decomposes on boiling, forming a small quantity of murexide; in presence of ammonia or ammonium carbonate, ammonium thionurate is produced. W. C. W.

Glycocine-derivative of α-Thiophenic Acid. By M. JAFFÉ and H. LEVY (*Ber.*, **21**, 3458—3461).—α-Thiophenic acid is not poisonous, and can be given to rabbits in the form of sodium salt in daily quantities of 2 grams by subcutaneous injection. It is excreted in the urine as α-thiophenuric acid, the glycocine-derivative of α-thiophenic acid.

α-Thiophenuric acid, $C_7H_7NSO_3$, crystallises from water in colourless, transparent, strongly refractive, thin prisms, closely resembling those of hippuric acid, melts at 171—172°, and is very sparingly soluble in ether, but readily soluble in alcohol and hot water. When boiled with baryta-water, it hydrolyses almost quantitatively into α-thiophenic acid and glycocine, but when hydrolysed with hydrochloric acid, it yields only small quantities of α-thiophenic acid, although the yield of glycocine is quantitative. The *silver* salt, $C_7H_6NSO_3Ag$, crystallises in colourless, microscopic needles, dissolves sparingly in water, and is unaffected by exposure to light; the *barium* salt (2 mols. H_2O) crystallises in colourless, slender needles, and is readily soluble in water, but insoluble in alcohol; the *calcium* salt (? 5 mols. H_2O) crystallises in thick, prismatic needles, and is extremely soluble in water.

W. P. W.

Influence of Light on the Action of Halogens on Aromatic Compounds. By J. SCHRAMM (*Monatsh.*, **9**, 842—853).—The present work, a continuation of the author's investigations (Abstr., 1885, 451), was conducted with the object of ascertaining the behaviour towards the halogens of aromatic compounds containing side-chains which are not normal.

Isopropylbenzene.—In the dark or in presence of iodine, bromine enters the benzene nucleus, a small quantity in the first case also displacing hydrogen in the side-chain. The product boils at 217—219° under a pressure of 739 mm., and on oxidation yields a mixture of para- and ortho-brombenzoic acids, chiefly the former. In direct sunlight, bromine (1 mol.) acts rapidly, the product being a clear liquid which solidifies at —20°. On distillation, this gives off large quantities of hydrogen bromide and about one-half of the original isopropylbenzene is recovered. It appears in this latter case that substitution in the side-chain takes place, a dibromisopropylbenzene being formed, which decomposes on distillation.

Isobutylbenzene.—In the dark or in presence of iodine, bromine enters the benzene nucleus, a *bromisobutylbenzene* being formed, which boils at 232·5—233·5° under a pressure of 739 mm., and solidifies at —18°. On oxidation, it yields parabrombenzoic acid. In direct sunlight, bromine reacts to form a compound which on distillation loses hydrogen bromide and yields a hydrocarbon boiling at 180—185°. This latter combines with bromine to form an oily bromide, but in other respects does not resemble Perkin's isobutenylbenzene.

Secondary butylbenzene, when treated with bromine in the dark or in presence of iodine, gives a *bromobutylbenzene* boiling at 235·5—237°. It is not readily oxidised, but yields parabrombenzoic acid when heated for seven days with a concentrated solution of alkaline permanganate. The action of bromine in sunlight is rapid, but the product was not examined.

By the action of bromine in the dark or in presence of iodine, tertiary butylbenzene (trimethylphenylmethane) is converted into a *bromobutylbenzene* boiling at 230—230·5° under a pressure of 736 mm., and of sp. gr. 1·2572. This compound cannot be oxidised unless with dichromate and excess of sulphuric acid, when it is destroyed. It is a remarkable thing that tertiary butylbenzene is not attacked by bromine in sunlight even when the solution is heated to the boiling point. As substitution of bromine in the side-chain always takes place with elimination of the hydrogen-atom attached to the carbon nearest the benzene nucleus, the absence of such a hydrogen-atom in tertiary butylbenzene may perhaps explain this behaviour.

In the dark or in presence of iodine, isoamylbenzene yields with bromine a *bromisoamylbenzene*, boiling at 253—255° under a pressure of 736 mm., and of sp. gr. 1·2144. On oxidation, it gives parabrombenzoic acid. Isoamylbenzene is readily acted on by bromine in direct sunlight, the product being a liquid *bromisoamylbenzene* which decomposes on distillation into hydrogen bromide and phenylisoamylene. Treated with another molecular proportion of bromine in the dark, it yields a *dibromisoamylbenzene* melting at 128—129°.

It appears from the author's researches that the action of halogens on aromatic hydrocarbons, in the dark and in direct sunlight, may be compared in its results to action at low and at high temperatures. By the first, substitution in the benzene nucleus takes place with formation of an ortho- or para-bromo-derivative, whereas by the second, substitution in the side-chain is effected. H. C.

Aromatic Cyanates and their Polymerides. By W. Frentzel (*Chem. Centr.*, 1888, 1361—1362).—*Ethyl pseudocumylcarbamate*, prepared from pseudocumidine and ethyl chlorocarbonate, dissolves readily in alcohol, and melts at 91·5°. Phosphoric anhydride eliminates 1 mol. H_2O from it with formation of *pseudocumylcyanate*, boiling at 221°. Triethylphosphine and, more readily, potassium acetate, change the cyanate into its polymeride, the *cyanurate* melting at 234°. *Dicumylcarbamide*, prepared from the cyanate, melts at 260—270°.

From unsymmetrical metaxylidine [$Me_2 : NH_2 = 1 : 3 : 4$], the *carbamate*, melting at 57°, and from this the *cyanate*, boiling at 205°, were prepared, and by means of potassium acetate, the *cyanurate* melting at 162° was obtained.

From the symmetrical metaxylidine [$Me_2 : NH_2 = 1 : 3 : 5$], the *carbamate* melting at 77·5°, the *cyanate* boiling at 208·5°, and, by means of carbonyl chloride, *dixylylcarbamide* melting at 275° were prepared. *Monoxylylcarbamide*, melting at 162°, was prepared from the last-mentioned compound by evaporating the aqueous solution of the hydrochloride with potassium cyanate. J. W. L.

New General Method for the Synthesis of Aromatic Compounds. By C. Friedel and J. M. Crafts (*Ann. Chim. Phys.* [6], 14, 433—472).—When dry air or oxygen is passed into cold benzene in presence of aluminium chloride, a very small quantity of phenol is formed, but when the mixture is heated almost to its boiling point this compound is produced in much larger quantities. After passing the gas, for some time, the mixture is poured into water, the supernatant oil separated and the phenol obtained in a perfectly pure state by extracting the acidified, aqueous solution with ether and evaporating. The oily product contains unaltered benzene and red compounds; the latter are soluble in ether, benzene, and carbon bisulphide, but insoluble in alcohol, acetic acid, and water, and cannot be distilled.

Metacresol can be obtained from toluene in like manner. In this reaction also oily bye-products are formed; these compounds are brown, soluble in toluene and cannot be distilled.

When benzene and powdered sulphur are heated together at 75—80°

in presence of aluminium chloride until the evolution of hydrogen chloride and hydrogen sulphide ceases, the mixture poured into water and the supernatant oil fractionated, the following compounds, together with unaltered benzene, are obtained: (1) Phenyl mercaptan boiling at 170—173°; (2) phenyl sulphide boiling at about 288°; and (3) diphenylene disulphide boiling at 364—366° (compare Stenhouse, *Annalen*, **149**, 252, and Graebe, this Journal, 1874, 469). A compound, $C_{12}H_8S_2O_2$, is obtained when diphenylene disulphide (1 mol.) is oxidised with chromic acid (1⅓ mol.) in glacial acetic acid solution (compare Graebe, *loc. cit.*). It crystallises from benzene in small prisms, melts at 241°, is readily soluble in glacial acetic acid, sparingly in cold benzene, and dissolves in concentrated sulphuric acid with a violet-red coloration.

Benzoic acid is produced, with evolution of hydrogen chloride, when a stream of dry carbonic anhydride is passed for some days through a mixture of benzene and aluminium chloride heated almost to its boiling point.

Phenylsulphinic acid is obtained by passing sulphurous anhydride into a warm mixture of benzene and aluminium chloride until the weight of the hydrogen chloride evolved is about half that of the aluminium chloride employed, and then gradually pouring the whole into cold water. If the reaction is continued too long or if the mixture is allowed to cool, a crystalline aluminium salt separates. The filtered aqueous solution is acidified with hydrochloric acid and the product extracted with ether.

When aluminium chloride is gradually added to a warm mixture of benzene and phthalic anhydride, hydrogen chloride is evolved and orthobenzoylbenzoic acid is formed.

Paratoluoylorthobenzoic acid, $C_6H_4Me{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$, is obtained when aluminium chloride (1½ parts) is added in small portions at a time to a mixture of phthalic anhydride (½ part) and toluene (1 part). The whole is then poured into a large quantity of water and, after keeping for some time, the crystalline product is separated. Further quantities can be obtained by evaporating the toluene. It crystallises from boiling toluene in white prisms, melts at 146°, is very readily soluble in benzene and alcohol, more sparingly in ether, and very sparingly in boiling water. Dilute aqueous solutions of the acid and solutions of many of its salts have a sweet taste. The *ammonium* salt crystallises from boiling water, in which it is very readily soluble, in silky needles. The *sodium* salt crystallises in small needles and is very readily soluble in water but more sparingly in alcohol. When heated with soda at about 340° it is decomposed almost quantitatively into sodium benzoate and sodium paratoluate. The *barium* salt (+ 4 mols. H_2O) crystallises from water in prisms or needles and loses its water at 110°. Most of the salts of the heavy metals are sparingly soluble in water.

Orthoduroylbenzoic acid, $C_6HMe_4{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$, obtained in like manner, crystallises from glacial acetic acid in plates, melts above 260°, and is readily soluble in alcohol, ether, acetone, benzene, and toluene, but insoluble in water. The *potassium* salt crystallises in microscopic needles and is readily soluble in cold water. The *sodium* salt is sparingly soluble in alcohol and separates from the solution again only partially, in the form of small plates. The *ammonium* salt crystallises in needles. The *barium* salt (+ 1 mol. H_2O) crystallises in slender needles and is moderately soluble in alcohol but sparingly in water. The *calcium* salt (+ 1 mol. H_2O) crystallises from water in needles. The lead, silver, and copper salts are insoluble in water.

Acetophenone is formed when benzene is treated with acetic anhydride in presence of aluminium chloride.

When pure, dry ethylene is passed into a mixture of benzene and aluminium chloride heated at about 70—90°, ethyl-, diethyl- and triethylbenzene are produced, together with other higher boiling compounds.

Aluminium phenyl is formed when mercury phenyl is heated with aluminium foil at 125—130°. This compound will be fully described in a subsequent paper. It melts at about 230° and absorbs moisture with great avidity, but only absorbs oxygen very slowly when exposed to dry air. It yields diphenylmethane when treated with benzyl chloride, but it does not react with chlorobenzene at 100° in benzene solution. Phenol is formed when oxygen is passed through a benzene solution of aluminium phenyl, and when a xylene solution is heated with sulphur, diphenylene disulphide, phenyl sulphide, and probably also phenyl mercaptan are produced. These results show that aluminium phenyl behaves like a mixture of benzene and aluminium chloride, and the authors consider that this fact is evidence in favour of the view that an organo-metallic compound, probably $C_6H_5{\cdot}Al_2Cl_5$, is temporarily formed in all reactions; similar to those described above and those already described (*Ann. Chim. Phys.* [6], 1, 449), in which aluminium chloride is employed.

Gustavson (Abstr., 1885, 363) considers that the brown liquid, which is formed when aromatic hydrocarbons are placed in contact with aluminium chloride or bromide, has a definite composition, which, in the case of benzene, is $AlCl_3(C_6H_6)_3$ or $AlBr_3(C_6H_6)_3$, and that it is this compound which reacts with the chloride, bromide, or iodide of the alcohol radicle. The authors find that when pure aluminium chloride or bromide is mixed with dry benzene or toluene this liquid is not formed or only produced in very small quantities, and that in the case of aluminium chloride a considerable quantity remains undissolved in presence of excess of the hydrocarbon. When hydrogen chloride or bromide is passed into the mixture, as recommended by Gustavson, it was observed that the liquid was formed in some cases but not in others; when, however, a small quantity of water was admitted, the liquid was always produced. Analyses of the liquid obtained in various experiments showed that it was a complex mixture, perhaps consisting of a compound of the hydrocarbon with aluminium chloride, or more probably with a chlorhydroxide of aluminium, the organo-metallic compound $C_6H_5{\cdot}Al_2Cl_5$, excess of the hydrocarbon, and hydrochloric acid. F. S. K.

Influence of the Presence of Halogens and Alkyl-groups on the Replacement of Oxygen in Quinone-derivatives by the Isonitroso-group. By F. KEHRMANN (*Ber.*, 21, 3315—3321).—

Chloroquinone melting at 54° and bromoquinone melting at 55—56° react with hydroxylamine hydrochloride in alcoholic solution at the ordinary temperature. The monoximes obtained have the constitution $[NOH:X:O = 1:3:4]$, and are unstable, decomposing when heated for a long time at 80—90°. They are not easily obtained in the pure state, crystallise in small, bright-yellow needles, and are very readily soluble in alcohol and ether, but only moderately so in hot water, and very sparingly in boiling benzene, light petroleum, acetone, and carbon bisulphide. When reduced with tin and hydrochloric acid, they yield halogen amidophenols $[NH_2:X:OH = 1:3:4]$, and when treated with cold, concentrated nitric acid, they are converted into orthochloroparoximidoquinone decomposing at 140°, and orthobromoparoximidoquinone decomposing at 142° respectively. They are with difficulty converted into halogen dioximes $[(NOH)_2:X = 1:4:3]$ when boiled for a long time with excess of hydroxylamine hydrochloride in aqueous solution.

The dioximes crystallise in small, greyish-yellow needles, are sparingly soluble in boiling water, alcohol, and ether, moderately so in benzene, and are converted into halogen dinitroso-derivatives when oxidised with alkaline potassium ferricyanide solution or warm dilute nitric acid.

The halogen dinitroso-derivatives are yellow, crystalline compounds with a smell resembling both that of quinone and iodoform. They are readily volatile with steam, and dissolve in fuming nitric acid, from which they are precipitated unchanged on adding water, but are only very sparingly soluble in ordinary solvents. They yield diamines which are readily oxidised to quinones when treated with chromic acid or ferric chloride.

Metadichloroquinone melting at 120—121°, metadibromoquinone melting at 130—131°, and metadi-iodoquinone melting at 179° $[O_2:X_2 = 1:4:2:6]$ do not form dioximes. The monoximes are yellow, crystalline compounds, and are readily soluble in alkalis, alcohol, and ether, but sparingly in boiling water, benzene, and carbon bisulphide. The chloro-derivative decomposes at 140°, the bromo-derivative at 145°. These oximes are readily converted into metadihalogenparanitrophenols when treated with cold, moderately concentrated nitric acid (compare Fischer and Hepp, Abstr., 1888, 456). Their constitution is, therefore $[O:NOH:X_2 = 1:4:2:6]$.

Paradichloroquinone (m. p. 161—162°), parachlorobromoquinone (m. p. 171—172°), and paradibromoquinone (m. p. 188—189°) $[O_2:X_2 = 1:4:2:5]$, react with hydroxylamine hydrochloride under the conditions described above, forming both monoximes and dioximes which can be separated by means of alcohol or benzene.

Paradichloroparoximidoquinone crystallises in bright yellow needles, decomposes without melting when heated at 138°, and is readily soluble in alcohol and ether, but only sparingly in hot water, benzene, and carbon bisulphide. It is slightly volatile with steam, but resinifies when boiled for a long time with water.

Paradichloroparanitrophenol, $[OH:Cl_2:NO_2 = 1:2:5:4]$, obtained by dissolving the oximidoquinone in well-cooled, concentrated nitric acid, crystallises from hot water or dilute alcohol in colourless needles, and from absolute alcohol in short, thick, quadratic prisms melting at 115—116°. It does not taste bitter, and is somewhat volatile with steam. It yields an *amine* which is converted into paradichloroquinone melting at 161—162° when oxidised with ferric chloride.

Paradichloroquinonedioxime separates from benzene in greyish-yellow, granular crystals, and is readily soluble in boiling benzene, but sparingly in alcohol and ether, and insoluble in boiling water.

Paradichloroparadinitrosobenzene, prepared by dissolving the dioxime in fuming nitric acid, crystallises in citron-yellow needles, explodes when heated at 120—130°, and is insoluble in the ordinary solvents. It is not oxidised when boiled with nitric acid. The *amine*, obtained by reducing the dioxime or the dinitroso-compound, is converted into paradichloroquinone when treated with ferric chloride.

Trichloroquinone and tribromoquinone yield dark brown resinous products when treated with hydroxylamine hydrochloride in alcoholic solution, and no crystalline compound except tetrachloroquinol was obtained.

Chloranil and bromanil are gradually reduced to the corresponding quinols when boiled with hydroxylamine hydrochloride in alcoholic solution.

Trichlorotoluquinone, tribromotoluquinone, metadichlorometaxyloquinone, $[O_2 : Me_2 : Cl_2 = 1 : 4 : 2 : 6 : 3 : 5]$, dichlorothymoquinone, $\beta\beta$-dichloro- and dibromo-α-naphthaquinone do not combine with hydroxylamine under the conditions described above. It seems, therefore, that the quinone-derivative cannot yield an oxime when the hydrogen adjacent to the CO-group is displaced by halogens or alkyls.

Parachlorotoluquinone yields both a monoxime and a dioxime, but bromotoluquinone, $[O_2 : Me : Br = 1 : 4 : 2 : 6]$, and dibromotoluquinone, $[O_2 : Me : Br_2 = 1 : 4 : 2 : 3 : 5]$, only yield monoximes.

Dihydroxythiobenzenes. By G. TASSINARI (*Chem. Centr.*, 1888, 1354, from *Rend. Acad. dei Lincei* [4], 4, ii, 47—51).—The author considers that the compounds he has obtained, as well as their homologues, have a symmetrical constitution. Several isomeric compounds were never obtained at the same time. The reaction is much more violent when the compounds are prepared from phenols in which the para-position to the hydroxyl-group is free, and the derivatives so prepared have a higher melting point than their isomerides.

In the action of parabromophenol on sulphur dichloride, considerable quantities of each of the reacting substances remain unchanged. The *acetyl*-derivative of the dihydroxythiobenzene (Abstr., 1888, 805) melts at 86—87°. From this the *acetylhydroxysulphone* was prepared by oxidation; it forms colourless crystals, which are sparingly soluble in cold alcohol and insoluble in water; it softens at 160°, and melts at 186—187°. By dissolving it in a little alcoholic potash and re-acidifying, a hydroxysulphone, *hydroxysulphonebenzid*, $C_{12}H_{10}O_4S$, was obtained, which must be either a di-meta- or a di-ortho-derivative. It is white, crystalline, melts at 186—187°, and is soluble in alcohol, little soluble in water and in acetic acid. The acetylhydroxysulphone becomes readily soluble in potassic hydrate after heating to 187°; it is therefore probable that the acetyl-group becomes separated by heating.

In order to determine the constitution of the dihydroxythiobenzene melting at 150°, Annaheim's hydroxysulphonebenzide was nitrated, in order to obtain the di- and tetra-nitro-derivatives. Picric acid was formed, as is also the case when the nitro-derivatives of hydroxysulphonebenzid are boiled with nitric acid.

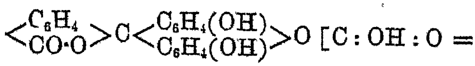
The *acetyl*-derivative of *orthodimethyldihydroxythiobenzene* crystallises from alcohol and melts at 44°. When oxidised with potassium permanganate, the corresponding *benzide*, $C_{14}H_{14}O_4S$, is formed, which melts at 132—133°, is insoluble in water, but soluble in hot alcohol. By saponifying with alcoholic potash, dimethylhydroxysulphonebenzide melting at 263° is formed; it dissolves in alkali hydroxides and carbonates, and is reprecipitated from these solutions by carbonic acid.

Diacetylparadimethyldihydroxythiobenzene melts at 83—84°, and when oxidised yields the corresponding *benzid* melting at 206—208°; the latter is little soluble in hot alcohol. Saponification with alcoholic potash gives *paradimethylhydroxysulphonebenzide*, which is rather soluble in alcohol and acetic acid, and melts at 209°; it dissolves in alkali hydroxides and carbonates, and is reprecipitated from such solutions by carbonic anhydride.

The *acetyl*-derivative of dihydroxythionaphthalene melts at 200°, is little soluble in, and decomposed by hot acetic acid. J. W. L.

Fluoresceïn. By R. MEYER and O. OPPELT (*Ber.*, **21**, 3376—3378).—When fluoresceïn is heated for eight hours with aqueous ammonia at 180—200°, a basic compound, $C_{20}H_{15}N_3O_2$, is formed, which on cooling crystallises in the tube in large, thick, reddish-yellow, monoclinic prisms and tables. It is a direct yellow dye for wool. The hydrochloride crystallises in tufts of reddish-yellow prisms, and from its very dilute and boiling solution, ammonia precipitates the base in scales of bronze-like lustre; under the microscope these are seen to consist of extremely characteristic X-like interpenetrating twins.

The authors point out that the constitution assigned to fluoresceïn by Knecht (*Annalen*, **215**, 83) is very improbable, and propose instead the formula



$$<\genfrac{}{}{0pt}{}{C_6H_4}{CO{\cdot}O}>C<\genfrac{}{}{0pt}{}{C_6H_4(OH)}{C_6H_4(OH)}>O \; [C:OH:O = 1:4:6],$$

that of the derived base being  $<\genfrac{}{}{0pt}{}{C_6H_4}{CO{\cdot}O}>C<\genfrac{}{}{0pt}{}{C_6H_4(NH_2)}{C_6H_4(NH_2)}>NH$. The base must contain at least one NH_2-group, inasmuch as its hydrochloride yields a diazo-compound when treated with nitrous acid. On treatment with cold aqueous soda, the lactone-ring is readily broken up, and the base yields a sodium salt crystallising in slender needles; the solution, when acidified and then precipitated by ammonia, is at once reconverted into the original base. Reduction with zinc-dust in the alkaline solution converts the sodium salt into a colourless compound, which is not precipitated on treatment first with hydrochloric acid and then with ammonia.

Orcinphthaleïn, when heated in like manner with aqueous ammonia, yields a base similar to that just described; the chief product, however, is a colourless, crystalline, neutral compound containing nitrogen. W. P. W.

Desmotropy in Phenols. By J. Herzig and S. Zeisel (*Monatsh.*, 9, 882—899).—An examination of the indifferent oil obtained in the preparation of pentethylphloroglucinol (Abstr., 1888, 822) has been undertaken. It was subjected to the action of hydrogen iodide, the product dissolved in ether, and then extracted with potash. The greater part is taken up by the potash, but a portion is not attacked and remains dissolved in the ether.

If the potash solution is acidified, and the product again dissolved in ether and crystallised, a crystalline mass is obtained, one portion of which is sparingly soluble in alcohol and melts at 209—212°, whilst the other is more readily soluble in alcohol, melts at 91—95°, and is in every way identical with the pentethylphloroglucinol already described. The sparingly soluble portion has the composition of a *tetrethylphloroglucinol.* One atom of the hydrogen is replaceable by a metal, and it is converted by the action of ethyl iodide into a monethyl salt, and by the action of acetic anhydride into a monacetate melting about 60—62°. It readily exchanges one atom of hydrogen for bromine, the product being probably a mixture of several isomerides. A similar reaction with bromine is found to occur in the case of pentethylphloroglucinol.

The portion of the original product, which is insoluble in potash, consists chiefly of a secondary hexethylphloroglucinol, which, as it is unattacked by hydrogen iodide, must be regarded as *hexethyltriketohexamethylene*, isomeric with the ethyl salt of the bi-secondary pentethylphloroglucinol already described. H. C.

Derivatives of Parabromobenzyl and Parachlorobenzyl Alcohols. By G. Errera (*Gazzetta*, 18, 236—243).—Parabromobenzyl chloride cannot be obtained by the bromination of benzyl chloride or by the action of chlorine on parabromotoluene, but the author has succeeded in preparing it from parabromobenzyl alcohol. The latter was prepared by Jackson and Lowery's method (Abstr., 1878, 64) of boiling parabromobenzyl bromide with water for several hours, using a reflux condenser, operating on small quantities at a time (4 to 5 grains) and using abundance of water (500 c.c.). The mixture bumps very much, but a metal vessel cannot be used as it acts on the bromide, in fact when the latter is boiled with zinc-dust nothing but paradibromobenzyl (m. p. 114°) is formed; the chloride is acted on in like manner.

The authors find that besides parabromobenzyl alcohol,

$$C_6H_4Br\cdot CH_2\cdot OH,$$

the corresponding ether is also formed; the two, however, can be easily separated by crystallisation from water, in which the latter is insoluble. The alcohol crystallises from water in long, flattened needles melting at 75°; Jackson and Lowery give 77°, the higher melting point being probably due to the presence of some of the ether.

Parabromobenzyl chloride, $C_6H_4Br\cdot CHCl_2$, is obtained when the alcohol is treated with phosphorus pentachloride, but as other products are formed at the same time, it is far better to heat the alcohol with fuming hydrochloric acid at 150° in closed tubes for three to four hours. The reaction is complete, and the chloride is obtained in a pure state by once recrystallising the product from alcohol. It forms lustrous, colourless needles which melt at 38—39°. It is very soluble in hot alcohol, and its vapour attacks the eyes, but much less than that of the bromide. It is isomorphous with parachlorobenzyl chloride and with parachlorobenzyl and parabromobenzyl bromides.

Parabromobenzyl ether, $(C_6H_4Br\cdot CH_2)_2O$.—As stated above, this ether is formed at the same time as the alcohol when parabromobenzyl bromide is boiled with water, and is left as an insoluble residue when the product is treated with boiling water. It may be purified by repeated crystallisation from boiling alcohol. It can also be prepared by the action of dehydrating agents, such as sulphuric acid, boric anhydride, or zinc chloride, on the alcohol; the two first-mentioned do not yield satisfactory results, but with zinc chloride the yield is almost theoretical. The ether crystallises from alcohol in long, flattened needles which melt at 85—86°. It is insoluble in water, and only sparingly soluble in alcohol even when boiling. If the ether is boiled for some time, it is decomposed, splitting up into parabromotoluene and parabromobenzaldehyde, $(C_6H_4Br\cdot CH_2)_2O = C_6H_4Br\cdot COH + C_6H_4Br\cdot CH_3$; these can be easily separated by distillation. The ether is attacked by nitric acid with formation of parabromobenzaldehyde and other products, but the amount of material at the author's disposal was too small to allow of a complete investigation of the reaction.

Parachlorobenzyl Ether, $(C_6H_4Cl\cdot CH_2)_2O$.—When parachlorobenzyl bromide is boiled with water or dilute soda solution, it does not behave like the bromine-derivative, as no trace of the ether is produced. The latter can be easily obtained, however, by boiling the alcohol with zinc chloride. It crystallises from alcohol in needles or plates which are much less soluble than parachlorobenzyl alcohol. It melts at 54—55°, and when boiled splits up into parachlorotoluene and parachlorobenzaldehyde. C. E. G.

Nitrobenzyl Ethyl Ethers. By G. ERRERA (*Gazzetta*, **18**, 232—235).—This is a continuation of former work (Abstr., 1887, 1103).

Paranitrobenzyl Ethyl Ether, $OEt\cdot CH_2\cdot C_6H_4\cdot NO_2$.—The general method for the preparation of the substituted benzyl ethyl ethers, that is, the action of alcoholic potash on the corresponding derivatives of benzyl chloride, is not applicable in the case of paranitrobenzyl ethyl ether, as paranitrobenzyl chloride under these circumstances is converted into paradinitrostilbene. In order to prepare it, the chloride is heated for a long time with ordinary alcohol in a close vessel in a boiling brine bath, as a higher temperature cannot be employed. The product, even after long heating, still contains much unaltered paranitrobenzyl chloride, and in order to remove it a few drops of alcoholic potash are added to the liquid whilst it is still hot; this at once converts the unattacked chloride into dinitrostilbene, which being almost insoluble in alcohol is precipitated, and can be removed by filtration. The potash is then neutralised with hydrochloric acid, and the product distilled with steam, when the ether passes over with the aqueous vapour, and solidifies on cooling. Paranitrobenzyl ethyl ether is pale yellow, and very soluble in alcohol and in ether, sparingly in light petroleum, from which it crystallises in needles, and insoluble in water. It melts at 24—24·5°, and at a higher temperature distils, but is at the same time partly decomposed. Treatment with fuming nitric acid converts it into paranitrobenzaldehyde.

Metanitrobenzyl Ethyl Ether.—This is prepared by heating metanitrobenzyl chloride with a slight excess of alcoholic potash on the water-bath, and, when the reaction is complete, neutralising the liquid with hydrochloric acid and distilling the product with a current of steam. This ether is a yellow oil, which solidifies to a crystalline mass in a mixture of snow and hydrochloric acid (melting point not given). It resembles the para-derivative in its behaviour to solvents, and yields metanitrobenzaldehyde when treated with nitric acid.

Orthonitrobenzyl Ethyl Ether.—The orthonitrobenzyl chloride employed for the preparation of this ether was obtained by the nitration of benzyl chloride. The liquid product, when cooled by a freezing mixture, deposits para- and ortho-nitrobenzyl chlorides which can be easily separated by fractional crystallisation. This may be much accelerated by introducing a crystal of one or other chloride into the supersaturated alcoholic solution, when crystals of the same species separate at once, while the other chloride remains in solution and is deposited later. It can then be obtained in a pure state by one recrystallisation. The orthonitrobenzyl ethyl ether, prepared like the para-derivative, is a yellow liquid which gradually becomes brown on exposure to the light. It does not solidify when cooled in a mixture of snow and hydrochloric acid, and is converted into orthonitrobenzaldehyde by the action of nitric acid. C. E. G.

Derivative of Tetrole and Synthesis of Tribenzamidophloroglucinol. By L. RÜGHEIMER (*Ber.*, 21, 3325—3331).—When ethyl hippurate (5 parts) is gradually heated with dry sodium ethoxide, so that in the course of about three hours the temperature rises to about 160—170°, alcohol distils, and on adding water to the residue two sodium salts are formed, one of which is only very sparingly soluble in dilute soda.

Dibenzamidodihydroxytetrole, $C_{18}H_{14}N_2O_4$, is obtained by separating the sparingly soluble sodium salt, dissolving it in boiling water, and adding hydrochloric acid to the warm filtered solution. It can also be prepared by heating ethyl hippurate with sodium at 160—170°. It crystallises from hot alcohol in needles containing $\frac{1}{2}$ mol. H_2O, loses its water at 108—110°, the anhydrous crystals melting at 137—138°. It is very readily soluble in hot benzene and alkalis, but only moderately so in alcohol; the alcoholic solution gives a violet coloration with ferric chloride. The *barium* salt is readily soluble in water. The *silver* salt is very unstable, and rapidly darkens. The *ethyl*-derivative was obtained in an impure state as an aromatic smelling oil; the acid seems to yield an acetyl-derivative when treated with acetic anhydride. When boiled for a long time with dilute hydrochloric acid, or better with eight times its weight of a mixture of equal parts of concentrated sulphuric acid, glacial acetic acid, and water, it is decomposed into benzoic acid and diamidoacetone. Its constitution is probably either

$\mathrm{COPh{\cdot}NH{\cdot}C}\Big<\begin{matrix}\mathrm{C(OH)}\\ \mathrm{C(OH)}\end{matrix}\Big>\mathrm{C{\cdot}NH{\cdot}COPh}$ or

$$\mathrm{COPh{\cdot}NH{\cdot}CH}\Big<\begin{matrix}\mathrm{CO}\\ \mathrm{CO}\end{matrix}\Big>\mathrm{CH{\cdot}NH{\cdot}COPh}.$$

Diamidoacetone platinochloride, $C_3H_8N_2O,H_2PtCl_6$, crystallises in small, orange plates, and turns bright yellow when warmed on the water-bath.

Tribenzamidophloroglucinol, $C_{27}H_{21}N_3O_6$, is formed when the readily soluble sodium salt obtained in the reaction described above is decomposed with hydrochloric acid. It crystallises from water in small needles containing 1½ mol. H_2O, and melting at 153·5—158·5°. It is very readily soluble in alcohol, but only very sparingly in hot water, and insoluble in ether; the alcoholic solution gives a blue coloration with a small quantity of ferric chloride, but on adding more of the reagent the colour changes to green. It is decomposed, with liberation of benzoic acid, when heated at a comparatively low temperature. The *lead* salt, $(C_{27}H_{18}N_3O_6)_2Pb_3$, is sparingly soluble in water, but the *calcium*, *barium*, and *silver* salts are readily soluble. The *copper* salt, $(C_{27}H_{18}N_3O_6)_2Cu_6$, is bright green. F. S. K.

Azotoluenes. By J. V. Janovsky (*Monatsh.*, 9, 828—841).—*Parazotoluene* is best prepared by adding to 100 parts of 20 per cent. aqueous soda heated to 100°, 100 parts of paranitrotoluene, and then adding slowly and with constant agitation 100—110 parts of zinc-dust. An orange-coloured oil is formed, which should at once be separated from the solution, and left to crystallise. One recrystallisation from glacial acetic acid is sufficient to obtain pure parazotoluene melting at 144°. It crystallises in rhombic needles, soluble in alcohol, ether, benzene, and light petroleum, and also in boiling hydrochloric acid. When oxidised with chromic mixture it gives an orange-coloured crystalline compound melting at 132°.

The acetic acid mother-liquor from the parazotoluene contains three other products which melt at 109°, 75°, and 70° respectively. The last of these is identical with the β-azoxytoluene of Melms and Petrieff, whilst the compound melting at 75° appears to be a peculiar isomeride of the same. Both these compounds yield two bromides when treated with bromine (2 mols.), those from the first melting at 85° and 57°, those from the second at 92° and 57°.

By acting with nitric acid on the bromide of parazotoluene melting at 128° (Abstr., 1888, 686), a nitrobromo-derivative melting at 138° has been obtained.

The nitration of parazotoluene with nitric acid of sp. gr. 1·5 yields chiefly *trinitro*-derivatives. Two of these are formed, one (α) melting at 189°, and the other (β) at 138°. A dinitro-compound melting at 114° is obtained at the same time. All these compounds give sulphonic acids with fuming sulphuric acid. By the further treatment of α-trinitrazotoluene with nitric acid, a *tetranitrazotoluene* melting at 198—200° is produced, and β-trinitrazotoluene when nitrated gives the same compound. A mononitrazotoluene is formed on treating parazotoluene with nitric acid of sp. gr. 1·45. It melts at 80°, and on further nitration yields the dinitro-compound melting at 114°. H. C.

Halogen-derivatives of Phenylhydrazine. By A. NEUFELD (*Annalen*, **248**, 93—99).—The preparation of parachloro- and parabromo-phenylhydrazine from the corresponding aniline-derivatives has already been described by Elsinghorst (*Inaug. Diss.*, *Erlangen*, 1884). These substances readily unite with aldehydes and ketones. *Acetoneparabromophenylhydrazone* crystallises in glistening plates and melts at 93°. *Acetaldehydeparabromophenylhydrazone* forms yellow needles and melts at 83°.

Dibromophenylhydrazine, $[N_2H_3 : Br_2 = 1 : 2 : 5]$, prepared from dibromaniline by reduction with stannous chloride or sodium sulphite, melts at 97°, and is freely soluble in alcohol, ether, and benzene. The hydrochloride is crystalline. *Symmetrical tribromophenylhydrazine*, $[N_2H_3 : Br_3 = 1 : 2 : 4 : 6]$, melts with decomposition at 146°. It is soluble in benzene, chloroform, warm alcohol and hot water. The hydrochloride and sulphate are stable salts. The acetone compound melts at 54.° *Tetrabromophenylhydrazine*,

$$[N_2N_3 : Br_4 = 1 : 2 : 3 : 4 : 6],$$

crystallises in prisms and melts at 167°. It dissolves in chloroform, benzene, and hot water. The hydrochloride is crystalline. The compounds with acetone and acetaldehyde are solid.

Pariodophenylhydrazine melts at 103°, and is freely soluble in alcohol, ether, chloroform, benzene, and acetic acid. The acetone compound crystallises in plates and melts at 114°. *Metadi-idophenylhydrazine*, $[N_2H_3 : I_2 = 1 : 2 : 4]$, forms silky crystals, which melt at 112° and are freely soluble in alcohol, ether, and benzene. The hydrochloride melts at 163° with decomposition. The base unites with acetone and acetaldehyde to form hydrazones. W. C. W.

Phenylhydrazones. By O. RUDOLPH (*Annalen*, **248**, 99—105).—*Metatoluylaldehydephenylhydrazone* is deposited when a solution of phenylhydrazine in acetic acid is added to toluylaldehyde suspended in water. The compound crystallises in prisms, melts at 87—88·5°, and dissolves in ether, chloroform, and alcohol. *Cumaldehydephenylhydrazone* melts at 127—129°. It rapidly turns red on exposure to the light. *Diphenylacetaldehydephenylhydrazone* is freely soluble in hot alcohol. *Metahydroxybenzaldehydephenylhydrazone*, prepared from metamidobenzaldehyde, forms colourless prisms. It melts at 130—131·5°, and dissolves freely in warm alcohol, chloroform, benzene, or acetic acid. *Parahydroxybenzaldehydephenylhydrazone* melts at 177—178° and is freely soluble in ether. *Anisaldehydephenylhydrazone* forms white needles or plates and melts at 120—121°. It is freely soluble in ether and in hot alcohol or benzene. *Piperonalphenylhydrazone* melts at 102—103°. *β-Resorcylaldehydephenylhydrazone* melts with decomposition between 156° and 160°. It dissolves freely in the usual solvents. *Resorcindialdehydephenylhydrazone* melts about 230° with decomposition. It dissolves in warm solutions of the alkalis. W. C. W.

Phenyltrimethylenimine. By L. BALBIANO (*Chem. Centr.*, 1888, 1356, from *Rend. Acad. dei Lincei* [4], **4**, ii, 44—46).—If dry phenyltrimethylenediamine hydrochloride is heated over a bare flame until the whole of the salt has volatilised, and the vapours are condensed in dilute hydrochloric acid, *phenyltrimethylenimine* and ammonium chloride are found in the solution. From the solution of the distillate, after concentrating to a syrup, alcohol precipitates the latter, whilst the base is separated from the solution by acidifying with hydrochloric acid, precipitating with potassium bismuth iodide, and washing the red precipitate. After treating with potash and distilling with steam, it may be precipitated as the platinochloride $C_3H_6\colon NPh,H_2PtCl_6$, an orange, crystalline compound, soluble in hot water. The hydrochloride could not be obtained in crystals from the aqueous solution. J. W. L.

Hippuroflavin. By L. RÜGHEIMER (*Ber.*, **21**, 3321—3325)—*Hippuroflavin*, $C_9H_5NO_2$, is prepared by gradually heating a mixture of ethyl hippurate (1 mol.) and phosphorus pentachloride (1 mol.) until the latter is dissolved, and then adding a little more phosphorus pentachloride and heating at 160° for about eight hours. The whole is poured into alcohol, and the crystalline product collected and washed with alcohol. It separates from hot nitrobenzene or hot glacial acetic acid in small, yellow crystals, partially decomposes, but without melting, when heated at 300°, and sublimes with partial decomposition in citron-yellow crystals. It is very sparingly soluble in glacial acetic acid and nitrobenzene, and almost insoluble in water, alcohol, and ether. When warmed with alcoholic soda, it is decomposed with evolution of ammonia, and when heated at 100° for 8 to 9 hours with concentrated ammonia the red solution obtained deposits a colourless, crystalline compound. It yields benzoic acid when warmed with alkaline potassium permanganate, or when heated at 130° with nitric acid of sp. gr. 1·15; and when treated with concentrated hydrochloric acid at 110°, it is completely decomposed into benzene, carbon, and dark-coloured products. When boiled with zinc-dust and glacial acetic acid, it yields a yellowish substance which dissolves in soda with a brown coloration, but is reprecipitated in greenish flocks on adding hydrochloric acid. It is gradually converted into a colourless compound when warmed with stannous chloride and hydrochloric acid in glacial acetic acid solution. Its constitution is probably  $\left\langle\begin{matrix}N(COPh)\cdot C\cdot CO\text{———}\\ \|\\ \text{———}CO\cdot C\cdot(COPh)N\end{matrix}\right\rangle$. F. S. K.

Phthalimidine and Methylphthalimidine. By P. Barbier (*Compt. rend.*, **107**, 918—921).—Phthalimidine is readily obtained by the gradual addition of small quantities of hydrochloric acid to an acetic acid solution of phthalimide containing the calculated quantity of granulated tin. It forms white needles melting at 150°, and can be recrystallised from boiling water; it is isomeric with oxindole, and is both an amine and an amide. It forms an unstable hydrochloride which can only exist in presence of free acid, and loses all its hydrochloric acid in a vacuum. The hydrochloride is completely decomposed by water; the platinochloride, $(C_8H_7NO)_2,H_2PtCl_6$, and the aurochloride, $(C_8H_7NO,HCl)_3,2AuCl_3$, are both unstable. A derivative, C_8H_6NOAg, is obtained as a white precipitate by adding silver nitrate to a solution of phthalimidine in potassium hydroxide solution.

When a solution of phthalimidine in potassium hydroxide is heated in sealed tubes at 100° for six hours with excess of methyl iodide, methylphthalimidine, C_9H_9NO, is obtained in slender, white needles, which melt at 120°. It forms an unstable hydrochloride and an unstable aurochloride, $(C_9H_9NO)_2,HAuCl_4$. The properties of methyl phthalimidine indicate that it has the constitution $C_6H_4<\substack{CO\\CH_2}>NMe$, and not $C_6H_4<\substack{CH_2\cdot NH\\CO\cdot CH_2}>$. This view is confirmed by the fact that a concentrated alcoholic solution of methylamine yields methylphthalimidine when heated with phthalide at 220° for 12 hours.

C. H. B.

Derivatives of Diphenylacetaldehyde. By W. G. M. Weise (*Annalen*, **248**, 34—56). Hydrobenzoïn is most conveniently prepared from benzoïn by the method described by Breuer and Zincke (Abstr., 1880, 118). It is converted into diphenylacetaldehyde by treatment with dilute sulphuric acid at 200°; this substance is converted into a nitrile by adding powdered potassium cyanide, and finally hydrochloric acid to its ethereal solution. When dry hydrogen chloride is passed into a mixture of the nitrile and absolute alcohol (in molecular proportions), crystals of *ethyl β-diphenylimidolactate hydrochloride*, $CHPh_2\cdot CH(OH)C(OEt){:}NH,HCl$, are deposited. The hydrochloride melts at 135° with decomposition; it is also decomposed by dissolution in water, yielding in this case ammonium chloride and *ethyl β-diphenyllactate*. The latter is a micro-crystalline powder, melts at 66°, and yields a monacetyl-derivative, $CHPh_2\cdot CH(OAc)\cdot COOEt$, melting at 53°. *β-Diphenyllactic acid*, $CHPh_2\cdot CH(OH)\cdot COOH$, crystallises in needles, and melts at 159°. It is freely soluble in alcohol, ether, and hot water. The salts of this acid do not readily crystallise. At 170° the acid is converted into the *anhydride*, $COOH\cdot CH(CHPh_2)\cdot O\cdot CO\cdot CH(OH)\cdot CHPh_2$. Hydriodic acid decomposes β-diphenyllactic acid at 150° into carbonic anhydride and

diphenylethane. If the reaction takes place at a higher temperature, dibenzyl is also formed.
W. C. W.

Passivity of certain Polyketones towards Hydroxylamine and Phenylhydrazine. By J. HERZIG and S. ZEISEL (*Ber.*, 21, 3493—3494; compare Kehrmann, this vol., p. 243).—Tetrethyl- and pentethyl-phloroglucinol (Abstr., 1888, 822) do not react with hydroxylamine or phenylhydrazine, and it would therefore seem that meta-diketones no longer give the characteristic ketonic reaction with these compounds when the hydrogen-atoms in the ortho-positions to the carbonyl-groups are almost completely or completely replaced by alkyl-groups.
W. P. W.

Nitriles. By J. A. MILLER (*Chem. Centr.*, 1888, 1359).—Paramethoxybenzaldehyde reacts with hydroxylamine with formation of *paramethoxybenzaldoxime*, $\mathrm{OMe\cdot C_6H_4\cdot CH{:}NOH}$, melting at 64°. By the action of sodium nitrite and hydrochloric acid, the aldehyde is regenerated. When heated with acetic chloride, the *nitrile*, $\mathrm{OMe\cdot C_6H_4\cdot CN}$, is formed, which melts at 61—62°. By treating this nitrile with hydroxylamine hydrochloride and soda, *paramethoxybenzenylamidoxime*, $\mathrm{OMe\cdot C_6H_4\cdot C(NH_2){:}NOH}$, is formed, melting at 122—123°. Its hydrochloride melts at 168°. *Paramethoxybenzenylamidoxime ethyl ether*, $\mathrm{OMe\cdot C_6H_4\cdot C(NH_2){:}NOEt}$, melting at 51—52°, is prepared by heating the amidoxime with sodium ethoxide and ethyl iodide.

Paramethoxylbenzenylacetylamidoxime, $\mathrm{OMe\cdot C_6H_4\cdot C(NH_2){:}NOAc}$, is formed when a chloroform solution of the amidoxime is treated with acetic chloride.

Paramethoxybenzenylethenylazoxime, $\mathrm{OMe\cdot C_6H_4\cdot C}{<}\genfrac{}{}{0pt}{}{\mathrm{N}}{\mathrm{N\cdot O}}{>}\mathrm{CMe}$, melting at 68°, is formed by heating the acetyl compound, or by the direct action of acetic anhydride on the amidoxime. With acetaldehyde, *paramethoxybenzenylethylideneimidoxime*,

$$\mathrm{OMe\cdot C_6H_4\cdot C}{<}\genfrac{}{}{0pt}{}{\mathrm{NH}}{\mathrm{N\cdot O}}{>}\mathrm{CHMe},$$

melting at 127·5° is formed. The *ethyl carbonate* of the amidoxime, $\mathrm{OMe\cdot C_6H_4\cdot C(NH_2){:}N\cdot O\cdot COOEt}$, melting at 119—120°, is formed by the action of ethyl chlorocarbonate on the amidoxime in chloroform solution. When treated with solution of soda or potash, this carbonate is changed into *paramethoxybenzenylimidoximecarbonyl*; this may also be prepared by heating the chlorocarbonate with the amidoxime. It melts at 208°.

Paramethoxybenzoylbenzenylamidoxime, $\mathrm{OMe\cdot C_6H_4\cdot C(NH_2){:}N\cdot OBz}$, melting at 148°, is prepared by the action of the amidoxime in alkaline solution on benzoic chloride at the ordinary temperature. If heat be employed *paramethoxybenzenylazoximebenzenyl*,

$$\mathrm{OMe\cdot C_6H_4\cdot C}{<}\genfrac{}{}{0pt}{}{\mathrm{N\cdot O}}{\mathrm{N}}{>}\mathrm{CPh},$$

is formed, which melts at 102°.

Paramethoxybenzenylazoximepropenyl-ω-carboxylic acid,

$$OMe{\cdot}C_6H_4{\cdot}C\begin{matrix}\diagup N \diagdown \\ \diagdown NO \diagup\end{matrix}C{\cdot}C_2H_4{\cdot}COOH,$$

melting at 140—141°, is formed by melting succinic anhydride with the amidoxime.

The salicyl derivatives are formed in a similar manner.

Salicylaldoxime melts at 57°; *salicylonitrile*, $OH{\cdot}C_6H_4{\cdot}CN$, melts at 99—100°; a polynitrile is formed at the same time as a secondary product; it is decomposed on heating with concentrated hydrochloric acid at 200° into phenol, carbonic anhydride, and ammonia. *Salicylamidoxime*, $OH{\cdot}C_6H_4{\cdot}C(NH_2){:}NOH$, melts at 98·5°. *Salicylamidoxime ethyl carbonate*, $OH{\cdot}C_6H_4{\cdot}C(NH_2){:}N{\cdot}O{\cdot}COOEt$, melts at 96°. *Salicylamidoximepropenyl-ω-carboxylic acid* melts at 116—117°. *Orthomethoxybenzonitrile*, $OMe{\cdot}C_6H_4{\cdot}CN$, boiling point 255—256°, is prepared from salicylonitrile by the action of methyl iodide; *orthomethoxybenzenylamidoxime*, $OMe{\cdot}C_6H_4{\cdot}C(NH_2){:}NOH$, melting at 123°, is formed from the last-named substance by the action of hydroxylamine. By melting this amidoxime with benzoic chloride, *orthomethoxybenzenylazoximebenzenyl*,  $OMe{\cdot}C_6H_4{\cdot}C\begin{matrix}\diagup N{\cdot}O \diagdown \\ \diagdown N \diagup\end{matrix}CPh$, is formed; it melts at 117°. J. W. L.

Derivatives of Metamethylphenylacetic Acid. By M. SÉNKOWSKI (*Monatsh.*, 9, 854—856).—*Methyl metamethylphenylacetate* is prepared by saturating a solution of the acid in five times the amount of methyl alcohol with hydrochloric acid. It is a liquid of sp. gr. 1·044 at 17·5°, boiling at 228—229°. The *ethyl* salt, prepared in similar manner, has a sp. gr. of 1·018 at 17·5°, and boils at 237—238°.

By dissolving metamethylphenylacetic acid in concentrated nitric acid, carefully cooled, a product is formed which melts at 70—110°, but cannot be obtained of constant melting point. It gives an ethyl salt which is still liquid at −30°. If the nitric acid solution of the acid is heated for some minutes on the water-bath, a *dinitro*-derivative, $C_6H_2Me(NO_2)_2{\cdot}CH_2{\cdot}COOH$, is obtained, melting at 173—174°. The salts of this acid are very unstable, decomposing in aqueous solution even at the ordinary temperature into dinitro-xylene and carbonic anhydride. The *methyl* salt, prepared by saturating the solution of the acid in methyl alcohol with hydrogen chloride, crystallises in yellow needles melting at 41°. The *ethyl* salt, similarly prepared, melts at 68°. H. C.

Scopoletin. By D. TAKAHASHI (*Chem. Centr.*, 1888, 1364—1365, from *Mitt. med. Fak. Univ. Tokio*).—Scopoletin, $C_{10}H_8O_4$, the fluorescent substance occurring in *Scopolia japonica*, is extracted from the roots by treatment with alcohol, evaporation of the alcoholic solution, treatment with strong hydrochloric acid, drying with admixture of sand, extraction with chloroform, and finally recrystallisation several times from absolute alcohol. It consists of colourless needles, melting at 198—199°, little soluble in cold water, readily soluble in alcohol, ether, and chloroform. *Acetylscopoletin*, $C_{10}H_7O_4Ac$, melts at 176°, and is little soluble in water, but soluble in alcohol. *Benzoylscopoletin* is insoluble in water, little soluble in alcohol, and melts at 158°. *Methylscopoletin*, $C_{10}H_7O_4Me$, is prepared by heating a mixture of scopoletin (1 mol.), methyl iodide (2 mols.), and potassium hydroxide (2 mols.), in methyl alcohol on the water-bath. It forms long, colourless needles, melts at 144°, is insoluble in cold water, soluble in hot water, alcohol, ether, benzene, and carbon bisulphide, insoluble in alkalis in the cold. This characteristic, together with the partial decrease in the fluorescence in alkaline solution indicate, in the same way as the characteristic reactions of coumarin, that scopoletin is also a coumarin-derivative.

Since dimethylæsculetin and methylscopoletin have been proved to be identical, and since also the bromine-derivatives are alike, scopoletin must be a derivative of hydroxyquinol. *Methylscopoletilic acid*, $C_{11}H_{10}O_5$, is prepared by heating monobromomethylscopoletin with potash, a reaction which is also similar to those which the dibromo-derivatives of coumarin undergo when heated with potash. If its silver salt is decomposed by carbonic anhydride, a colourless, pleasant-smelling oil is obtained, which, when treated with strong aqueous soda and distilled with steam, becomes converted into dimethoxycoumarin, $C_{10}H_{10}O_3$, melting at 58°.

Methyl trimethylæsculetate, $C_6H_2(MeO)_3\cdot CH{:}CH\cdot COOMe$, is prepared by melting methylscopoletin with potash, extracting the mass with methyl alcohol, and heating with methyl iodide in a closed flask for three hours. By recrystallising several times from alcohol the product remaining after the alcohol has been evaporated off, it is obtained as a yellow, crystalline substance, melting at 102°, insoluble in water, but readily soluble in alcohol and ether; it yields the free acid on hydrolysis, &c. By reduction with sodium amalgam, *trimethoxyphenylpropionic acid*, $C_6H_2(OMe)_3\cdot CH_2\cdot CH_2\cdot COOH$, is formed, from which by oxidation with potassium permanganate trimethoxybenzoic acid is obtained. From this, trimethoxyquinol can be obtained; the constitution of scopoletin is, therefore, concluded to be

$<\begin{matrix}CO—O\\CH{:}CH\end{matrix}>C_6H_2(OMe)\cdot OH$.

J. W. L.

Homo-orthophthalic Acid. By M. LE BLANC (*Chem. Centr.*, 1888, 1352—1353).

—*Dipropylhomo-orthophthalimide*, $C_9H_5Pr_2NO_2$, prepared by the action of propyl iodide on homo-orthophthalimide in alcoholic solution, melts at 141·5°. *Dipropylhomo-orthophthalic anhydride*, $C_9H_4Pr_2O_3$, prepared by heating the imide at 240° with fuming hydrochloric acid, melts at 88°. *Dipropylhomo-orthophthalic acid*, $C_9H_6Pr_2O_4$, prepared by treating the anhydride with potash, melts at 127°. *Homo-orthophthalopropylimide*, prepared by distilling a solution of homo-orthophthalic acid in propylamine, crystallises in leaves which melt at 69—70°. *Nitrobenzenehomo-orthophthalopropylimide*, prepared from the last-named imide by treating it with nitrobenzaldehyde, melts at 119°. *Salicylhomo-orthophthalopropylimide*, prepared in like manner to the last-named compound, melts at 157°. Aldehydes of the fatty series, such as isovaleraldehyde, react in a manner quite different from the aromatic aldehydes.

Dibromo-orthophthalimide, prepared by the action of bromine on phthalimide in acetic acid solution, melts at 168·5°. J. W. L.

Synthesis of Dialkyl Phthalides. By R. Kothe (*Annalen*, **248**, 56—71).—*Dimethylphthalide*, $C_6H_4<\begin{matrix}CMe_2\\CO\end{matrix}>O$, prepared by acting on a mixture of methyl iodide and phthalic anhydride with zinc-dust, melts at 67—68°, and boils at 270—271°. It is easily obtained in large crystals, exhibiting the phenomenon of double refraction. It dissolves in a solution of potassium hydroxide, forming the potassium salt of orthohydroxyisopropylbenzoic acid. Reduction with sodium amalgam converts dimethylphthalide into dimethylhydrophthalide, $C_6H_4<\begin{matrix}CMe_2\\CH(OH)\end{matrix}>O$, and hydriodic acid reduces it to orthoisopropylbenzoic acid. Potassium cyanide acts on dimethylphthalide at 250°; dilute sulphuric acid converts the product into an acid, probably orthopropenylbenzoic acid. The acid melts at 60—61°, and forms a crystalline barium and silver salt.

Diethylphthalide is an oily liquid boiling at 210—214° under 210 mm. pressure. It appears to be identical with the compound described by Wischin (*Annalen*, **143**, 262).

Benzyl chloride acts energetically on a mixture of zinc-dust and phthalic anhydride, yielding an amorphous product soluble in ether and benzene. This substance melts at 73°, and is non-volatile. It does not contain oxygen. W. C. W.

γ-Ketonic Acids. By A. Dittrich and C. Paal (*Ber.*, **21**, 3451—3457).—*Ethyl β-benzoyl-α-ethylisosuccinate* (*ethyl phenacylethylmalonate*), $COPh·CH_2·CEt(COOEt)_2$, is prepared by treating ethylic ethylsodomalonate suspended in absolute ether with the calculated quantity of bromacetophenone (phenacyl bromide). It is an oil which dissolves in the ordinary organic solvents, and decomposes when distilled in a vacuum. The corresponding *acid* crystallises from most solvents in slender, white needles or long scales, but can be obtained in cruciform aggregates of fairly large, four-sided prisms with oblique terminal faces, by the slow evaporation of its solution in a mixture of chloroform and light petroleum; the prisms, however, contain chloroform of crystallisation and effloresce on exposure to the air. The acid melts at 150° with evolution of carbonic anhydride; is insoluble in light petroleum, sparingly soluble in hot water and benzene, and readily soluble in alcohol, ether, chloroform, and acetic acid. Treatment with phosphorus pentachloride converts it into the *dichloride*, which is readily decomposed by water. The *ammonium*, *potassium*, *calcium* (1 mol. H_2O), and *silver* salts are described. The *hydrazone*, $C_{25}H_{26}N_4O_3$, crystallises in concentrically-grouped, slender, white needles, melts at 132°, is readily soluble in the ordinary organic solvents, and, when heated above its melting point, loses carbonic anhydride and is converted into a substance insoluble in alkalis or alkaline carbonates.

β-Benzoyl-α-ethylpropionic acid (*phenacylethylacetic acid*), $COPh·CH_2·CHEt·COOH$, is formed when β-benzoyl-α-ethylisosuccinic acid is heated above its melting point. It crystallises from acetic acid in small aggregates, melts at 81—83°, decomposes on distillation, and yields a *hydrazone* insoluble in alkalis. The *calcium* salt, $(C_{12}H_{13}O_3)_2Ca + H_2O$, crystallises in white scales and is insoluble in absolute alcohol, but readily soluble in water; the *ethyl* salt is a yellowish oil.

2 : 4-*Phenylethylthiophen*, C_4H_2SPhEt, is obtained by distilling sodium β-benzoyl-α-ethylpropionate or sodium hydrogenβ-benzoyl-α-ethylisosuccinate with phosphorus pentasulphide. It crystallises in small, white scales, melts at about 40°, and has the characteristic odour of the two known phenylethylthiophens. W. P. W.

Reissert's Deoxypyranilpyroic Dibromide and Bromodeoxypyranilpyroic Acid. By R. ANSCHÜTZ and F. HENSEL (*Annalen*, **248**, 269—281).—The authors have previously shown (Abstr., 1888, 1092) that Reissert's dihydropyranilpyroic acid (Abstr., 1888, 696) is identical with the pyrotartaric-anilic acid. On repeating Reissert's experiments on the action of bromine-water on dihydropyranilpyroic acid, they find that the so-called deoxypyranilpyroic dibromide consists of a mixture of tribromaniline and pyrotartaric-parabromanilic acid, and the so-called monobromodeoxypyranilpyroic acid is impure pyrotartaric-parabromanilic acid.

Pyrotartaric-parabromanilic acid is the chief product of the reaction of bromine-water on sodium pyrotartrate; no tribromaniline is produced.

Parabromaniline unites with pyrotartaric anhydride in benzene solution, forming the parabromanilic acid of pyrotartaric acid (m. p. 158—158·5°). It is converted into the corresponding parabromanil by the action of phosphorus pentachloride.

Dibromaniline [1 : 2 : 4] yields a pyrotartaric-dibromanilic acid melting at 139°; but tribromaniline does not combine with pyrotartaric anhydride in solution in benzene. W. C. W.

Dyes from Diamidoethoxydiphenylsulphonic Acid. By A. FEER and H. MÜLLER (*Chem. Centr.*, 1888, 1358, from *Bull. Soc. indust. Mulhouse*, 1888, 488—490).—Diazobenzene and sodium paraphenolsulphonate react together with formation of a dye, of the constitution $PhN_2\cdot C_6H_3(OH)\cdot SO_3Na$ [= 1 : 4], of light-yellow colour, little soluble in cold water, readily so in alkaline solutions. If this is heated in a sealed tube with ethyl bromide and soda in molecular proportion, the corresponding ethyl salt of *ethoxyazobenzenesulphonic acid* is formed. Reduction with stannous chloride in hydrochloric acid or with zinc-dust in alkaline alcoholic solution leads to the formation of *diamidoethoxydiphenylsulphonic acid*,

$$NH_2\cdot C_6H_4\cdot C_6H_4(NH_2)(OEt)\cdot SO_3H\ [OEt : SO_3H = 1 : 4].$$

Sodium acetate precipitates the free acid in crystals from its concentrated solution. By treating the hydrochloric acid solution of this sulphonic acid with sodium nitrite (2 mols.), tetrazoethoxydiphenylsulphonic acid is obtained, which, by treatment with phenol (2 mols.) or amines in dilute alkaline solution, yields yellow, red, and violet dyes;

these dye cotton without the use of a mordant, although the dye is not so fast as when one is used. J. W. L.

Indole-derivatives. By L. Wolff (*Ber.*, **21**, 3360—3366).—3 : 2′ : 3′-*Trimethylindole*, $C_{11}H_{13}N$, is obtained when β-bromolevulinic acid is heated with three times its weight of paratoluidine. It crystallises in white scales having a peculiar odour, melts at 121·5°, boils at 297° (corr.), is volatile with steam, and dissolves sparingly in water, but readily in alcohol, chloroform, and light petroleum. When allowed to remain for a few days, it becomes yellow and finally brown, and its acetic acid solution is coloured at first green and afterwards an intense blue on boiling with a small quantity of ferric chloride. The *picrate* crystallises from alcohol in brownish-red needles, and melts at 189°; the *nitroso*-derivative, $C_{11}H_{12}N{\cdot}NO$, forms lustrous, golden-yellow needles, melts at 73°, and is sparingly soluble in water, readily soluble in alcohol and acetic acid.

1 : 2′ : 3′-*Trimethylindole*, prepared in like manner from orthotoluidine, crystallises in white scales, melts at 79°, boils at 282—283°, and closely resembles the 3 : 2′ : 3′-derivative in its solubility and behaviour with ferric chloride. The *picrate*, $C_{11}H_{13}N,C_6H_2(NO_2)_3{\cdot}OH$, crystallises in purple-red needles, and melts at 152°.

Ethyldimethylindole, [Et : Me : Me = 1′ : 2′ : 3′], obtained in like manner from ethylaniline, is a yellow oil which boils at 280—282°, has the persistent indole odour, dissolves readily in alcohol, ether, and benzene, and when boiled in acetic acid solution with a small quantity of ferric chloride or potassium dichromate, yields a very characteristic, intense red coloration. The *picrate*, $C_{12}H_{15}N,C_6H_2(NO_2)_3{\cdot}OH$, crystallises in small, dark-red needles, melts at 105°, and is soluble in benzene.

2″ : 3″-*Dimethyl-β-naphthindole*, formed under similar conditions from β-naphthylamine, crystallises from alcohol in colourless, brittle, strongly refractive tablets, melts at 132°, boils above 360°, and is only slightly volatile with steam. It is insoluble in water, soluble in alcohol and acetic acid, and readily soluble in ether and benzene, and its solution in acetic acid is coloured green on boiling with ferric chloride. The *picrate* crystallises in lustrous, dark-brown needles melting at 175°.

2″ : 3″-*Dimethyl-α-naphthindole*, prepared in like manner from α-naphthylamine, crystallises from alcohol in small, white granules or prisms, melts at 150°, and is insoluble in water, sparingly soluble in cold alcohol and acetic acid, and readily soluble in ether and benzene. When heated in acetic acid solution with a trace of ferric chloride, it yields a beautiful cherry-red coloration, whilst with potassium dichromate it gives an intense blue. W. P. W.

Indoles. By B. Trenkler (*Annalen*, **248**, 106—113).—Valeraldehydephenylhydrazone boils at 220° under a pressure of 150 mm. It is converted into 3′-isopropylindole by fusion with zinc chloride. 3′-*Isopropylindole* is a pale-yellow, crystalline mass freely soluble in alcohol, ether, benzene, chloroform, light petroleum, and acetic acid. It boils at 287—288°. The picrate crystallises in needles and melts at 98—99°. *Hydroisopropylindole*, prepared by the action of zinc-dust and strong hydrochloric acid on an alcoholic solution of isopropylindole, resembles hydroscatole in its properties (Abstr., 1887, 957).

3′-*Pentylindole*, from œnanthaldehydephenylhydrazone, boils at 345—347° and is freely soluble in alcohol, ether, and benzene. The picrate is crystalline. 2′ : 3′-*Methylphenylindole*, from methylbenzylketonephenylhydrazone, crystallises in colourless prisms and melts at 59—60°. It does not stain pinewood. The picrate and the nitroso-compound are crystalline. 2′ : 3′-*Benzylphenylindole*, from dibenzylketone, forms six-sided prisms and melts at 100—101°. It is freely soluble in alcohol, ether, benzene, chloroform, and acetic acid, and does not exhibit the pinewood reaction. W. C. W.

Decomposition of Benzidine Hydrochlorides by Water. By P PETIT (*Compt. rend.*, **107**, 839—841).—Benzidine monohydrochloride is stable in solution, and when potassium sulphate is added, an insoluble sulphate, $(C_{12}H_{12}N_2)_2,H_2SO_4$, is precipitated, but no free acid is liberated. In the case of the dihydrochloride, dissociation takes place according to two distinct laws. If the concentration of the solution does not exceed 5·4 grams per litre, a constant fraction (0·034) of the salt is dissociated into the monohydrochloride and hydrochloric acid. When the concentration exceeds 5·4 grams, part of the monohydrochloride formed is precipitated and the quantity of dihydrochloride decomposed is the sum of two quantities, namely, the fraction corresponding with a concentration of 5·4 grams, and a quantity proportional to the excess of dihydrochloride over and above 5·4 grams per litre. C. H. B.

Similar Reactions of Carbazole and Pyrroline. By S. C. HOOKER (*Ber.*, **21**, 3299—3301).—Carbazole, like pyrroline, gives the pinewood reaction, a fact which is not in accordance with Fischer's conclusion respecting this reaction (compare Abstr., 1886, 806). Carbazole gives with isatin and concentrated sulphuric acid a deep blue solution, from which water precipitates an indigo-blue substance, the colour of which rapidly becomes lighter. When a small quantity of sulphuric acid, diluted with one or two volumes of acetic acid, is added to an acetic acid solution of carbazole and quinone, a carmine-red solution is obtained, from which water precipitates a red or reddish-violet substance, soluble in ether, chloroform, and alcohol. (Compare Meyer and Stadler, Abstr., 1884, 1045.) A green solution is produced when oxidising agents, such as quinone, are added to a solution of carbazole in sulphuric acid, and the colouring matter, which is precipitated by water, is insoluble in ether. (Compare Gräbe and Glaser, this Journal, 1872, 302.) Pyrroline also yields a green substance when treated with a very small quantity of an oxidising agent in dilute sulphuric acid solution; this green compound is rapidly destroyed by strong oxidising agents. (Compare Meyer and Stadler, *loc. cit.*).

Pyrroline yields a crystalline compound with picric acid; it melts at about 71° and is unstable. Phenylpyrroline also combines with picric acid. F. S. K.

Malachite-green and Derivatives of Paramidodiphenylmethane. By A. MANNS (*Chem. Centr.*, 1888, 1363).—The leuco-base of malachite-green, when distilled over zinc-dust, is reduced to aniline, dimethylaniline, and paramidodiphenylmethane, together with hydrocarbons of the fatty and aromatic series.

Paramidodiphenylmethane was prepared synthetically from paranitrobenzyl chloride by means of Friedel-Craft's aluminium chloride reaction in benzene solution.

Nitrodiphenylmethane thus obtained melts at 30—31°. It is reduced by tin and hydrochloric acid to *paramidodiphenylmethane*, and from this *diazoamidodiphenylmethane*, $C_{26}H_{23}N_3$, is prepared by treatment with nitrous acid. *Methylparamidodiphenylmethane*, $C_{13}H_{11}\cdot NHMe$, is obtained from amidodiphenylmethane by the action of methyl iodide; it boils above 360°, and is a light yellow oil. The hydriodide melts at 150°. *Acetylparamidodiphenylmethane* melts at 127·5°; the *benzoyl*-derivative melts at 162°. *Diphenylmethane hydrazine*, $C_{13}H_{11}\cdot NH\cdot NH_2$, is obtained as hydrochloride by reducing diazodiphenylmethane with stannous chloride in hydrochloric acid solution. The free base crystallises in yellow scales, melts at 85°, and boils above 360° without decomposition.

Parabenzyl-α-quinoline, $C_{16}H_{13}N$, is prepared from paramidodiphenylmethane by means of Skraup's reaction; it melts at 80·5°, boils above 360°, and is characterised by the large number of well-crystallised simple and double salts it forms. *Diparadiphenylmethanethiocarbamide*, $CS(NH\cdot C_{13}H_{11})_2$, prepared by the action of carbon bisulphide on amidodiphenylmethane, crystallises in yellow scales and melts at 147°. The sulphur-atom is replaced by oxygen by the action of plumbic oxide. If, however, an excess of amidodiphenylmethane is employed, *triparadiphenylmethaneguanidine*, $C_{40}N_{35}N_3$, is formed, melting point 100°. *Paradiphenylmethanecarbamide*, $NH_2\cdot CO\cdot NH\cdot C_{13}H_{11}$, melting at 160°, is prepared from paramidodiphenylmethane hydrochloride by the action of potassium cyanate. The *disubstituted carbamide*, $CO(NH\cdot C_{13}H_{11})_2$, is prepared by the action of carbonyl chloride on the base, or by fusing the last-named carbamide; it melts at 226°. *Ethyl diphenylmethanecarbamate*, $C_{13}H_{11}\cdot NH\cdot COOEt$, melts at 65°, and is prepared by the action of ethyl chlorocarbonate on the base. J. W. L.

Arrangement of Atoms in Space. Part III. Members of the Stilbene-group. By J. WISLICENUS and A. BLANK (*Annalen*, **248**, 1—34).—After referring to the researches of Grimaux, Zinin, Goldenberg, Zagoumenny, Limpricht, and others, on the action of reducing agents on benzoïn, the authors state the results of their own experiments on the action of zinc-dust and acetic acid on an alcoholic solution of benzoïn. The yield of deoxybenzoïn diminishes if the reduction is carried on for more than three hours; the amount of deoxybenzoïnpinacone increases. Small quantities of stilbene are formed, together with a substance crystallising in needles and melting at 172°, which proves to be β-deoxybenzoïnpinacone. Both the α- and β-pinacones decompose on distillation, yielding phenyl benzyl ketone and phenyl benzyl carbinol. The pinacones are optically inactive and probably stand in the same relation to each other as mesotartaric and racemic acids.

Wislicenus suggests the formula  $\begin{matrix}\text{Ph·C·Cl}\\ \|\\ \text{Ph·C·Cl}\end{matrix}$ for α-tolane dichloride, melting at 143°, and  $\begin{matrix}\text{Ph·C·Cl}\\ \|\\ \text{Cl·C·Ph}\end{matrix}$ for β-tolane dichloride, which melts at 63°. A determination of the molecular weight by Raoult's method, and the vapour-density, show that the substances are isomeric. When tolane tetrachloride is reduced by zinc, the yield of α-tolane dichloride is increased and that of the β-dichloride diminished, by raising the temperature from 20° to 80° or 130°.

Ditolane hexachloride, $CPhCl_2·CPhCl·CPhCl·CPhCl_2$, is formed by dissolving tolane tetrachloride and α-dichloride in molecular proportion in boiling alcohol; on cooling, the hexachloride is deposited in rhombic plates, soluble in benzene; it melts at 150°. Although Raoult's method gives 266 as the molecular weight of this compound instead of 568·4, the authors regard it as a definite compound, and not as a mixture of the di- and tetra-chlorides, as it is formed by the action of chlorine on a mixture of the α- and β-dichlorides.

β-Dichlorotolane will not unite directly with the tetrachloride to form the hexachloride. W. C. W.

Nitroparadiphenols. By E. KUNZE (*Ber.*, **21**, 3331—3335).—*Metadinitroparadiphenol*, $[(NO_2)_2 : (OH)_2 = 3 : 3' : 4 : 4']$, is formed when the calculated quantity of nitric acid, of sp. gr. 1·45, is added to paradiphenol in glacial acetic acid solution. It separates from glacial acetic acid in brown needles or nodular crystals melting at 272°.

Metadiamidoparadiphenol, $[(NH_2)_2 : (OH)_2 = 3 : 3' : 4 : 4']$, crystallises in colourless plates, decomposes when heated, and dissolves in alcoholic ammonia with a green coloration. The *hydrochloride*, $C_{12}H_6(OH)_2(NH_2)_2,2HCl$, crystallises in colourless needles. The *acetyl*-derivative, $C_{12}H_8N_2O_2Ac_4$, crystallises in colourless needles and melts at 225°.

Diethenyldiamidodiphenol,  $CMe\lessgtr\overset{O}{\underset{N}{}}\gtrless C_6H_3·C_6H_3\lessgtr\overset{O}{\underset{N}{}}\gtrless CMe$, is obtained when the acetyl-derivative is heated above its melting point. It crystallises in colourless prisms melting at 193°.

Tetrazodiphenol,  $N\lessgtr\overset{O}{\underset{N}{}}\gtrless C_6H_3·C_6H_3\lessgtr\overset{O}{\underset{N}{}}\gtrless N$, obtained by diazotising the diamidodiphenol, dissolves in hydrochloric acid with a red coloration, but is reprecipitated unchanged when ammonia is gradually added to the solution.

Diphenoldihydrazine hydrochloride, $[(N_2H_3)_2 : (OH) = 3 : 3' : 4 : 4']$, prepared by reducing the tetrazo-compound with stannous chloride and hydrochloric acid, crystallises in slender needles. When ammonia is added to the aqueous solution, the free *base* is precipitated in colourless crystals; it melts at 140° with decomposition, and reduces Fehling's and ammoniacal silver solutions.

Diacetonediphenoldihydrazone, $C_{18}H_{22}N_4O_2$, is obtained when acetone is added to an aqueous solution of the dihydrazine hydrochloride until the mixture commences to become turbid. It crystallises in colourless rhombic plates, melts at 200°, and is readily soluble in soda, but only sparingly in ammonia, and insoluble in alcohol and ether. Analogous condensation-products are obtained with ethyl acetoacetate, pyruvic acid, benzaldehyde and salicylaldehyde.

The tetranitrodiphenol, which is formed when paradiphenol or metadinitroparadiphenol is nitrated in glacial acetic solution, or when benzidine is treated with nitric acid (compare Caro; Griess and Schmidt; Schultz, Abstract, 1881, 909), has the constitution $[(NO_2)_4 : (OH)_2 = 3 : 3' : 5 : 5' : 4 : 4']$. It yields *tetramidoparadiphenol* when reduced with tin and hydrochloric acid.

Tetramidoparadiphenol crystallises in colourless needles, and decomposes, but does not melt when heated. It oxidises very readily, turns blue on exposure to the air, and is converted into a brownish-black crystalline compound, $C_{12}H_{12}N_4O_2$, when a stream of air is passed for a long time through an ammoniacal alcoholic solution. F. S. K.

New Method of Formation of Benzhydrol-derivatives By K. Albrecht (*Ber.*, **21**, 3292—3299).—*Dimethylamidobenzhydrol*, $OH{\cdot}CHPh{\cdot}C_6H_4{\cdot}NMe_2$, can be obtained by heating a mixture of benzaldehyde (1 mol.) and dimethylaniline (1 mol.) with 20 times its weight of concentrated hydrochloric acid at 100° for 50 hours, neutralising the solution, distilling the unchanged compounds with steam, and recrystallising the residue first from alcohol and then from light petroleum. It can also be prepared by reducing dimethylamidobenzophenone with sodium amalgam in alcoholic solution. It crystallises in slender needles, melts at 69—70°, and is very readily soluble in most solvents, but only moderately so in light petroleum, and insoluble in water. It dissolves in acids, yielding colourless solutions which become yellow when warmed. It is converted into leucomalachite-green when heated with dimethylaniline and zinc chloride.

Paranitrodimethylamidobenzhydrol, $NO_2{\cdot}C_6H_4{\cdot}CH(OH){\cdot}C_6H_4{\cdot}NMe_2$, is prepared by heating a mixture of paranitrobenzaldehyde (151 grams), dimethylaniline (121 grams), and hydrochloric acid (3 kilos.) for 40 hours, neutralising the filtered solution, washing the precipitate, and separating the dimethylaniline by distilling with steam. The yield is 80 per cent. of the theoretical. It crystallises from dilute alcohol in slender, yellow needles, melts at 96°, and is very readily soluble in most ordinary solvents, but insoluble in water and light petroleum. The cold acid solutions are colourless but turn yellow when heated. It yields paranitroleucomalachite-green (m. p. 176—177°) when warmed with dimethylaniline and zinc chloride, and when treated with alkaline reducing agents it is converted into the corresponding azoxy-, azo-, and hydrazo-compounds. When heated with methyl iodide in methyl alcoholic solution, a colourless, crystalline compound, probably the *methiodide*, is obtained: it melts at about 175° with liberation of methyl iodide. The salts are all very readily soluble and difficult to obtain crystalline. The *platinochloride*, $(C_{15}H_{16}N_2O_3)_2,H_2PtCl_6$, crystallises in needles and is decomposed by boiling water.

Dimethyldiamidobenzhydrol, $NH_2\cdot C_6H_4\cdot CH(OH)\cdot C_6H_4\cdot NMe_2$, prepared by reducing paranitrodimethylamidobenzhydrol with zinc and hydrochloric acid, melts at 165°, and loses 1 mol. H_2O when heated above its melting point. It dissolves in acetic acid with a blue coloration, and crystallises from benzene in shining needles containing benzene, which melt and lose their benzene at 142°. It yields tetramethylparaleucaniline when condensed with dimethylaniline.

The leuco-bases obtained by the condensation of dimethyldiamidobenzhydrol with other aromatic bases yield reddish-violet or blue dyes, whereas those obtained from paranitrodimethylamidobenzhydrol yield greenish colouring matters.

Dimethyldiamidodiphenylmethane, $NH_2\cdot C_6H_4\cdot CH_2\cdot C_6H_4\cdot NMe_2$, is obtained by boiling paranitrodimethylamidobenzhydrol or the corresponding diamido-derivative with zinc and hydrochloric acid. It is a colourless, crystalline compound, melts at 93°, and gives a bluish-violet coloration with chloranil or lead peroxide but not with acids.

The condensation of paranitrobenzaldehyde and dimethylaniline is best effected by dilute hydrochloric acid or dilute sulphuric acid; the hydrol formation only takes place in presence of excess of acid; if alcohol is also present, the ethyl ether is produced. When only a small quantity of acid is employed or if it is very dilute, nitroleucomalachite-green is formed. Hydrols are not formed, or only in very small quantities when phosphoric acid, acid salts, or organic acids are employed, and with excess of concentrated sulphuric acid the only product is tetramethylbenzidine, which is obtained in small quantities.

Dimethylaniline, diethylaniline, methylaniline, and ethylaniline, on the one hand, and paranitro- and metanitro-benzaldehyde on the other hand, condense without difficulty, and the hydrols formed resemble paranitrodimethylamidobenzhydrol.

The ethyl compounds melt at a lower temperature than the corresponding methyl-derivatives; the dialkylhydrols melt at a lower temperature than the monalkyl-derivatives, and the para-compounds at a higher temperature than the isomeric meta-bases. Aniline also combines with paranitrobenzaldehyde, but not so readily as the secondary and tertiary bases.

The amidohydrols dissolve in cold mineral acids and in dilute acetic acid, yielding colourless or only slightly coloured solutions; the diamido-derivatives behave in like manner towards excess of concentrated mineral acids, but dissolve in acetic acid, forming deep blue solutions especially on warming. The diamido-derivatives also give blue solutions when an insufficient quantity of mineral acid is added, or when dilute, only slightly acid solutions are warmed.

The author finds that tetramethyldiamidobenzhydrol does not dissolve in alcohol with a blue coloration as stated by Michler and Dupertius (this Journal, 1877, ii, 333), but that it dissolves in all neutral solvents, forming colourless solutions. F. S. K.

Formation of Benzamarone. By F. R. JAPP and F. KLINGEMANN (*Ber.*, **21**, 2934—2936).—Benzamarone is formed when deoxybenzoïn and benzaldehyde (each 5 grams) are dissolved in cold alcohol, treated with an alcoholic solution of potash (2 grams), and kept over night. The yield is 5 grams. A small quantity of the compound was also obtained by keeping a mixture of benzil, deoxybenzoïn, and weak alcoholic potash for some days in a closed vessel; in this case the benzaldehyde necessary for its formation is produced, together with benzoic acid (which was found in the product) by the slow decomposition of the benzil. Benzamarone, prepared as described above, or by Zinin's method (this Journal, 1871, 539), melts at 214—215° (not 225°). Its mode of formation points to the formula $C_{35}H_{28}O_2$ rather than to the double formula (Knoevenagel, *Ber.*, **21**, 1356).

N. H. M.

Constitution of certain Dichloronaphthalenes. By H. ERDMANN (*Ber.*, **21**, 3444—3448).—*Orthoparadichlorophenylparaconic acid* can be prepared by the action of succinic acid on orthoparadichlorobenzaldehyde, and crystallises from water in white scales melting at 164·5—165·5°. On distillation it yields *orthoparadichlorophenylisocrotonic acid*, $C_6H_3Cl_2{\cdot}CH{:}CH{\cdot}CH_2{\cdot}COOH$ [Cl : Cl : CH = 1 : 3 : 4], which crystallises from carbon bisulphide in white prisms. When this acid is heated for some minutes at its boiling point, it decomposes into *dichloro-α-naphthol*, $C_{10}H_5Cl_2{\cdot}OH$ [Cl : Cl : OH = 1 : 3 : 4′], which crystallises from carbon bisulphide in large prisms melting at 132°. The corresponding *dichloro-α-naphthylamine*, $C_{10}H_5Cl_2{\cdot}NH_2$, can be prepared by heating the dichloro-α-naphthol with aqueous ammonia; it melts at 116—117°, yields a hydrochloride melting at 204—205°, and when diazotised and treated either with alcohol or with stannous chloride and cupric chloride, is converted into 1 : 3 dichloronaphthalene, which crystallises in white needles melting at 60—61°. The author has, therefore, now prepared synthetically the two dichloronaphthalenes melting at about the same temperature, one of which is homo- and the other hetero-nucleal (compare this vol., p. 150). The remainder of the paper is devoted to a reply to Armstrong and Wynne's criticism of the constitution assigned by Erdmann and Kirchhoff (*loc. cit.*) to the heteronucleal dichloronaphthalenes melting at 48° and at about 61·5° (Proc., 1888, 104).

W. P. W.

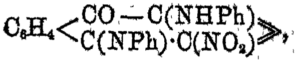
Note by Abstractor.—The author puts forward as original the discovery of the existence of two isomeric dichloronaphthalenes melting at about 61°; a reply to this and other claims in the paper has been published in the Proceedings, 1889, p. 5.

W. P. W.

Action of Chlorine on Phenols. Part III. β-Naphthol. By T. ZINCKE and O. KEGEL (*Ber.*, **21**, 3378—3390, 3540—3559; compare Abstr., 1888, 708).—Cleve has described the preparation of chloro-β-naphthol [Cl : OH = 1 : 2] by the action of chlorine on β-naphthol in acetic acid solution (Abstr., 1888, 597). Experiments show that dichloro-β-ketonaphthalene is simultaneously formed, and the best method of obtaining the chloro-β-naphthol consists in treating the β-naphthol dissolved in acetic acid with a slight excess of chlorine, and reducing the dichloro-β-ketonaphthalene formed by addition of an excess of concentrated stannous chloride. The *acetyl* compound, $C_{10}H_6Cl{\cdot}OAc$, crystallises in thick, colourless, oblique-angled tables, melts at 42—43°, and is very soluble in alcohol.

αβ-Dichloro-β-naphthol, $C_{10}H_5Cl_2{\cdot}OH$ [Cl : OH : Cl = 1 : 2 : 3], can be obtained by the reduction of tetrachloro-β-ketohydronaphthalene (see below), but when prepared from this source is always mixed with a larger or smaller quantity of the isomeric αα-dichloro-β-naphthol. It is best prepared, however, by reducing trichloro-β-ketonaphthalene dissolved in acetic acid, either with stannous chloride or a sulphite. It crystallises in aggregates of slender, lustrous needles, melts at 80—81°, and is readily soluble in alcohol, ether, benzene, and acetic acid. The *acetyl*-derivative, $C_{10}H_5Cl_2{\cdot}OAc$, crystallises in flat, rhombic tables showing a peculiar striation on some of the faces, melts at 79—80°, and is readily soluble in alcohol and acetic acid. When treated with chlorine in acetic acid solution, αβ-dichloro-β-naphthol is converted into β-trichloro-β-ketonaphthalene, which by further addition of chlorine forms β-pentachloro-β-ketohydronaphthalene. Chromic acid converts it into a yellow, amorphous substance, probably a diquinone-derivative, but on careful oxidation with nitric acid (sp. gr. = 1·4), it yields chloro-β-naphthaquinone as chief product, a second quinone-like compound, probably an αβ-nitrochloro-β-naphthaquinone, being simultaneously formed, which melts at 172°, and is characterised by dissolving in aqueous alkali with an intense bluish-green colour, and in alcoholic alkali with a deep blue colour.

αα-Dichloro-β-naphthol, $C_{10}H_5Cl_2{\cdot}OH$ [Cl : OH : Cl = 1 : 2 : 4], is obtained, together with the αβ-derivative, by the reduction of tetrachloro-β-ketohydronaphthalene with stannous chloride in the cold, and is separated from its isomeride by repeated crystallisation from light petroleum. It crystallises in long, hard, white, asbestos-like needles, melts at 123—124°, and is readily soluble in ether, alcohol, and acetic acid. Its *acetyl*-derivative, $C_{10}H_5Cl_2{\cdot}OAc$, crystallises in small, colourless needles, and melts at 90—91°. On treatment of its acetic acid solution with the calculated quantity of chlorine, it is converted into α-trichloro-β-ketonaphthalene, which by the further action of chlorine yields α-pentachloro-β-ketohydronaphthalene (?). When oxidised with chromic acid, it is converted into a yellow, amorphous substance, whilst with nitric acid (sp. gr. = 1·4), it yields as chief product αβ-chloronitro-β-naphthaquinone, α-chloro-β-naphthaquinone being formed simultaneously in very small quantities. *αβ-Chloronitro-β-naphthaquinone*,  $C_6H_4<\begin{matrix}CO{\cdot}CO\text{———}\\CCl{:}C(NO_2)\end{matrix}>$, crystallises in red or brownish-red needles, melts at 184°, and is readily soluble in hot benzene or acetic acid, sparingly soluble in alcohol, light petroleum, and cold benzene or acetic acid. It dissolves in concentrated alkali with an intense greenish-blue, and in dilute alkali with a reddish-brown colour. When treated with aniline, it yields *anilidonitronaphthaquinone anilide*,



$$C_6H_4<\begin{matrix}CO-C(NHPh)\\C(NPh){\cdot}C(NO_2)\end{matrix}\gg,$$

which crystallises in dark violet scales showing a metallic lustre, melts at 249—250°, and is insoluble in alkalis, sparingly soluble in acetic acid and benzene, but more soluble in toluene. The salts of this base are decomposed by alcohol or acetic acid unless acid is present, when they dissolve with a violet colour.

α-Chloro-β-naphthaquinone,
$C_6H_4<\begin{matrix}CO\cdot CO\\ CCl{:}CH\end{matrix}>$,
crystallises in reddish-brown, strongly dichroic needles, melts at 136°, and yields *β-hydroxynaphthaquinone anilide*,
$C_6H_4<\begin{matrix}CO—C(OH)\\ C(NPh)\cdot CH\end{matrix}\gg$,
on treatment with aniline.

Trichloro-β-naphthol, $C_{10}H_4Cl_3\cdot OH$ [Cl : OH : Cl : Cl = 1 : 2 : 3 : 4], is obtained by the reduction of β-pentachloro-β-ketohydronaphthalene with stannous chloride or sodium sulphite. It crystallises in colourless needles, melts at 162°, and is less soluble than the dichlorinated derivatives. Its *acetyl*-compound, $C_{10}H_4Cl_3\cdot OAc$, crystallises from acetic acid in white, lustrous needles and melts at 133·5—134°. On treatment in acetic acid solution with chlorine, it is converted into tetrachloro-β-ketonaphthalene. Chromic acid oxidises it to a yellow, amorphous substance, containing probably a diquinone, whilst nitric acid (sp. gr. = 1·4) converts it into αβ-dichloro-β-naphthaquinone.

α-Dichloro-β-ketonaphthalene (*β-naphthaquinone chloride*),

$$C_6H_4<\begin{matrix}CCl_2\cdot CO\\ CH{:}CH\end{matrix}>,$$

is obtained by treating chloro-β-naphthol or β-naphthol dissolved in acetic acid or chloroform with the calculated quantity of chlorine. It is a liquid, and rapidly decomposes on distillation in a vacuum. When treated with aniline, it is converted into β-hydroxynaphthaquinone anilide if dissolved in alcohol, but into anilidonaphthaquinone anilide,
$C_6H_4<\begin{matrix}CO\cdot C(NHPh)\\ C(NPh)—CH\end{matrix}\gg$,
if dissolved in acetic acid. Phenylhydrazine reacts with the compound in a peculiar manner, inasmuch as it does not convert it into the so-called benzeneazo-β-naphthol, but into a chlorinated azo-compound, *β-benzeneazo-α-chloronaphthalene*,

$$C_{10}H_6Cl\cdot N{:}NPh\ [Cl : N_2Ph = 1 : 2],$$

which crystallises in slender, reddish or pale-orange needles, melts at 115°, is readily soluble in alcohol, benzene, and acetic acid, and on reduction in acetic acid solution with stannous chloride yields not chloro-β-naphthylamine but a basic compound free from chlorine. A mixture of brown substances is formed by the action of hydroxylamine on dichloro-β-ketonaphthalene.

β-Trichloro-β-ketonaphthalene (*β-chloro-β-naphthaquinone chloride*),
$C_6H_4<\begin{matrix}CCl_2\cdot CO\\ CH{:}CCl\end{matrix}>$,
is formed by withdrawing the elements of hydrogen chloride from tetrachloro-β-ketohydronaphthalene. It is not, however, necessary to first prepare this compound in the pure state, since the product obtained by treating a well-cooled 10 to 12 per cent. solution of β-naphthol in acetic acid with an excess of chlorine, readily evolves hydrogen chloride when poured into an equal volume of alcohol,

and yields the trichloroketone. It crystallises from alcohol or acetic acid in thick, yellow needles, which darken in colour on exposure to light and melt at 95—96°; whilst from ether it separates in large, monoclinic prisms, which show, however, a marked rhombic habit if the solution is impure. When finely powdered, it dissolves slowly in dilute alkali, and yields, in addition to brown, resinous substances, ββ-chlorhydroxynaphthaquinone, $C_6H_4<\begin{matrix}CO\cdot C(OH)\\CO — CCl\end{matrix}>$, whose formation is accounted for by supposing that the β-chloro-α-hydroxy-β-naphthaquinone, which would most probably be formed in the first instance, undergoes isomeric change. When heated either with dilute alcohol or with dilute acetic acid, it forms resinous compounds, together with some chlorhydroxynaphthaquinone and a compound which crystallises in needles and seems to be a dichloro-β-naphthol. Stannous chloride and sulphites reduce it to αβ-dichloro-β-naphthol; phenylhydrazine in alcoholic solution reduces it, hydroxylamine converts it into resinous products and orthotoluylenediamine reacts with it, forming crystalline compounds. When the hot alcoholic or acetic acid solution of the trichloroketone is treated with aniline, *ββ-chlorhydroxynaphthaquinone anilide*, $C_6H_4<\begin{matrix}CO—C(OH)\\C(NPh)\cdot CCl\end{matrix}>$, is obtained, melting at 253°; if, however, a cold alcoholic solution is used this compound is formed only in relatively small quantities, the chief product being *αβ-dichloro-β-hydroxy-α-naphthylphenylamine*, $C_6H_4<\begin{matrix}CCl{:}C(OH) —\\C(NHPh){:}CCl\end{matrix}>$. This crystallises from chloroform in colourless, transparent, hard, thick crystals, from acetic acid in slender, lustrous needles, and from a mixture of ether and light petroleum in large prisms, melts at 162°, and dissolves without decomposition in alkalis. Its *acetyl*-derivative, $C_{16}H_{10}NCl_2\cdot OAc$, crystallises from alcohol or acetic acid in small, lustrous prisms, and melts at 164°. In one preparation of this compound, a third substance was once obtained, which crystallised in small, white scales, melted at 223°, and gave results on analysis indicating it to be a chlorhydroxydiphenylnaphthylenediamine.

α-Trichloro-β-ketonaphthalene (*α-chloro-β-naphthaquinone chloride*), $C_6H_4<\begin{matrix}CCl_2\cdot CO\\CCl{:}CH\end{matrix}>$, is prepared by treating an acetic acid solution of αα-dichloro-β-naphthol with the calculated quantity of chlorine. It crystallises from light petroleum in thick, white needles, and from a mixture of ether and benzene in well-formed, transparent, rhombic prisms, melts at 86—87°, and is readily soluble in hot alcohol, benzene, ether, and acetic acid. On treatment with alkali, it yields β-hydroxynaphthaquinone; aniline converts it in alcoholic solution into β-hydroxynaphthaquinone anilide, and in acetic acid solution into anilidonaphthaquinone anilide; stannous chloride reduces it to αα-dichloro-β-naphthol, and hydroxylamine reacts with it, forming an oxime.

Tetrachloro-β-ketonaphthalene (*dichloro-β-naphthaquinone chloride*), $C_6H_4<\begin{matrix}CCl_2\cdot CO\\CCl{:}CCl\end{matrix}>$, is obtained by suspending trichloro-β-naphthol in acetic acid, and passing chlorine until the whole has gone into solution and the liquid has a distinct odour of the gas. It crystallises from alcohol or acetic acid in yellowish scales, and melts at 96—97°. When treated with concentrated alkali, it yields dichlorhydroxyindenecarboxylic acid, which can be recognised by transforming it into dichloroketoindene,  $C_6H_4<\substack{CO\\CCl}>CCl$; alcoholic potash, on the other hand, converts it into the supposed ethyl-derivative of chlorhydroxy-β-naphthaquinone,  $C_6H_4<\substack{CO——CO\\C(OH):CCl}>$. Aniline reacts with it, forming ββ-chlorhydroxynaphthaquinone anilide.

Tetrachloro-β-ketohydronaphthalene,  $C_6H_4<\substack{CCl_2——CO\\CHCl\cdot CHCl}>$, is the most easily prepared of all the keto-derivatives of β-naphthol, and is obtained by treating a carefully cooled solution of β-naphthol in acetic acid with an excess of chlorine, and at once precipitating the product with water. It is necessary that the chlorination should be completed in one operation, since a partially chlorinated solution, after remaining 12 hours, gave on further chlorination a crystalline separation consisting of thick, yellowish needles, which had the composition $(C_{10}H_6Cl_2O)_n$, melted at 193°, and were sparingly soluble in most solvents. Obtained in this way, the tetrachlorhydroketone crystallises with 1 mol. H_2O in white, lustrous scales, melts at 90—91°, and is converted into the anhydrous form by repeated crystallisation from light petroleum; it then crystallises in white, lustrous scales melting at 102—103°, white needles melting at 101—102°, or, occasionally, in colourless, monoclinic prisms. It dissolves in cold alcohol, but on standing, or more rapidly on warming, it undergoes conversion into β-trichloro-β-ketonaphthalene. Stannous chloride and sulphites reduce it to αβ-dichloro-β-naphthol on warming, and to a mixture of this with the αα-derivative in the cold; solution of sodium carbonate converts it into β-chloro-β-naphthaquinone; aqueous soda dissolves it with the formation of ββ-chlorhydroxynaphthaquinone, and aniline reacts with it as with β-trichloro-β-ketonaphthalene.

When α-trichloro-β-ketonaphthalene is further chlorinated, it yields a compound crystallising in small forms, which resemble rhombic sulphur crystals both in colour and shape. Although this compound always shows the same melting point, it is very probable that it is a mixture of tetrachloro-β-ketonaphthalene and hexachloro-β-ketonaphthalene in molecular proportions, which cannot be separated by crystallisation, and not α-pentachloro-β-ketohydronaphthalene, inasmuch as a portion of the finely powdered substance dissolved rapidly in alkali, yielding a solution in which dichlorhydroxyindenecarboxylic acid could be detected, whilst the residue was white, and resembled hexachloro-β-ketohydronaphthalene in its properties.

β-Pentachloro-β-ketohydronaphthalene,  $C_6H_4<\substack{CCl_2—CO\\CHCl\cdot CCl_2}>$, is obtained by saturating a solution of β-trichloro-β-ketonaphthalene in acetic acid with chlorine. It crystallises in well-formed, colourless, triclinic prisms, which melt at 116—117°; if crystallised from ether, however, it forms very large and apparently rhombohedral crystals, and when crystallised from benzene yields both transparent forms and crystals which effloresce on exposure to the air. On reduction with stannous chloride, sodium sulphite, or less readily with phenylhydrazine, it is converted into trichloro-β-naphthol, and only reacts with aniline at the boiling point, when it yields ββ-chlorohydroxynaphthaquinone anilide. When treated in alcoholic solution with 25 per cent. aqueous potash, the ring is split, and *orthodichlorovinyldichlorobenzylcarboxylic acid*, $C_2HCl_2{\cdot}C_6H_4{\cdot}CCl_2{\cdot}COOH$, is obtained, which crystallises from chloroform in transparent, lustrous forms, and from light petroleum in thick, white needles, melts at 130—131° with decomposition and evolution of hydrogen chloride, but not of carbonic anhydride, and is readily soluble in the ordinary solvents. It dissolves in aqueous sodium carbonate without decomposition, but is slowly converted into the corresponding benzoylcarboxylic acid by caustic alkalis. On oxidation, it yields dichlorovinylbenzoic acid. The *methyl* salt, $C_9H_5Cl_4{\cdot}COOMe$, crystallises in slender, white needles, melts at 99—100°, and is readily soluble in alcohol and ether.

Orthodichlorovinylbenzoylcarboxylic acid, $C_2HCl_2{\cdot}C_6H_4{\cdot}CO{\cdot}COOH$, is prepared by dissolving the finely-powdered pentachloroketone in 25 per cent. aqueous potash and acidifying. It crystallises from dilute alcohol in long, slender, yellowish needles, melts without decomposition at 106—107°, and is readily soluble in alcohol and acetic acid, but only sparingly in light petroleum. The *methyl* salt has not been solidified, and no solid compound could be obtained by the action of hydroxylamine.

Hexachloro-β-ketonaphthalene,  $C_6H_4{<}\begin{matrix}CCl_2{-}CO\\CCl_2{\cdot}CCl_2\end{matrix}{>}$, is prepared by heating the tetrachloroketone with 1 part of manganese dioxide and 5 parts of fuming hydrochloric acid (sp. gr. = 1·19) at 140—150° for 6 to 8 hours. It crystallises in long, colourless, prismatic needles or in compact, seemingly monoclinic, and occasionally tabular crystals, melts at 129°, and dissolves in ether, benzene, hot alcohol, and hot acetic acid. On reduction, it is converted into trichloro-β-naphthol. When treated in warm alcoholic solution with concentrated aqueous potash, the ring is split, and *orthotrichlorovinyldichlorobenzylcarboxylic acid*, $C_2Cl_3{\cdot}C_6H_4{\cdot}CCl_2{\cdot}COOH$, can be obtained from the solution by saturating it with hydrochloric acid. It crystallises in colourless needles or long, thick tables, melts at 150° with decomposition, and is readily soluble in alcohol and ether. On oxidation, it yields orthotrichlorovinylbenzoic acid. The *methyl* salt, $C_9H_4Cl_5{\cdot}COOMe$, crystallises in colourless, slender needles, and melts at 83—84°. When the acid is dissolved in concentrated aqueous soda and afterwards acidified, an oil is obtained which could not be crystallised, and probably consists of the corresponding ketonic acid.

W. P. W.

Reduction Products of the Azo-dyes of the Naphthalene Series. By O. N. WITT (*Ber.*, 21, 3468—3489).—The azo-dyes obtained by the action of diazotised bases on the isomeric mono- and di-sulphonic acids of α- and β-naphthol and naphthylamine are converted by reduction into two amines, one being the base from which the diazo-compound was obtained, and the second being the amido-compound of the naphthalene-derivative employed. The actual or supposed instability of these reduction products has hitherto led to the neglect of this method of determining the constituents of the naphthalene azo-dyes, but this instability is to be ascribed to the secondary action of the reducing agent employed, the use of alkaline reducing agents such as zinc-dust with ammonia or soda, or the addition of alkali to the reduction product, leading in all cases to decomposition. The method, however, is the only one capable of giving trustworthy results, and experiment shows that with a suitable reducing agent, a solution of "tin salt" in hydrochloric acid, the reduction products of the naphthalene azo-dyes can be isolated for subsequent identification. For analytical purposes, 1 gram of the azo-dye, freed from dextrin, sodium sulphate, and like impurities, is dissolved in 10 c.c., or in the case of the less soluble dyes 20 c.c. of boiling water, the source of heat is then removed, and 6 c c. of a solution of 40 grams of "tin salt" in 100 c.c. of pure hydrochloric acid (sp. gr. = 1·19), corresponding to 2 grams of tin salt, is added. The amidonaphthol- or naphthalenediamine-sulphonic acid formed may separate from the warm or cold solution, or not at all, according to the nature of the substance, and in the last case precipitation with sodium acetate, salt, or hydrochloric acid, as determined by experiment, must be resorted to. This process is termed by the author a normal reduction.

In order to isolate and characterise the reduction products, the aniline-azo-dyes derived from β-naphthol, β-naphthylamine, and their mono- and di-sulphonic acids were alone employed, but the method presents no difficulties when applied to those azo-dyes found in commerce which are derivatives of these naphthalene-compounds.

Derivatives of β-Naphthol.—The azo-dyes derived from β-naphthol are known to give amido-β-naphthol on reduction (Liebermann, *Ber.*, **14**, 1310). β-Naphthol-orange (mandarin) on normal reduction yields a clear and colourless solution from which white needles and stellar aggregates of amido-β-naphthol hydrochloride separate on cooling. This salt dissolves readily in hot water, but cannot be precipitated either by alkalis or soda, the solution becoming dark brown in colour. Sodium acetate, however, precipitates amido-β-naphthol from the solution in lustrous scales, which dissolve readily in ether, and crystallise in small, quadratic tables on spontaneous evaporation of the solvent. The addition of ferric chloride to the hydrochloride in aqueous solution converts it into β-naphthaquinone.

Derivatives of the β-Naphtholsulphonic Acids.—(1.) *Amido-β-naphthol-α-sulphonic acid*, $NH_2 \cdot C_{10}H_5(OH) \cdot SO_3H$.—The orange from diazobenzene chloride and Bayer's β-naphthol-α-sulphonic acid on normal reduction yields amidonaphtholsulphonic acid, which crystallises from the hot solution in small, well-formed, rectangularly striated, pale rose-coloured scales, and can be purified by recrystallisation from a dilute solution of sodium acetate. It is very sparingly soluble in hot water and in sodium acetate solution; alkalis and alkaline earths, however, dissolve it readily, and the solutions very rapidly become deep orange-brown on exposure to air. Oxidising agents colour both the neutral and alkaline solutions of the acid deep yellow or brown, and silver salts are at once reduced by it and each of the following acids in both acid and ammoniacal solution. It does not yield a diazo-compound on treatment in acid solution with sodium nitrite, and diazo-compounds do not react with it, but decompose with the evolution of nitrogen and formation of a brown colour. When treated with nitrosodimethylaniline hydrochloride in a 50 per cent. acetic acid solution, it forms a characteristic violet colouring matter which in aqueous solution is coloured red on addition of aqueous soda.

(2.) *Amido-β-naphthol-β-sulphonic Acid* (Meldola, Trans., 1881, 47; Griess, Abstr., 1882, 50).—The orange from diazobenzene chloride and Schäffer's β-naphthol-β-sulphonic acid on normal reduction yields this amido-acid which separates from the hot solution as a crystalline magma. It is insoluble in alcohol, and cannot be purified by solution in water since decomposition ensues with the formation of brown solutions, which on the addition of hydrochloric acid become violet. It is soluble in hot 20 per cent. aqueous sodium acetate in the presence of acetic acid, and is precipitated from the solution on addition of hydrochloric or dilute sulphuric acid. With oxidising agents and sodium nitrite, it behaves like the preceding compound, but differs from it in not yielding a colouring matter with nitrosodimethylaniline hydrochloride. It is characterised by readily yielding, on treatment with diazo-compounds, beautiful colouring matters, which, however, do not dye wool; thus with diazobenzenesulphonic acid a magenta colouring matter is obtained whose shade is rendered bluish on addition of hydrochloric acid, whilst with tetrazostilbenedisulphonic acid a reddish-violet colouring matter is formed, which on addition of hydrochloric acid is precipitated in beautiful blue flocks soluble in water to a blue solution.

(3.) *Amido-β-naphthol-δ-sulphonic Acid.*—The aniline-azo-derivative of Casella's naphtholsulphonic acid F, on normal reduction, yields this amido-acid, which crystallises from the warm solution in shimmering, rose-red needles. It closely resembles amido-β-naphthol-β-sulphonic acid in its properties and reactions, but is less sensitive, and is characterised by reacting only with some diazo-compounds, and then but slowly. Thus, addition of the diazo-compound from Brönner's β-naphthylamine-β-sulphonic acid results in decomposition and the evolution of nitrogen, whereas amido-β-naphthol-β-sulphonic acid forms with it a reddish-violet colouring matter. Diazobenzenesulphonic acid produces with it a transitory red coloration followed by decomposition and evolution of nitrogen; tetrazostilbenedisulphonic acid, however, reacts with it, forming a dull brownish-violet colouring matter, which is precipitated without change of colour by hydrochloric acid.

(4.) *Amido-β-naphthol-γ-sulphonic Acid.*—The aniline-azo-derivative of β-naphthol-γ-sulphonic acid, on normal reduction, yields this amido-acid, which separates in a crystalline form from the warm solution, and can be purified by repeated solution in hot aqueous sodium acetate and precipitation with hydrochloric acid. It is the most sparingly soluble as well as the most stable of the isomerides, and forms small, rose-red aggregates, which are scarcely soluble in hot water. With alkalis, oxidising agents, and silver salts, it behaves like its isomerides, and is characterised by reacting neither with diazo-compounds nor with nitrosodimethylaniline hydrochloride in acetic acid solution.

Derivatives of β-Naphtholdisulphonic Acids. (1.) *Amido-β-naphthol-α-disulphonic acid.*—"Ponceau 2 G," the aniline-azo-derivative of β-naphthol-α-disulphonic acid (R-acid), on normal reduction yields a clear solution, which after cooling and standing some time deposits slender, snow-white, silky needles; an immediate separation in the form of satiny needles is, however, produced by the addition of an equal volume of saturated salt solution directly the reduction is complete. The *sodium hydrogen* salt of the amido-acid, $NH_2 \cdot C_{10}H_4(OH)(SO_3H) \cdot SO_3Na$, thus obtained, is collected, washed with alcohol and ether and dried, but is still impure, owing to the presence of amido-β-naphthol-β-sulphonic acid obtained from the Schäffer's acid, which is always present in the R-acid employed technically; it can be purified by rapidly dissolving it in 10 times its weight of acidified water, adding an equal volume of ice-cold alcohol, and at once immersing the solution in a freezing mixture in order to bring about rapid crystallisation. In the dry state the compound is stable, but in aqueous solution it is extraordinarily unstable, decomposing at once into what is almost certainly *sodium ammonium dihydroxynaphthalenedisulphonate*, $SO_3Na \cdot C_{10}H_4(OH)_2 \cdot SO_3NH_4$, which separates from the solution on addition of salt in grey scales. This compound is readily soluble in water, less so in alcohol, decomposes rapidly on addition of alkalis with the formation of brown solutions, and is a salt of the supposed amido-β-naphthol-α-disulphonic acid described by Griess (Abstr., *loc. cit.*). The amido-acid is rapidly oxidised by alkalis, does not react with diazo-compounds and nitrosodimethylaniline, and immediately reduces silver salts to metallic silver.

(2.) *Amido-β-naphthol-γ-disulphonic Acid.*—"Orange G", the aniline-azo-derivative of β-naphthol-γ-disulphonic acid (pure G-acid), on normal reduction, yields a clear solution from which salt solution precipitates the *sodium hydrogen* salt of the amido-acid, $NH_2 \cdot C_{10}H_4(OH)(SO_3H) \cdot SO_3Na$, in snow-white prisms or small aggregates of prisms. It is much more stable than its isomeride, and although it shows all the reactions given by the α-derivative, yet the decompositions take place so much more slowly as to afford a means of distinguishing between the two, for example, with silver salts the reduction only commences some minutes after the solutions have been mixed.

Derivatives of β-Naphthylamine.—The azo-dyes derived from β-naphthylamine are known to give α-β-orthonaphthylenediamine on reduction. The aniline-azo-derivative formed by the action of diazobenzenesulphonic acid on β-naphthylamine, on normal reduction yields the hydrochloride of this diamine which crystallises from the warm solution in slender, white needles, and is characterised by forming naphthaphenanthrazine when treated in aqueous solution containing acetic acid and sodium acetate with an aqueous solution of the bisulphite compound of phenanthraquinone. Naphthaphenanthrazine crystallises in yellowish-white, sparingly soluble needles, and dissolves in sulphuric acid with a blackish-violet colour, which becomes yellow on dilution. The azo-dyes obtained from phenyl-β-naphthylamine and the toluyl-β-naphthylamines have already been shown to yield azines on treatment with acids (Abstr., 1887, 590).

Derivatives of β-Naphthylaminesulphonic Acids.—(1.) The β-naphthylamine-α-sulphonic acid (Badische acid) reacts with diazobenzenesulphonic acid, but yields a yellow diazoamido- and not an azo-compound, which on normal reduction is converted into phenylhydrazine and unchanged Badische acid.

(2.) *Orthonaphthylenediamine-β-sulphonic acid*, $C_{10}H_5(NH_2)_2 \cdot SO_3H$.—"Gold brown," the aniline-azo-derivative of β-naphthylamine-β-sulphonic acid (Brönner's acid), on normal reduction, yields crystals which separate from the hot solution, and can be purified by solution in aqueous sodium acetate and precipitation with acetic or hydrochloric acids. It forms slender, pointed needles, is very sparingly soluble in water, and in alkaline solution becomes rapidly brown on exposure to the air; an excess of soda, however, precipitates a sodium salt in silvery scales. Potassium ferricyanide produces a brown colour with the alkaline solution, which subsequently changes to a pure yellow, and ferric chloride forms a dull green precipitate in the aqueous solution. The acid is characterised by yielding the citron-yellow *sodium naphthaphenanthrazinesulphonate*, $C_{24}H_{13}N_2 \cdot SO_3Na$, when its solution in sodium acetate and acetic acid is treated with an aqueous solution of the bisulphite compound of phenanthraquinone. This salt dissolves in sulphuric acid with a reddish-violet colour, and on fusion with potassium hydroxide is converted into a *eurhodol*, which is obtained in brown, gelatinous flocks on acidifying the solution of the melt, dissolves in sulphuric acid with a pure ultramarine colour, and is slowly precipitated as a cherry-red sulphate on addition of water to the solution.

(3.) *Orthonaphthylenediamine-δ-sulphonic Acid.*—The aniline-azo-dye obtained from β-naphthylamine-δ-sulphonic acid (F-acid), on normal reduction yields a clear solution which deposits only a few flocks on standing. An indistinctly crystalline precipitate is obtained by adding salt solution and hydrochloric acid, and this, when purified by solution in sodium acetate and precipitation with hydrochloric acid, forms a grey powder which dissolves in water more readily than the β-acid. In its behaviour with alkalis, potassium ferricyanide, and ferric chloride, it resembles the β-acid, but excess of soda does not precipitate a crystalline sodium salt from its solution. The corresponding *sodium naphthaphenanthrazinesulphonate* crystallises from dilute alcohol in slender needles and dissolves in sulphuric acid with a reddish-violet colour, and the *eurhodol* forms a pure violet solution with sulphuric acid, which on dilution yields a brownish-red precipitate of the sulphate.

(4.) *Orthonaphthylenediamine-γ-sulphonic Acid.*—The aniline-azo-derivative of β-naphthylamine-γ-sulphonic acid (Dahl's acid) on normal reduction yields this acid, which crystallises from the hot solution, and can be purified by solution in sodium acetate and precipitation with hydrochloric acid. It crystallises in shimmering brown scales, is more soluble in water than the β-compound, reduces silver salts, and in aqueous solution yields a deep green coloration with ferric chloride, the solution subsequently depositing a dark-green precipitate. The alkaline solution slowly assumes a brown colour. The corresponding *sodium naphthaphenanthrazinesulphonate* dissolves in sulphuric acid with a violet colour, which on dilution becomes orange, and the *eurhodol* dissolves in sulphuric acid with a black-violet colour, and the solution on dilution with water first becomes cherry-red, and afterwards deposits the sulphate in dark-red flocks.

Derivatives of β-Naphthylaminedisulphonic Acids.—The β-naphthylamine-γ-disulphonic acid (amido-G-acid), according to Schultz, does not combine with diazo-compounds.

The aniline-azo-derivative of β-naphthylamine-α-disulphonic acid (amido-R-acid), on normal reduction, yields a clear solution on cooling, from which hydrochloric acid precipitates the *sodium hydrogen salt*, $SO_3H \cdot C_{10}H_4(NH_2)_2 \cdot SO_3Na$. This can be purified by dissolving it in water and precipitating with salt solution and fuming hydrochloric acid. When obtained by precipitation with hydrochloric acid, it forms a sandy powder consisting of well formed and often twinned prisms, whilst salt solution precipitates it in the form of slender, pointed needles. It is readily soluble in water, and the solution fluoresces green in the absence of mineral acids, yields sparingly soluble precipitates with barium and calcium chlorides, and becomes coloured deep green on addition of ferric chloride. It resembles orthonaphthylenediamine-γ-sulphonic acid in its behaviour with alkalis and silver salts. The corresponding *sodium naphthaphenanthrazinedisulphonate* forms a transparent, citron-yellow, gelatinous mass which could not be crystallised, and dissolves in sulphuric acid with a very characteristic bluish-magenta coloration, which on dilution becomes first yellow and then orange. The *eurhodol* is insoluble in water and yields a deep greenish-blue solution in sulphuric acid, which on dilution becomes first violet and then bordeaux-red; further dilution precipitates the eurhodol itself in yellowish-brown flocks.

W. P. W.

Constitution of β-Naphthol-α-Sulphonic Acid. By O. N. WITT (*Ber.*, **21**, 3489—3492).—When amido-β-naphthol-α-sulphonic acid (see preceding Abstract) is heated with concentrated hydrochloric acid at 120° for 4—5 hours, it yields a dihydroxynaphthalene, which on oxidation with ferric chloride is converted into β-naphthaquinone. It follows therefore that amido-β-naphthol-α-sulphonic acid has the constitution [$NH_2 : OH : SO_3H = 1 : 2 : ?$], and consequently Bayer's β-naphthol-α-sulphonic acid cannot have the constitution [$SO_3H : OH = 1 : 2$]. W. P. W.

Note by Abstractor.—Throughout the paper the author regards Armstrong as the authority for the 1 : 2 formula hitherto frequently assigned to Bayer's acid; this, however, is due to a misconception (compare Armstrong, Proc., 1889, 8). The acid has been shown to be heteronucleal by Armstrong and Wynne (Proc., 1888, 104; 1889, 7).

W. P. W.

Action of Fuming Sulphuric Acid on Brönner's β-Naphthylamine-β-Sulphonic Acid. By S. FORSLING (*Ber.*, **21**, 3495—3499).

When Brönner's β-naphthylamine-β-sulphonic acid, dried at 160°, is heated with 3 to 4 parts of fuming sulphuric acid at about 110° until a test specimen dissolves in water, a mixture of β-naphthylaminedisulphonic acid, together with a small quantity of a second acid, is obtained; the yield of the latter is increased by allowing the sulphonation to proceed at a higher temperature for a longer time.

β-Naphthylaminedisulphonic acid, $NH_2{\cdot}C_{10}H_5(SO_3H)_2$, cannot be obtained by acidifying the solution of a normal salt, since the corresponding acid salt is thereby formed. It can be prepared, however, by treating the barium salt with sulphuric acid, and crystallises in white needles which are extremely soluble in water, but only sparingly in alcohol. The *potassium* salt crystallises with 2 mols. H_2O in large, yellow crystals; the *potassium hydrogen* salt, with 1 mol. H_2O, in long, white, slender needles; the *sodium* salt in long, white needles; the *sodium hydrogen* salt, with 2 mols. H_2O, in long, white, slender needles; the *ammonium* salt, with 1 mol. H_2O, in large, red, triclinic crystals, and the *ammonium hydrogen* salt in anhydrous, slender, white needles; the *barium* and *calcium* salts are also described. The normal salts are readily soluble in water, the acid salts, on the contrary, are somewhat sparingly soluble in cold water. When diazotised in alcoholic solution with nitrous acid, the acid salts of the acid are converted into the corresponding diazonaphthalenedisulphonates, which are relatively stable, and can be boiled with absolute alcohol without decomposition; the *potassium* and *ammonium* salts crystallise in microscopic, yellow, rhombic tables, the *sodium* salt in needles.

The *potassium* salt of *β-chloronaphthalenedisulphonic acid*,

$$C_{10}H_5Cl(SO_3K)_2 + 5H_2O,$$

is obtained by heating potassium diazonaphthalenedisulphonate with cuprous chloride and hydrochloric acid. It crystallises in white needles, and is only sparingly soluble in cold water. The *disulphochloride*, $C_{10}H_5Cl(SO_2Cl)_2$, crystallises from benzene in thick tables, and from chloroform in small, colourless prisms, melts at 124·5°, and is very sparingly soluble in light petroleum. The *trichloronaphthalene*, $C_{10}H_5Cl_3$, crystallises in dendritic aggregates of slender needles, melts at 91°, and is sparingly soluble in alcohol, but readily soluble in chloroform.

W. P. W.

Filicic Acid. By E. Luck (*Ber.*, **21**, 3465—3468).—A reply to the criticisms of Daccomo (*Ber.*, **21**, 2962, this vol., p. 54). Pure filicic acid melts at 184·5°, but if the specimen is allowed to solidify and the melting point again taken, it is found to sinter at about 130°, and melt at 150—160°.

W. P. W.

Transformation of Terpilene into Menthene. By G. Bouchardat and J. Lafont (*Compt. rend.*, **107**, 916—918).—When terpin is treated with concentrated hydriodic acid, it yields a crystalline terpilene dihydriodide identical with that obtained from terebenthene. The terpin is mixed with hydriodic acid saturated at 0°, and as soon as the temperature is raised, the liquid separates into two layers and iodine is liberated, which indicates that hydrogen has combined with the hydrocarbon. The mixture was heated at 100° for 20 to 24 hours, the weight of hydriodic acid varying from 16 to 60 times that of the terpin. The principal reaction is represented by the equation $C_{10}H_{16},2HI + HI = C_{10}H_{18}HI + I_2$, whilst part of the terpilene is polymerised. The principal product is isomeric if not identical with menthene hydriodide, $C_{10}H_{19}I$, but it cannot be isolated from the accompanying diterpilene, since it decomposes even at a somewhat low temperature.

If the free iodine and acid are removed, and the hydriodide is heated at 100° with potassium acetate, potassium iodide is deposited and an oily liquid is obtained which is lighter than water. When distilled it separates into two fractions, one of which boils at 210—225° under a pressure of 30 mm., and consists of diterpilene mixed with hydrides of similar boiling point, whilst the other has the composition $C_{10}H_{18}$, and boils at 167—170° under ordinary pressure; sp. gr. at 0° = 0·837.

The latter hydrocarbon combines very slowly with hydracids, and differs in this respect from terpilene. If heated at 100° for 10 hours with 6 to 8 volumes of hydrochloric acid saturated at 0°, combination is complete, but only a monohydrochloride is formed. This is an oily liquid, lighter than water. It has an agreeable odour, does not solidify at −60°, and boils without decomposition at 105—110° under a pressure of 30 mm. Under ordinary pressure, it decomposes into hydrogen chloride and the hydrocarbon. When treated with alkalis, the hydrochloride yields the hydrocarbon, but there is no appreciable formation of any oxygen compound. All its properties agree with those of a menthol-derivative, and the hydrocarbon is identical or isomeric with Oppenheim's menthene. It is evident also that there is a close relation between terpilene and menthene. C. H. B.

Essential Oil of Daucus Carota. By M. LANDSBERG (*Chem. Centr.*, 1888, 1273).—By means of fractional distillation, this oil was divided into two principal fractions, the one boiling at 159—161° and the other at 240—260°. The former contains no oxygen, and is a terpene of the formula $C_{10}H_{16}$. It is dextrorotatory; a column 100 mm. long rotating the plane 32·3°; sp. gr. = 0·8525 at 28°. With bromine, it forms an additive compound, $C_{10}H_{16}Br_2$; from this, cymene was obtained by boiling its alcoholic solution with an aqueous solution of potassium cyanide. On heating the terpene in a closed tube at 280°, it is split up into two terpenes, the one boiling at 178—182°, and the other not distilling at 300°. Both combine with bromine to form additive compounds; that from the former, $C_{10}H_{16}Br_4$, melts at 123—125°; that from the latter has the formula $C_{10}H_{16}Br_2$. They may be considered as polymerides of the original terpene, which belongs to the group of pinenes.

The second component of the essential oil (boiling point 240—260°) proved to be a monohydrated terpene of the formula $C_{10}H_{18}O$. When heated to 280°, it loses the elements of water, and the residue consists of the same polymeric terpene of high boiling point as is obtained by heating the first-named terpene at 280°. The behaviour of the monohydrated terpene with bromine and with hydrogen chloride or bromide proved it to be identical with Wallach's cineole. J. W. L.

Constitution of Quassin. By V. OLIVERI (*Gazzetta*, 18, 169—170).—In a previous communication (Abstr., 1888, 1312), the author pointed out that quassic acid contained two ketonic groups, since it gave rise to a dioxime of the formula $C_{28}H_{36}O_8(C:NOH)_2$. It seemed, however, desirable to establish that these CO-groups existed also in quassin, and for this purpose the author prepared the compound of quassin with phenylhydrazine. Quassin (3 grams) and phenylhydrazine hydrochloride (4 grams) were dissolved in the smallest possible quantity of alcohol, a solution of sodium acetate added (6 grams in 15 c.c. water), and the whole heated at 100° for an hour. The yellow, amorphous deposit formed on allowing it to remain for a day was thoroughly washed with water, and attempts made to obtain it in a crystalline state but without success. An analysis showed that it had the composition $C_{30}H_{40}O_8(CH\cdot NHPh)_2$. It is formed from phenylhydrazine and quassin, with elimination of the elements of water, thus: $C_{30}H_{40}O_8(CO)_2 + 2NH_2\cdot NHPh = C_{30}H_{40}O_8(CN\cdot NHPh)_2 + 2H_2O$.
C. E. G.

Methysticin. By C. POMERANZ (*Monatsh.*, 9, 863—864).—Methysticin is a non-nitrogenous, non-volatile, neutral substance, which occurs in the alcoholic extracts from the roots of *Macropiper methysticum*. It crystallises in long, silky needles melting at 131°, sparingly soluble in hot water, ether, and light petroleum, readily soluble in alcohol, benzene, and chloroform. It contains about 65·4 per cent. carbon and 5·1 per cent. hydrogen. When fused with potash, it gives chiefly protocatechuic acid. Heated with 30 times the amount of 10 per cent. potash solution, it completely dissolves, and from the solution, which smells strongly of piperonal, hydrochloric acid precipitates a yellowish compound, which separates from alcohol in small white crystals melting at 180°. This compound, which contains 64·26 per cent. carbon and 4·85 per cent. hydrogen, is readily soluble in alkaline carbonates, and yields piperonylic acid on oxidation with permanganate. H. C.

Note.—No reference is made to Davidoff's researches on this subject (compare Abstr., 1888, 1207).

Andromedotoxin. By P. C. PLUGGE and H. G. DE ZAAYER (*Arch. Pharm.* [3], 26, 997—998, from *Arch. ges. Physiol.*, 40. See Abstr., 1883, 349).—Plugge first obtained andromedotoxin, which he extracted from *Andromeda japonica*, *A. polifolia*, *A. catesbaci*, and *A. calyculata*.

The aqueous extract of *Rhododendron ponticum* leaves was treated successively with normal and basic lead acetate. From the filtrate, the lead was separated by hydrogen sulphide, and the liquid was concentrated by slow evaporation in the air, and treated repeatedly with considerable quantities of chloroform. The residue left on evaporating the chloroform was purified by re-solution in chloroform (or alcohol) and precipitation by the addition of a considerable amount of ether. This treatment several times repeated finally yielded well formed, crystalline needles which melted at 228—229°. At 125°, water dissolves 2·81 per cent.; alcohol (of 94 per cent.) 11·1; amyl alcohol, 1·14; chloroform, 0·26; ether, 0·07; benzene, 0·004. The solutions in water, alcohol, and amyl alcohol are lævorotatory, whilst that in chloroform is dextrorotatory. Andromedotoxin, $C_{31}H_{51}O_{10}$, is an indifferent non-nitrogenous compound; its solution in indifferent liquids has a neutral reaction, and it is not precipitated by any of the so-called general alkaloïd reagents. Its reaction with dilute and concentrated mineral acids is characteristic, as with them it gives intensely red decomposition-products. Concentrated sulphuric acid gives a dark reddish-brown, which becomes deeper red on warming, and turns light mulberry-red on dilution with water. The addition of alkali removes the colour, which reappears on acidifying. Evaporation with dilute (1 : 5) sulphuric acid gives a beautiful rose-red colour. The pure material gives off no odour during this evaporation, but if not completely purified, a strong and very characteristic odour of ericinol is evolved. Evaporation with dilute hydrochloric acid gives a residue somewhat more violet-red in tint. Evaporation with phosphoric acid gives a mulberry-red residue, clearly perceptible with very minute quantities, as in the case of the other acids. The fatal dose for small animals has been found to vary from 0·1—0·45 mgrm. per kilo. body-weight. No chemical antidote is known as yet. In investigating poisoning cases, Dragendorff's process is recommended; but no acid should be used for extraction, as the solubility of the poison is not thereby increased. After extraction and purification by evaporation, taking up in alcohol, &c., the substance may be agitated with light petroleum, then with chloroform, and to the residue left by the chloroform the characteristic tests given above may be applied.

J. T.

Chlorophyll. By E. SCHUNCK (*Proc. Roy. Soc.*, **44**, 448—454; compare Abstr., 1887, 972).—Crude chlorophyll from grass is treated with boiling alcoholic soda, and hydrogen chloride passed into the solution until it is strongly acid. Crystals separate, which after purification form a semi-metallic purple mass, which softens at 205°, and shows the absorption-spectrum of phyllocyanin-derivatives. This compound is an ethyl ether. On treating it with boiling alcoholic soda, a dark-green sodium salt is obtained, which when decomposed by acetic acid and crystallised from ether gives purple crystals of a new substance, *phyllotaonin*, melting at 184°, and insoluble in water, but soluble in boiling alcohol and ether. The solution shows the same bands as phyllocyanin, but if the smallest quantity of acid be added, the third band from the end becomes fainter, and the fourth and fifth bands split into two. It forms a compound with acetic acid. Phyllotaonin forms compounds with potassium, sodium, copper, iron, and silver. With tin and hydrochloric acid, it gives a red compound, similar to that produced from phyllocyanin with the same reagents. A compound similar to the ether mentioned above may be obtained by treating phyllotaonin with ethyl iodide and potassium hydroxide; it is a black substance, whose solution gives an absorption-spectrum similar to that of the above ether. When chlorophyll is treated with alkalis and then with acids, it probably yields phyllotaonin, which in the nascent state, in contact with alcohol and hydrochloric acid, undergoes etherification. Crystallographic measurements of phyllotaonin are given. H. K. T.

Hydroxyhydroquinoxalines. By O. HINSBERG (*Annalen*, **248**, 71—84).—The author has repeated the experiments of Plöchl (Abstr., 1886, 351) and of Leuckart (*ibid.*) on the reduction of nitrotolylglycin by tin and hydrochloric acid, and finds that the product is identical with the dihydrohydroxytoluquinoxaline which is formed by the action of ethyl chloracetate on toluylenediamine. This substance rapidly oxidises, forming hydroxytoluquinoxaline, which Plöchl and Leuckart mistook for dihydrohydroxytoluquinoxaline. The substance described by Leuckart and Hermann (Abstr., 1887, 383) as chlorodihydrotoluquinoxaline, is also a derivative of hydroxytoluquinoxaline. Ethyl α-chloropropionate acts on toluylenediamine, forming an unstable compound, which oxidises on exposure to the air, yielding *hydroxymethyltoluquinoxaline*, $C_7H_6{<}\begin{matrix}N{:}C(OH)\\ N{:}CMe—\end{matrix}{>}$. The substance is crystalline, and melts at 238°. It is probably a mixture of two isomeric quinoxalines.

Dimethyloxydihydrotoluquinoxaline,  $C_7H_6{<}\begin{matrix}NH{\cdot}CMe_2\\ NH{\cdot}CO—\end{matrix}{>}$, prepared by the action of ethyl bromisobutyrate on toluylenediamine, is a stable crystalline compound, soluble in alcohol and ether. It melts at 227°, and yields a crystalline acetyl derivative, $C_{11}H_{13}N_2OAc$, melting at 206°. The *nitroso-derivative*, $C_{11}H_{13}N_2O{\cdot}NO$, melts at 153—154° with decomposition. The *dinitro*-compound melts at 280°. Dimethyloxydihydrotoluquinoxaline does not, like its apparent homologues, lose 2 atoms of hydrogen on oxidation, but undergoes a deeper change. Its whole behaviour shows that it does not belong to the class of hydroxyquinoxalines. W. C. W.

Metabromoquinolines. By A. CLAUS and G. N. VIS (*J. pr. Chem.* [2], **38**, 387—394).—The metabromoquinoline nitrate (m. p. 163°) previously obtained by Claus and Tornier (Abstr., 1888, 163), is really a mixture, and the oil obtained from it is not pure metabromoquinoline, as then described, but a mixture of both bromoquinolines, and generally contains some unaltered metabromaniline. When this nitrate is further fractionally crystallised, a nitrate melting at 185° (uncorr.) is obtained; the base separated from this crystallises in beautiful, colourless needles, melting at 48° (uncorr.), and as it has a higher melting point than the bromoquinoline previously described as anabromoquinoline (Abstr., 1888, 163), it is doubtless the real *anabromoquinoline*. Moreover this bromoquinoline can be obtained from ana-amidoquinoline by converting it into ananitroquinoline, and treating the latter by Sandemeyer's method.

The other bromoquinoline, previously described as anabromoquinoline (Abstr., 1888, 163), whose true melting point is 34°, is the real *metabromoquinoline;* its nitrate melts at 199°; its *methiodide* forms anhydrous yellow needles or prisms, melting at 240° (uncorr.).

When metabromoquinoline (1 part) is nitrated with a mixture (5 parts) of 2 parts of sulphuric acid and 1 part of nitric acid, two nitro-derivatives are obtained. *α-Nitrometabromoquinoline* crystallises in large, transparent prisms, which melt at 192° (uncorr.); its *platinochloride* is bright-red, and decomposes at 240°.

α Amidometabromoquinoline forms colourless needles which melt at 62° (uncorr.).

β-Nitrometabromoquinoline crystallises from alcohol in white aggregates of needles which melt at 142° (uncorr.), and has feeble basic properties; its *platinochloride* forms small, golden-yellow, anhydrous laminæ.

The *methiodide* of anabromoquinoline crystallises from hot water in yellow needles melting at 205° (uncorr.). Two nitro-derivatives are obtained by nitrating anabromoquinoline: *α-nitranabromoquinoline*, which crystallises in slender, nearly colourless needles, and melts at 146° (uncorr.), and *β-nitranabromoquinoline*, which also forms nearly colourless needles; it melts at 126° (uncorr.), and is a stronger base than the α-compound. The *platinochlorides* of both are described. A. G. B.

A Cerium Quinoline Nitrate. By G. WILLIAMS (*Chem. News*, **58**, 199—200).—When moderately concentrated solutions of ceric and quinoline nitrates are mixed, glistening, orange-red, rhombic plates of the double nitrate, $Ce(NO_3)_4,(C_9H_7N,HNO_3)_2$, form. The air-dried salt is amorphous, and melts readily, giving off nitrous fumes and an odour of nitrobenzene. On ignition it frequently deflagrates. D. A. L.

Additive Product of Papaverine with Orthonitrobenzyl Chloride. By E. v. SEUTTER (*Monatsh.*, **9**, 857—862).—20 grams of papaverine and 12 grams of orthonitrobenzyl chloride, finely powdered and mixed together, are heated for five hours on a water-bath. The product is extracted with water, excess of the chloride removed by agitation with ether, and the additive product obtained from the solution in light yellow crystals. These contain varying amounts of water according to the method used in drying them. The anhydrous product gives numbers for the chlorine and nitrogen which point to the composition $C_{20}H_{21}NO_4,C_7H_6NO_2Cl$. The nitrate, picrate and dichromate are described, as also the platinochloride. H. C.

Constitution of the Cinchona Alkaloïds. By Z. H. SKRAUP (*Monatsh.*, **9**, 783—827).—This paper contains the details of the investigation of the syrupy oxidation product of cinchonine and quinine (Abstr., 1887, 164). The syrup after removal of chromium by means of ammonia is treated with barium chloride and extracted with alcohol, and is thus separated into two portions, one, which is insoluble, containing the whole of the barium, and the other free from barium, which is soluble.

The barium salt of the organic acid present in the insoluble portion is converted into a lead salt, and this on analysis has the composition $(C_8H_{12}NO_4)_2Pb$. It is the salt of the monobasic acid $C_8H_{13}NO_4$ mentioned in the former paper, to which the name *cincholeuponic acid* is now given. By heating the lead salt with acetic anhydride at 120—130°, one of the hydrogen-atoms of this acid may be displaced by acetyl. Distilled with zinc-dust, a mixture of pyridine and its higher homologues is obtained, together with a large quantity of a non-volatile resin. The action of nitrous acid yields, among a variety of other products, a bibasic acid of the composition $C_8H_{12}N_2O_5$. On treatment with hydrogen chloride, this acid loses nitrous acid and becomes converted into the compound $C_8H_{13}NO_4,HCl$, a change which shows that the acid $C_8H_{12}N_2O_5$ is a nitroso- or isonitroso-derivative. On removing the hydrogen chloride from the above hydrochloride by means of silver oxide, cincholeuponic acid may be obtained in crystals. This acid, although monobasic, probably contains two carboxyl-groups, one of which only becomes active in the acetyl- and nitroso-derivatives.

That portion of the original syrup which is soluble in alcohol contains the three bases mentioned in the former paper. Of these the last, which is of doubtful origin and whose composition should have been given as $C_{13}H_{16}NO_2$, has been submitted to no further examination. The base $C_9H_{17}NO_2$, separated by means of its crystalline compound with gold chloride, is here named *cincholeupone*. It forms a crystalline compound with 1 mol. HCl; this has a slight optical rotatory power. When oxidised with chromic acid, cincholeuponic acid is obtained along with a number of basic substances. Heated with zinc-dust it gives β-ethylpyridine as the chief product, but no quinoline is formed. By means of acetic anhydride, one hydrogen-atom may be displaced by acetyl; the derivative thus obtained has the properties of a monobasic acid. By the action of alkyl iodides, 1 atom of hydrogen may be displaced by an alcohol radicle. The nitroso-derivative, $C_9H_{16}N_2O_3$, produced by the action of nitrous acid, has likewise the properties of a monobasic acid. The third base present, C_9H_7NO, which is separated by means of its platinochloride, is here identified with kynurine.

The author discusses the above results with reference to the constitution of cinchonine. He looks on cincholeupone as a secondary amine, being most likely a β-ethylpyridine-derivative, and considers it probable that cinchonine contains a quinoline-ring connected by at least two of its carbon-atoms with an ethylated pyridine-ring.

H. C.

Colchicine. By G. JOHANNY and S. ZEISEL (*Monatsh.*, 9, 865—881). —The view put forward by one of the authors (Abstr., 1888, 613) that colchicine is methylated colchiceïne, and this latter an acetyl-derivative of trimethylcolchicinic acid, is supported by synthetical evidence. By the action of methyl iodide on sodium colchiceïne, colchicine is produced, as also by passing hydrogen chloride through a solution of colchiceïne in methyl alcohol. In the first of these reactions a substance is also formed which appears to be *methylcolchicine*, $C_{22}H_{24}NMeO_6$; this, when boiled with dilute hydrogen chloride, yields methylcolchiceïne. Colchiceïne is produced by the action of acetic anhydride on trimethylcolchicinic acid.

Trimethylcolchicinic acid is found to crystallise with 2 mols. MeOH. When heated with sodium methoxide and methyl iodide in molecular proportions, a substance is obtained which the authors call *trimethylcolchidimethinic acid*, $COOH\cdot C_{15}H_9(OMe)_3\cdot NMe_2$, in which the hydrogen-atoms of the amido-group in the original acid have been substituted by methyl-groups. It melts at 126°. By the action of a further quantity of methyl iodide, the methiodide of the methyl salt of the above acid is obtained. This substance on treatment with silver oxide gives off trimethylamine, thus showing that it contains the NMe_3I group. H. C.

Action of Acid Chlorides on the Methyl Salt of Ecgonine Hydrochloride. By A. EINHORN and O. KLEIN (*Ber.*, **21**, 3335—3338).—The methyl salt of ecgonine hydrochloride, $C_8H_{14}NO\cdot COOMe,HCl + H_2O$, is obtained by saturating a solution of ecgonine hydrochloride in methyl alcohol with hydrogen chloride and heating the product in a reflux apparatus for an hour. It crystallises from alcohol in beautiful, transparent prisms and melts at 212° with decomposition.

The methyl salt of benzoylecgonine or cocaïne, $C_{17}H_{21}NO_4$, can be prepared by heating equal weights of the methyl salt of ecgonine hydrochloride and benzoic chloride at 100° for some hours until hydrogen chloride is no longer evolved. The base obtained by adding an alkali to the product has all the properties of the natural alkaloïd (compare Liebermann and Giesel, this vol., p. 168).

The methyl salt of *isovalerylecgonine*, $C_{15}H_{25}NO_4$, is formed by heating equal weights of the methyl salt of ecgonine hydrochloride and isovaleric chloride at 100° for 15 minutes. The base is an oil and could not be crystallised, although its hydrochloride, hydrobromide, and hydriodide crystallise well. The *platinochloride*, $(C_{15}H_{25}NO_4)_2,H_2PtCl_6$, forms large scales.

The methyl salt of *phenylacetylecgonine*, $C_{18}H_{23}NO_4$, is obtained by heating equal weights of the methyl salt of ecgonine hydrochloride and phenylacetic chloride at 100° for some hours. It is an oil which could not be crystallised, although its hydrobromide and hydriodide crystallise well from absolute alcohol. The *platinochloride*, $(C_{18}H_{23}NO_4)_2,H_2PtCl_6$, is crystalline.

The dimethyl salt of *orthophthalyldiecgonine*, $C_{28}H_{36}N_2O_8$, is prepared under like conditions from the methyl salt of ecgonine hydrochloride, and orthophthalic chloride. It is crystalline, and yields a hydriodide crystallising from alcohol in scales. The *platinochloride*, $C_{28}H_{36}N_2O_8,H_2PtCl_6$, crystallises in scales. W. P. W.

Cinnamylcocaïne. By C. LIEBERMANN (*Ber.*, **21**, 3372—3376).—*Cinnamylecgonine*, $C_9H_7O\cdot C_9H_{14}NO_3$, is prepared by heating a mixture of ecgonine (1 mol.) and half its weight of water with cinnamic anhydride (1 mol.) on a water-bath for an hour, grinding the product with 6—8 times its weight of water, filtering from unattacked cinnamic anhydride and from cinnamic acid, extracting the filtrate with ether to remove all cinnamic acid, and finally concentrating to the crystallising point. It crystallises in beautiful, vitreous, spear-like, anhydrous needles, melts at 216° with decomposition, is readily soluble in alcohol, and is precipitated from the alcoholic solution by ether. When boiled with hydrochloric acid, it is readily converted into cinnamic acid and ecgonine, and on treatment with dilute potassium permanganate solution it is at once oxidised, an odour of benzaldehyde being produced at the same time. The *aurochloride*, $C_9H_7O{\cdot}C_9H_{14}NO_3,HAuCl_4$, is anhydrous.

Cinnamylcocaïne, $C_9H_7O{\cdot}C_9H_{13}MeNO_3$, is obtained when a concentrated solution of cinnamylecgonine in methyl alcohol is treated with hydrogen chloride and allowed to remain in the cold for 24 hours in a closed vessel. It separates from a mixture of benzene and light petroleum in beautiful crystals with vitreous lustre, showing many faces, melts at 121°, and is insoluble in water, but soluble in alcohol, ether, acetone, chloroform, and benzene. The *hydrochloride* crystallises in colourless needles, and the *platinochloride*, $(C_{19}H_{23}NO_4)_2,H_2PtCl_6$, crystallises in microscopic needles melting at 217°. W. P. W.

Imperialine. By K. Fragner (*Ber.*, 21, 3284—3287).—*Imperialine*, $C_{35}H_{60}NO_4$, occurs in the bulbs of *Frittilaria imperialis*, and can be obtained in the pure state as follows:—The crushed bulbs are rubbed up with lime, the mixture dried at 100°, and extracted with hot chloroform. The extract is shaken with water acidified with tartaric acid, the alkaloïd precipitated from the concentrated aqueous solution with sodium carbonate, washed and recrystallised from alcohol. The yield is 0·08—0·12 per cent. It crystallises in short, colourless needles, turns yellow when heated at 240°, brown at 248°, and melts at 254°. It is very readily soluble in chloroform, moderately in hot alcohol, more sparingly in ether, benzene, light petroleum, and amyl alcohol, and very sparingly in water; the solutions have a bitter taste, and the specific rotatory power in chloroform solution is $[\alpha]_D = -35{\cdot}4°$. The *hydrochloride*, $C_{35}H_{60}NO_4,HCl$, separates from alcoholic hydrochloric acid in large crystals and is readily soluble in water and alcohol. A yellowish-red *platinochloride*, $(C_{35}H_{60}NO_4)_2,H_2PtCl_6$, and a yellow *aurochloride*, $C_{35}H_{60}NO_4,HAuCl_4$, are precipitated in oily drops when ether is added to an alcoholic solution of the hydrochloride and platinic or auric chloride; after having been washed with ether, both salts separate from hot dilute hydrochloric acid in a crystalline condition. The *sulphate* is very hygroscopic and was not obtained in a crystalline condition; the *oxalate* crystallises only from very concentrated solutions. Most of the usual reagents for alkaloïds produce precipitates in solutions of the salts. The free base turns pale yellow when treated with sulphuric acid, and when previously mixed with sugar it first becomes yellowish-green, then pale-green, flesh colour, cherry-red, and, after a long time, dark violet. Fröhde's reagent colours it greenish-yellow, and with Mandelin's reagent it gives an olive-green coloration which passes through reddish-brown and becomes dark brown. When mixed with potassium nitrate or potassium chlorate, and then moistened with sulphuric acid, it turns orange-yellow; if, however, the mixture is previously warmed, it turns dark reddish-yellow. The solution in hydrochloric acid fluoresces, becomes brownish-green when warmed, and turns brownish-red when the heating is continued for a long time. F. S. K.

Humous Substances. By F. Hoppe-Seyler (*Zeit. physiol. Chem.*, **13**, 66—121).—On the death of plants or parts of plants, substances of a brown colour are formed which are called humous substances. Wood, however, often remains white for years. In dry air, or at a high temperature, plants can be dried without browning. The browning of the surface of a cut apple may be taken as a very rapid example of the process. Bacteria do not seem to be concerned in this change. This brown coloration does not occur to any extent in dead animal tissues. It is not, however, due to the chlorophyll of plants, as it occurs equally quickly in plants which contain no chlorophyll. The almost universal distribution of tannic acid and carbohydrates, and especially of cellulose, suggests that these may be sources of the humous substance, or it may come from the hydrocyanic acid, phenol, and nitrogenous compounds of plant tissues.

Pure cellulose when mixed with mud containing micro-organisms, ferments and yields carbonic anhydride and methane in the absence of oxygen, but no humous substance is formed (Abstr., 1886, 923); in the presence of oxygen, the cellulose (filter-paper) still remains quite white; all sorts of mud being used in the experiments. By heating with water at 188—200°, or with caustic alkalis, humous substances are formed. Water in glass tubes produced a brown residue, and the liquid was found to contain formic acid, catechol, and protocatechuic acid; when platinum tubes were employed, there was a brown residue, but the other products obtained in glass tubes were absent, as they are due to the decomposition of the humous substance produced by a small quantity of alkali, dissolved out from the glass at the high temperature to which the tubes were subjected. Other experiments were performed with strong alkalis, and the resulting gases, as well as the residue, were analysed.

The fermentation of wood-gum was found to be similar to that of cellulose; and it is supposed that the lignic acid may be instrumental in the formation of humous substances in turf, peat, &c.

Tannin red, obtained from certain plants by extracting with water, and the phlobaphen of Stähelin and Hofstetter, an amorphous brown substance, are apparently derivatives of tannic acid, and may be included under humous substances. The preparation and properties of a large number of these substances are described. They are formed by the action of alkalis on various carbohydrates (dextrose, lactose, cane-sugar, glycuronic acid, &c.); from various aromatic substances; and those obtained from various vegetable sources are also described. They are amorphous, differing in percentage composition, mostly containing nothing but carbon, hydrogen, and oxygen. A few contain nitrogen, like those described by Udránszky in urine (Abstr., 1887, 1133; 1888, 180). A derivative of humous substances called humic acid is described, and various names are given to various other members of the group.

The original paper must be consulted for details concerning their preparation and analysis; the following summary will, however, indicate the methods adopted in their separation.

Humous substances fall into three groups: the first includes those which are soluble neither in caustic alkalis nor in alcohol, but unite with alkalis, forming a slimy mass. This group includes the humin and ulmin of Mulder. The second group consists of those which are completely soluble in alkalis, and precipitable from such solutions by acids; the precipitate formed is voluminous and jelly-like, and is insoluble in alcohol. A part of the tannin reds, and of humic and ulmic acids, belong to this group. The substances in the third group resemble those in the second with regard to their solubility in alkalis; but the precipitate produced by acid is easily soluble in alcohol. Phlobaphen, a part of humic and ulmic acids, and the brown acids included under the name hymatomelanic acids (which are formed from the members of the first two groups by heating with caustic alkalis) belong to the third group. W. D. H.

Cholamide and Hippuramide. By G. Pellizzari (*Chem. Centr.*, 1888, 1350—1351, from *L'Orosi*, **11**, 233—235).—By heating glycocholic acid for one day at 160—170° with alcoholic ammonia under pressure, a residue was obtained on evaporating the liquid, which, when recrystallised from aqueous alcohol, appeared as long, silky, very deliquescent needles. These are insoluble in acids and alkalis, little soluble in boiling water, readily soluble in alcohol and ether, and melt about 125°. The composition corresponds with that of Hüfner's cholamide, $C_{23}H_{39}O_3 \cdot CONH_2$. Isoglycocholic acid reacted with ammonia in a similar way.

Hippuric acid, when heated with alcoholic ammonia for four hours at 210—220°, reacted with formation of hippuramide melting at 183°. By heating at 260°, a further change took place, ethyl benzoate and benzamide being formed. J. W. L.

Chinethonic Acid. By V. Lehmann (*Zeit. physiol. Chem.*, **13**, 181—186).—Phenetoïl leaves the body partly in union with glycuronic acid in the urine. After administration of this substance, an acid occurs in the urine called chinethonic acid (Kossel, Abstr., 1881, 631). It may be prepared as follows:—The urine is concentrated, acidified with sulphuric acid, and extracted with ethyl acetate; this is separated, treated with excess of barium carbonate and distilled off; the residue boiled with water, filtered hot, and the filtrate evaporated to a small bulk. In a few days, the barium double salt crystallises out; this is recrystallised, dissolved in hot water, and neutral potassium sulphate added as long as a precipitate of barium sulphate forms; this is filtered off, the filtrate evaporated to dryness, and the residue extracted with boiling alcohol; the potassium salt goes into solution, and on cooling, crystallises out; the potassium salts of the ethereal hydrogen sulphates remain in solution. Some of these latter are formed from the phenetoïl administered. The relation of total sulphuric anhydride to that combined as ethereal hydrogen sulphates was, in a dog, before the experiment = 8·92; after the administration of 12 grams of phenetoïl it fell to 2·74.

The potassium salt, $C_{14}H_{17}O_8K + H_2O$, of the new acid, occurs in monoclinic crystals, and the silver salt has the formula $C_{14}H_{17}O_8Ag + H_2O$. The free acid, $C_{14}H_{18}O_8$, obtained by treating the potassium salt with sulphuric acid, is crystalline, and melts at 146°. When treated with dilute sulphuric acid, an oily substance which subsequently crystallised was obtained; it had the formula $C_8H_{10}O_2$, that is, contained one atom of oxygen more than phenetoïl. The question arises whether the oxygen is united to the benzene nucleus, or is derived from oxidation of the ethyl-group. It was found that on decomposing chinethonic acid with hydrogen iodide, quinol is formed, and with oxidising agents, quinone is formed easily. The constitution of chinethonic acid is therefore $OEt\cdot C_6H_4\cdot C_6H_9O_7$. W. D. H.

Physiological Chemistry.

Digestion in Hydra. By M. GREENWOOD (*J. Physiol.*, 9, 317—344).—The paper includes many points of histological interest; those which relate to digestion are summarised thus:—(1.) The ingestion of solids is performed by slow advance over the prey of lip-like projections of the hydra's substance. Entomostraca, Nais, beetle larvæ, and raw meat prove the most acceptable food; innutritious matter does not act as a stimulus to digestion. (2.) The digestion of enclosed food takes place entirely outside the endoderm cells which line the enteric cavity, and among these may be distinguished: (*a*) pyriform cells destitute of large vacuoles, holding secretory spherules during hunger, and these empty during digestive activity; (*b*) ciliated vacuolate cells often pigmented: the water of the digestive fluid is probably derived from these vacuoles. (3.) The pigment occurs as brown or black grains; its basis is proteïd in nature. The pigment resists solution in most chemical reagents; it dissolves slowly in nitric acid. It may be expelled into the alimentary cavity during digestion. (4.) A reserve substance of proteïd nature accumulates during digestive acts in the basal part of the vacuolated cells, and eventually takes the form of spheres; the excretory pigment probably takes its rise in some residue from this absorbed proteïd; it is also possible that fat is similarly formed. (5.) The medium in which digestive activity goes on is probably not acid.

These observations relate to *Hydra fusca*. In *H. viridis*, which contains chlorophyll (the chloroplastids of Ray Lankester) the mode of nutrition seems to be different; gland cells do not form a conspicuous feature in its endoderm, and apparently digestive secretion is less active. W. D. H.

Influence of the Consumption of Water on the Alimentation of Animals. By W. HENNEBERG (*Bied. Centr.*, 1888, 813—818).—The author controverts the statements of Märcker and others who state that about 40 per cent. of the water consumed by animals reappears in the form of vapour. Making use of the statistics of several experiments, it is shown that the water which appears as urine and as dung forms, in sheep 61 to 92 per cent. of the whole water consumed, and in oxen, 83 to 93 per cent.; consequently Märcker's figure for vaporised water, namely, 40 per cent., is much too high; it should be for sheep on the average 25·8, for cattle 12·6. E. W. P.

Coagulation of the Blood. By L. C. Wooldridge (*Proc. Roy. Soc.*, **44**, 282—284).—An answer to criticisms by Halliburton (Abstr., 1888, 974).

Influence of Ethyl-alcohol on Metabolism in Man. By H. Keller (*Zeit. physiol. Chem.*, **13**, 128—134).—The experiment was carried out on the author's person, and lasted a week; the daily nourishment consisted of 500 grams of meat, 500 grams of bread, 100 grams of butter, 1500 c.c. of spring water, and 2 grams of common salt. On the 4th day, 150 c.c. of pure 96 per cent. ethyl-alcohol was mixed with the water.

The urine was carefully collected, and in it the chlorides, sulphates, phosphates, and total nitrogen were estimated. The following table gives the results obtained:—

Day.	Volume of urine.	Body-weight.	In the Urine.				Remarks.
			Cl.	P_2O_5.	SO_3.	N.	
	c.c.	gram.					
1	1746	62800	3·919	2·956	3·399	20·9	
2......	1317	—	1·848	3·280	3·255	22·0	
3......	1246	62250	1·459	3·288	3·311	22·2	
4.. ..	1720	62250	1·930	3·348	3·368	20·8	150 c.c. alcohol.
5......	880	61400	1·416	2·891	3·494	23·1	
6......	987	61850	1·200	2·696	3·323	23·1	
7......	1080	61905	1·441	3·112	3·458	23·1	

From this the following conclusions are drawn:—

1. Alcohol acts as a diuretic. This is what previous authors have observed (K. B. Lehmann, *Münchner med. Wochensch.*, 1886, No. 51, 1887, No. 23).

2. There is a slight lessening of the nitrogenous output on the day on which alcohol was taken. This is perhaps explicable from the destructive action of alcohol on digestive and absorption processes. The following days showed a slight increase of the total nitrogen in the urine.

3. The increase of phosphoric acid is too slight, and the length of the experiment too short to draw any certain conclusions concerning it.

4. The increase of chlorine is also very slight, and perhaps depends only on the diuretic action of the alcohol. W. D. H.

Metabolism of Acetanilide in the Human Body. By K. A. H. MÖRNER (*Zeit. physiol. Chem.*, **13**, 12—25).—The urine of patients taking this drug (antifebrin) was, as Müller first observed (*Deutsch. med. Wochensch.*, **13**, 27), red, from excess of urobilin. The amount of ethereal hydrogen sulphates in the urine is increased, and the urine reduces alkaline solutions of cupric oxide and is strongly lævorotatory. The urine was evaporated to a syrup, extracted with 90—93 per cent. alcohol; to the extract, half its volume of ether was added, and then a warm concentrated alcoholic solution of oxalic acid. The potassium ethyl oxalate and the ethereal hydrogen sulphate form a compound which can be crystallised and purified by recrystallisation. Three preparations were made and analysed, and the numbers obtained correspond with the formula $NHAc{\cdot}C_6H_4{\cdot}SO_4K,C_2O_4KEt$.

On taking antifebrin, then, a part of it is oxidised to form paracetamidophenol, and is excreted as an ethereal sulphate; whether other similar acids are formed it is not at present possible to say.

The strongly lævorotatory reducing substance is probably a derivative of glycuronic acid. W. D. H.

Metabolism of Furfuraldehyde in Fowls. By M. JAFFÉ and R. COHN (*Ber.*, **21**, 3461—3465).—When furfuraldehyde is given to dogs and rabbits, a glycocine compound of furfuracrylic acid is excreted in small quantity in the urine (Abstr., 1887, 1032). It is possible, however, that this compound is the chief transformation-product of furfuraldehyde, and that the greater part is further oxidised in the organism, a small proportion only escaping oxidation and appearing in the urine, since experiment shows that rabbits fed with furfuracrylic acid in quantities amounting to 6 grams, excrete barely 0·5 gram of the glycocine compound of the acid, and about 2 grams of pyromykuric acid, no less than 60—70 per cent. of the furfuracrylic acid undergoing decomposition in the organism.

Furfuraldehyde in aqueous solution was given to fowls, partially by the mouth and partially by subcutaneous injection, in quantities of 0·5—1 gram per day. The action was very marked, and resulted in death in the majority of cases after a few days. Pyromucic acid and pyromucornithuric acid were present in the excreta, but no trace of furfuracrylic acid or its derivatives could be detected.

Pyromucornithuric acid, $C_{15}H_{16}N_2O_6$, crystallises in very small, colourless needles or short, thin prisms, melts at 186°, carbonises when strongly heated with the evolution of a pungent odour resembling that of acraldehyde, and is sparingly soluble in ether, but readily soluble in alcohol, acetic acid and hot water. When heated with baryta-water, it hydrolyses quantitatively into pyromucic acid and ornithine (Abstr., 1878, 584). W. P. W.

Is the Benzene-nucleus destroyed in the Body? By N. JUVALTA (*Zeit. physiol. Chem.*, **13**, 26—31).—A dog was fed on meat mixed with a known weight of neutral sodium phthalate; before and after the experiment it was fed on bone, so that the fæces during the time of experiment could easily be distinguished from those before and after. The urine and the fæces were examined.

The fæces contained 29·55 per cent., and the urine 12·95 of the salt given; 57·5 per cent. was therefore unaccounted for; in a second experiment 68·76 per cent. was lost. There was no increase in ethereal hydrogen sulphates in the urine, and glycuronic acid compounds were also absent. Hence, not being able to account for the loss, the author concludes that the substance had been destroyed, and therefore that the benzene-nucleus can be destroyed by the animal body. W. D. H.

Chemical Examination of the Suprarenal Capsules. By F. Marinò-Zuco (*Gazzetta*, **18**, 199—207).—In 1883, Foa and Pallacani proved the poisonous nature of the extract of the suprarenal capsules, but did not succeed in isolating the compound which gave this property to the extract. The author commenced his researches by confirming this statement as to the poisonous nature of the extract, and found that a few c.c. of it was sufficient to cause death in a large rabbit when injected hypodermically. If, however, the solution was rendered slightly acid or alkaline, it no longer had any toxic power.

After various fruitless attempts to isolate the poisonous substance, the following method was adopted: Some 500 suprarenal capsules of the ox were ground up with about five times their bulk of water, and the mixture heated on the water-bath for some four to five hours. When cold, the liquid portion was expressed, and the residue again treated four times successively in the same manner. The extracts were united, and their proteïd matters precipitated by adding to the liquid its own volume of alcohol and half its volume of ether. After separating the precipitate, the alcohol and ether were removed by distillation, and acetate of lead added to the filtered solution. The abundant brown precipitate thus formed was removed, and the clear solution carefully precipitated with basic acetate of lead, which then threw down a dirty white precipitate consisting of lead chloride and organic lead salts. The clear solution, after treatment with magnesia or, better, with argentic oxide and filtration, gave precipitates with all the general reagents for alkaloïds, such as auric chloride, potassium mercuro-iodide, &c. The aurochloride was prepared and analysed, when it was found to have the composition of neurine aurochloride, $C_5H_{12}ON,HAuCl_4$, with which it agreed in physical properties and in yielding trimethylamine when decomposed. The platinochloride, $(C_5H_{12}ON)_2,H_2PtCl_6$, was also prepared and analysed.

The lead precipitate was next examined; after being well washed, it was suspended in water, decomposed by hydrogen sulphide, filtered, and the filtrate treated with baryta-water, which threw down a precipitate of barium phosphate. The excess of baryta was then removed from the solution by means of carbonic anhydride, and the clear liquid precipitated by basic acetate of lead, which threw down lead chloride mixed with lead salts of organic phosphatic acids. It was found to be impossible to separate these acids, but the presence of glycerophosphoric acid in the mixture was proved.

Now, although the presence of neurine in the suprarenal capsules will not of itself account for the powerfully toxic action of the extract, it was found that if the mixture of organic phosphatic acids mentioned above is saturated with neurine, a liquid is obtained which, even when very dilute, has all the poisonous properties of the extract itself. Experiments were also made with neurine orthophosphate and glycerophosphate prepared synthetically. It was found that the phosphate is far more poisonous than the hydrochloride; whilst the glycerophosphate is intensely poisonous, 0·1 of a milligram being sufficient to kill a frog.

The poisonous principle being a compound of neurine with an organic phosphatic acid, it is easy to understand how the action of acids or alkalis by destroying this combination renders the extract innocuous. C. E. G.

Sugar and Allantoïn in Ascitic Fluid. By R. Moscatelli (*Zeit. physiol. Chem.*, **13**, 201—204).—In a small number of cases of cirrhosis of the liver, sugar occurs in the urine (Cobrat, *Lyon. Méd.*, 1875, No. 15; Lépine, *Gaz. méd. de Paris*, 1876, 126; Quincke, *Berlin. klin. Wochensch.*, 1876, No. 38).

In the present case of liver cirrhosis, the urine was scanty, and gave no sugar reaction. The ascitic fluid, however, contained 0·15 per cent. of sugar. This was estimated by Fehling's method. Confirmatory tests, including the fermentation test, were also successful.

A crystalline substance was also separated in small quantities from the same pathological fluid, which chemically and crystallographically was identified as allantoïn. W. D. H.

Antiseptic Action of Bile Acids. By P. Limbourg (*Zeit. physiol. Chem.*, **13**, 196—201).—Bile and the bile acids have long been supposed to have an antiseptic action in the alimentary canal. The present research is directed to determining more accurately whether this is the case, by means of quantitative analysis.

Hirschler (Abstr., 1887, 310) has shown that phosphomolybdic acid precipitates some of the products of digestion (peptone, propeptone, &c.), while it does not precipitate certain others (amido-acids); these may be respectively termed Groups 1 and 2.

Artificial pancreatic juice was mixed with "Witte's peptone," and infected with bacteria from dog's fæces. Digestion was then allowed to take place, a solution of sodium cholate being added to a certain number of the specimens.

At the end of a certain interval, the following determinations were made:—(1) Total nitrogen; (2) nitrogen of substances belong to group 2; and (3) ammonia. The following tables (p. 292) give the results in percentages in two series of experiments.

The quantity of amido-acids and of ammonia in the specimens where the bile salt was present is thus smaller than in those where the salt was absent. In other words, these experiments performed outside the body fully confirm what one has been accustomed to believe occurs in the alimentary canal, namely, that bile prevents or hinders changes of a putrefactive nature there. W. D. H.

Time.	Nitrogen in Group 1.		Nitrogen in Group 2.		Nitrogen in Ammonia.

Carbohydrates in Normal Urine. By N. Wedenski (*Zeit. physiol. Chem.*, **13**, 122—127).—Brücke, Bence-Jones, Pavy, Huizinga, Abeles, and others have affirmed the constant presence of small quantities of dextrose in normal urine; while others—Seegen, Külz, Moscatelli, &c., have denied it. The more recent work of Udránszky (Abstr., 1888, 180, 863) shows that carbohydrates are normally present in small quantities, and Landwehr (*Centr. Med. Wiss.*, 1885, 369) prepared animal gum from normal human urine.

In the present research, the urine was shaken with excess of benzoic chloride; insoluble benzoyl compounds of the carbohydrates are thus formed and crystallise out. Estimation of the carbon and hydrogen in these gave a result intermediate between those obtained by control experiments with glycogen on the one hand and dextrose on the other. This led to the conclusion that probably a mixture of two carbohydrates is present; this was confirmed by treatment with sodium hydroxide; part went into solution and the remainder was undissolved. The insoluble residue was soluble in alcohol and gave the tests for grape-sugar; the soluble part was found to consist of a substance having the reactions of animal gum. W. D. H.

Glycogen in Diabetic Urine. By W. Leube (*Chem. Centr.*, 1888, 1278—1279, from *Virchow's Archiv*, **113**, 392—393).—In the precipitate obtained by the addition of alcohol to the urine of healthy persons and of those suffering from diabetes insipidus, the author could not find any carbohydrate or glycogen; in the urine of persons suffering from diabetes mellitus, however, a carbohydrate in varying quantity was detected which proved to be glycogen. J. W. L.

Physiological Action of Paraxanthine. By G. Salomon (*Zeit. physiol. Chem.*, **13**, 187—195).—Recent researches on the physiological action of caffeïne and allied substances have suggested the necessity of working out the action of paraxanthine which is an isomeride of theobromine.

The experiments were made mostly on frogs; the lethal dose for these animals was found to be a weight equal to 0·15 to 0·2 per 1000 of body-weight when administered subcutaneously. Given by the mouth, larger doses are necessary to produce both physiological effects and death; this is even more the case when paraxanthine is given in the solid state—for the crystals are very insoluble. Like xanthine, theobromine, and caffeïne, this drug has an action both on the central nervous system and on the muscles; the action on the muscles occurs when the drug is applied locally to them. Their excitability is lessened, and ultimately disappears altogether. The muscles become hard, but complete rigor of the muscles during life is never seen. The action on the central nervous system is seen in abolition of reflexes.

The action of all these drugs is thus very similar; all produce the same creeping movements; then the disappearance of all spontaneous muscular activity and complete abolition of reflexes without a preliminary increase; the heart remains intact. Respiration is similarly affected by both theobromine and paraxanthine; it is first hurried, then slowed, and after death the lungs are found to be fully distended.

Caffeïne produces a rapid rigor of the muscles after death; this is not markedly the case with paraxanthine.

A few experiments on warm-blooded animals (mice) gave the following results: paresis of the hinder extremities and increase of reflex activity, producing tetanus; peculiar creeping, dragging movements are thus produced. The dose of the poison must be twice to four times as large as for frogs.
W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Constituents of Hedera Helix. By H. Block (*Arch. Pharm.* [3], **26**, 953—984).—The author confirms Davis' view that Posselt's hederic acid obtained from the fruit of the ivy is not an acid. Posselt's results were confirmed as to the presence of hederatannic acid, oleïc acid, and another acid, and glycerol. Cholesterin was also found in the fruit. From the leaves was obtained *hederaglucoside*, $C_{32}H_{52}O_{10} + 2H_2O$, which loses 1 mol. of water at 100°. Treatment with 4 per cent. sulphuric acid slowly causes decomposition, thus: $C_{32}H_{52}O_{10} + 2H_2O = C_6H_{12}O_6 + C_{26}H_4O_4 + 2H_2O$. The leaves also yielded carotin. An aqueous extract made from 20 grams of different parts of the plant was titrated with normal potash solution, the amount of alkali used was respectively for the root, 11·1 c.c.; stem, 14·2; small leaves, 18·6; middle-sized leaves, 17·6; large leaves, 17·8. The mineral constituents of 100 grams dried at 100° are given in the following table:—

	Root.	Stem.	Leaves.
K_2O	0·5333	0·6778	1·2381
Na_2O	0·0261	0·0234	0·2179
CaO	2·7100	1·5139	5·0432
MgO	0·1550	0·2902	0·3450
Fe_2O_3	0·0345	0·0681	0·0781
MnO	0·0059	0·0148	0·0074
Al_2O_3	0·0022	0·0031	0·0393
HCl	0·0364	0·0124	0·0819
SO_3	0·1214	0·1737	0·7115
P_2O_5	0·2192	0·2333	0·5841

Total	6·3400	4·9200	12·6000
Soluble in water	0·8557	1·2610	2·5080
Insoluble in water	5·4843	3·6590	10·0920

J. T.

Rare Constituents of the Ash of the Sugar-beet. By E. O. v. LIPPMANN (*Ber.*, **21**, 3492—3493).—The author has detected boric acid, vanadium, manganese, cæsium, and copper in minute quantities in the ash of the sugar-beet. The occurrence of boric acid and cæsium, either in the sugar-beet or in products derived from it, seems hitherto to have escaped notice. W. P. W.

Presence of Nitrites in Plants. By T. MODDERMAN (*Ann. Agronom.*, **14**, 423—424).—In the water exuding from the curved teeth on the leaves of a fuchsia plant, the author has detected nitrites by the following tests: potassium iodide, starch, and sulphuric acid; ferrous sulphate and sulphuric acid; sulphanilic acid and naphthylamine sulphate; diphenylamine and sulphuric acid; rosaniline in glacial acetic acid; and phenol and mercury nitrate. In the soil itself nitrites could only be detected by the extremely sensitive reaction with sulphanilic acid. J. M. H. M.

Occurrence of Boric Acid in the Vine and in Wine. By G. BAUMERT (*Ber.*, **21**, 3290—3292).—The author has examined German, French, and Spanish wines, and found that boric acid was present in every case; boric acid is also contained in the leaves, tendrils, &c., of the grape vine (compare Ripper, *Weinbau u. Weinhandel*, No. 36, 1888, and Solstein, *Pharm. Zeit.*, **33**, 312).
F. S. K.

Vegetable Fats. By H. JACOBSON (*Zeit. physiol. Chem.*, **13**, 32—65.)—The fats in peas, beans, vetch and lupinus seeds were investigated. The raw fats form thick, nearly black masses with a strong aromatic odour, and are easily soluble in ether, chloroform, carbon bisulphide, &c.

The fat was first saponified with 25 per cent. sodium hydroxide; the lead soap was also prepared; ether extracts of the two soaps were prepared, and also the fatty acids. There were, therefore, the following preparations to be investigated:—

(1.) The mother-liquor after saponifying with soda.
(2.) The ethereal extract from the sodium soap.
(3.) The ethereal extract from the lead soap.
(4.) The fixed fatty acids.

Fat from Beans.—The seeds contained 1·17 per cent. of fat. (1.) The mother-liquor from the soda soap contained the black pigment which was not further investigated, glycerol, and volatile fatty acids, especially valeric. A considerable quantity of chlorine, trimethylamine, and glycerophosphoric acid was also obtained; the last from decomposition of lecithin. The choline was identified by elementary analysis: its platinochloride was also prepared. (2.) The ethereal extract from the soda soap contains a substance like cholesterin. In elementary composition it agreed pretty well both with animal cholesterin and also with the paracholesterin prepared by Reinke and Rodewald (Abstr., 1881, 753) from *Aethalium septicum*, and the phytosterin prepared by Hesse (*Annalen*, **192**, 179) from peas. These compounds are probably isomeric. Its melting point is 131·5° to 132·5° (uncorr.); its specific rotatory power $[\alpha]_D = -31°$ to $-32°$, which is the same as that of phytosterin. The benzoic acid compound was prepared: it crystallises in thin, bright, rectangular plates, easily soluble in ether and chloroform, and melting at 145—145·5° (uncorr.). The acetyl-compound was also prepared. (3.) The ethereal extract of the lead soap contained the lead salts of oleic and erucaic acids. (4.) The fixed fatty acids separated by the fractional method consisted chiefly of palmitic acid, and an acid of the formula $C_{24}H_{48}O_2$ (see also Stürcke, *ibid.*, **223**, 307). Stearic acid was absent.

Fat from Vetches.—The seeds contained 3 per cent. of fat. (1.) The mother-liquor from the soda soap contained only small quantities of volatile fatty acids. Lecithin was also present. (2.) The ethereal extract of the soda soap contained a substance exactly similar to the cholesterin of bean fat. (4.) The fatty acids consisted of oleic and other acids, which were not further investigated.

Fat from Peas.—The seeds contained 1·79 per cent. of fat. (1.) The mother-liquor from the soap contained lethicin; volatile fatty acids were also present in greater quantities than in either beans or vetches. (2.) Cholesterin was prepared from the ethereal extract of the soda soap, as in previous cases; after removing it, a substance resembling ceryl alcohol in elementary composition, crystalline form and melting point was separated out. (3.) The fixed fatty acids consisted chiefly of palmitic acid. Stearic acid was absent, or only present in mere traces. Oleic acid composed 90 per cent. of the fatty acid obtained from the fat of peas.

Fat from Lupine Seeds.—The seeds contained 8 per cent. of fat. Volatile fatty acids (rather less abundant than in peas), lecithin, cholesterin, ceryl alcohol were present, as in pea fat. Of the fatty acids, oleic acid was by far the most abundant, then came palmitic acid, and then arachidic acid. Mere traces of stearic acid were present. W. D. H.

Gluten and its Presence in Wheat-grain. By W. JOHANNSEN (*Ann. Agronom.*, **14**, 420—423).—Against the hypothesis of a special ferment which, in the ordinary process of obtaining gluten from flour, converts certain globulins (vegetable myosin) into that substance, the author cites the following observations:—An artificial flour, made by mixing dried and pulverised gluten with pure starch, or by mixing moist gluten with starch, and drying and pulverising the mixture, yields a paste of gluten by the ordinary process, just like common flour, and, moreover, behaves in exactly the same way to heat, acids, and mercuric chloride, in respect of the quantity of gluten yielded. The injurious effect of mercuric chloride is immediate when strong solutions (1 per cent.) are employed; with weak solutions it is gradual, and increases with the length of time during which the mixture of flour and water is left at rest before washing on the sieve; and the quantity of gluten obtained when mercuric chloride is added is always greater with a fine sieve than with a coarser one. Hence the author believes this injurious influence to consist simply in a tanning or coagulating action on pre-existing particles of gluten. Using the microscope, the author finds that gluten does not exist in the grain in the position usually assigned to it, namely, the peripheral layers of endosperm cells, which really contain small and slightly resisting particles of nitrogenous matter, lodged in a soft protoplasmic mass rich in fatty globules. The alleged aleurone grains observed in these cells by Hartig, the author states to be fat globules disengaged by contact with water. The deeper and smaller cells, inside of the peripheral endosperm, are the ones containing the gluten, which is in a dry condition, inclosing grains of starch. Teasing in a drop of water sets these starch grains free, leaving the gluten in the form of viscous filaments. J. M. H. M.

Erythroxylon Coca grown in India. By C. J. H. WARDEN (*Chem. News*, **58**, 249—251, 260—262, 273—276).—Several samples of *Erythroxylon coca* leaves, grown in various districts in India, have been examined by the author; the mode of culture, altitude, and meteorological characters of the district, the kind of soil and manuring, and the methods of curing, being taken into consideration. The alkaloïd was estimated by Squibb's modified method:—the dry pulverised leaves were moistened with alcohol acidified with sulphuric acid, percolated with alcohol, the percolate mixed with acidified water, and extracted with ether, then rendered alkaline with sodium carbonate, and again extracted with ether. This extract was washed twice with water, dried and weighed; the amounts of "crude alkaloïd" so determined are given in the following table:—

District where grown.	Moisture.	Per cent. dry leaves.	
		Ash.	Crude alkaloïd.
Ranchi, young leaves	6·18	6·71	1·139
" mature leaves	8·22	8·99	0·883
Arcuttipore, Cachar	6·08	7·39	1·369
" "	6·72	6·36	1·671
Darjeeling	10·37	7·58	1·115
Alipore, Calcutta	10·42	10·23	0·358
Matelli	9·30	12·18	1·022
Chulsa, Dooars	5·71	7·62	0·610
Jaunpore	10·05	12·64	0·571

The crude alkaloïd was very faintly yellow, and in no case showed any tendency to crystallisation, although attempts were made to induce crystallisation by extracting at various temperatures, and without applying heat, and by employing different acids and solvents. The alkaloïd obtained is, nevertheless, quite similar to cocaïne from other sources in its physiological action, except that it seems to be more active. It dissolves readily in hydrochloric acid, and yields a soluble and insoluble platinochloride, the former containing 18·75, the latter 18·88 per cent. of platinum; discrepancies from the theoretical are assumed to be due to a variable quantity of cocamine (Hesse, Abstr., 1887, 1125) in the alkaloïd from Indian leaves. Both platinum salts yielded bases producing marked anæsthetic effects on the tongue; Howard has observed that the insoluble platinochloride obtained from other leaves was devoid of this property (Abstr., 1887, 1126). In one instance stellate crystals of the base from the soluble platinum salt were obtained. Applying Williams' method, the crude alkaloïd showed 2·89 per cent. of impurity, but the precipitates were not crystalline. It is noted that after the addition of ether to the acidified alcoholic solution, larger deposits of the sulphur-yellow cocatannic acid were obtained from those samples containing the highest percentages of alkaloïds, it is hence suggested that possibly cocaïne exists in the leaves as cocatannate.

Methods of cultivating the plants are described: the leaves are first gathered 1½ years after transplanting, subsequently, whenever they are sufficiently mature; and, although the method of curing does not appear to affect the quality or quantity of the alkaloïd obtained, nevertheless it is best, taking into consideration Paul's experience, to dry them, soon after gathering, at as low a temperature as possible, and when dry and cold to pack them closely in air-tight chests, as they are very hygroscopic. The quantity of alkaloïd produced increases with the age of the plants (which attain a height of from 2 to 6 feet) up to 10 years, and after 20 years a slight falling off is observed, although they are in their prime even when 35 or 40 years old.

From the above results, obtained from plants and leaves of various ages, it would seem that, in India, neither altitude nor rainfall have much influence on the proportion of alkaloïd in the leaves. The ash, in all cases except one, was white, the exception being an ash of a reddish hue from mature Ranchi leaves. A partial examination of some of the ash showed that they contained the following percentages:—

Samples from	Soluble constituents.	K cal. as KHO.
Darjeeling	44·42	29·26
Alipore, Calcutta	34·60	19·13
Arcuttipore, Cachar	59·02	29·84
Matelli	64·17	31·36

So that both nitrogenous and potash manures will probably be required in the future to keep up the yield from the same plantation.

D. A. L.

Volatile Alkaloïd in Pepper. By W. Johnstone (*Chem. News*, **58**, 235).—A volatile alkaloïd, seemingly from the analytical data piperidine, has been observed by the author in pepper, and chiefly in the husks. Nine samples of black pepper contained a maximum of 0·77, a minimum of 0·39, and a mean of 0·56 per cent. Long pepper 0·84, pepper refuse 0·74, three samples of white pepper 0·34, 0·21, 0·42 respectively, whilst the corresponding black pepper gave a maximum of 13·03, a minimum of 5·21, and a mean of 8·25 per cent.

D. A. L.

Composition of Rain-water. By A. Lévy (*Bied. Centr.*, 1888, 793—795).—The results of a second set of 11 years' examination of rain-water for nitrogen are here given, and the quantities obtained during the warm and cold seasons of the year are kept separate. The average during the several months of 10 years are as follows:—

Ammoniacal Nitrogen per Square Metre.

January..	82·3 milligrams.	July	72·1 milligrams.
February .	59·6 „	August ..	102·7 „
March ...	66·3 „	September	93·3 „
April	95·3 „	October..	88·3 „
May	70·7 „	November	83·5 „
June.....	95·4 „	December	91·5 „

making a total of 1001·0 mgrm. per square metre per annum, or 10·01 kilos. per hectare.

As to the nitric acid nitrogen, the average was 3·85 kilos. per hectare. Dew, fog, and snow-water are richer in ammonia than rain, whilst they are poorer in nitric acid. E. W. P.

Salt in Rain-water. By G. Bellucci (*Bied. Centr.*, 1888, 795).—At Perugia, 120 kilom. from the sea, and at a level of 412 metres above it, there was found in the rain-water during the months of March to December, 1886, an amount of sodium chloride equal to 3·734 kilos. per hectare per month, and during the whole of the year 1887 there was carried down a total of 42·531 kilos., or 3·544 kilos. per month per hectare; taking the rainfall for the two periods into account there was found 5 mgrms. per litre. As in England so in Italy, the rain of the winter months contains more salt than that of the summer. E. W. P.

American Red Clover. By F. Nobbe (*Bied. Centr.*, 1888, 821—826).—The yield and hardiness of American red clover are compared with that of European clovers, with the following results:—American clover stands considerably behind Holstein, Silesian, or Saxon seed. The heaviest crop was obtained from Holstein seed, whilst the lightest was from Steiermark. Cow-grass proves to be a plant of feeble power, for in the second year of its growth, the crop was very small and innutritious. The presence of rye-grasses reduces the yield of clover, so that it is unadvisable to mix clover seeds with more than 6—8 kilos. of grass seeds per hectare. E. W. P.

Value of Basic Slag as a Manure, as compared with Soluble Phosphate and Bone-meal. By E. Heiden (*Bied. Centr.*, 1888, 798—800).—The crop was a mixture of vetches and oats (2 : 1) manured with superphosphate, basic slag, and boiled-bone meal, all assisted by nitre. The results were unsatisfactory, and from them no definite conclusion can be drawn save that basic slag was not in this case the best manure. E. W. P.

Manuring Experiments on Heavy Soil. By E. HEIDEN (*Bied. Centr.*, 1888, 809—812).—In a former communication, an account was given of the experiments in which for 10 years plots had been manured respectively with the same manure; in 1885 they were all manured with farmyard manure, yet the yields were not equal, but in 1886 nitrogen and soluble phosphates were added, and then the results were equal; finally peas were sown in 1887, and manured with phosphoric acid and potash, with the result that the plot previously manured with lime brought the highest crop, next followed superphosphate, the lowest yield being off the ammonium sulphate plot. These crops show how necessary the presence of lime is for leguminosæ, especially on soils poor in that substance; they also show that for this purpose the addition of lime as lime is preferable to its addition as phosphate. E. W. P.

Influence of the Concentration of the Cream in Butter-making. By J. SEBELIEN (*Landw. Versuchs-Stat.*, 35, 321—335).—To examine a statement of Kirchner's (*Milchzeitung*, 1887, 733), the author made a series of experiments in which cream was taken and divided into two portions, from one of which butter was made after the addition of half, or once or twice its weight of skim-milk, and from the other portion without any addition. In some of the experiments, the cream was soured before churning; in others it was churned sweet. With a few exceptions, the experiments pointed to the following conclusions. Both with sweet and sour cream, the percentage of fat in the butter-milk was smaller when the cream was diluted than when it was unmixed, the difference being greatest when it was churned sweet; but on calculating the absolute amount of fat left in the butter-milk coming from equal amounts of cream, it was found that more fat was left in the butter-milk when the cream had been diluted, and the differences were again greatest in the case of the sweet cream. The time taken in churning was longest when the cream had been diluted. The dilution appeared not to affect the composition of the butter. H. H. R.

Analytical Chemistry.

Apparatus for Estimating the Amount of Gas Disappearing in a Reaction. By C. F. CROSS and E. J. BEVAN (*Chem. News*, 58, 215).—The authors describe an apparatus suitable for the determination of the volume of a gas disappearing in combination. It consists of a bottle fitted with a well-paraffined india-rubber stopper, through which two tubes pass, the one of narrow bore, bent at right angles, and fitted with a stopcock; the other of wide bore, terminating within the bottle in a large thin bulb, and carrying a piece of india-rubber tubing at the other end. In experimenting with lignocellulose, for example, the bulb is filled with the fibre, and a glass rod is thrust through the piece of india-rubber tubing, so as to press on the fibre; the bottle is filled with chlorine, the stopper inserted, and the bent tube, with the stopcock closed, connected with a gas apparatus having a suitable intervening stopcock for adjusting levels, which is done, with both stopcocks open, as soon as the temperature is right; the stopcocks are then closed, the bulb broken by means of the rod, the bent tube stopcock opened, the rising column of mercury then indicates the progress of the reaction, which is vigorous and well defined with lignocelluloses. A tube filled with fibre is placed between the bent tube and gas apparatus to intercept any chlorine, though none has been observed to diffuse. D. A. L.

Graduation of Tubes for Gasometric Purposes. By BERTHELOT (*Ann. Chim. Phys.* [6], **14**, 279—286).—The author recommends the following method for graduating very exactly, or for verifying the graduation of tubes throughout their length. The tube placed vertically is filled with pure mercury so that the level of the metal is slightly above the orifice of the tube, care being taken to expel all air-bubbles. A moderately thick piece of perfectly flat glass is then pressed over the mouth of the tube, the whole inverted and weighed to within about 1 cgrm. A corner of the glass plate is then slightly separated from the tube so that a small quantity of mercury escapes. After replacing the plate, the whole is placed on a horizontal surface and the graduation corresponding to the horizontal tangent at the surface of the meniscus carefully noted by means of a magnifying glass or small telescope. The loss in weight is then ascertained by weighing the tube as before or by weighing the mercury which has escaped, and this value, divided by the density of mercury at the temperature of the experiment, gives the exact volume of the tube shown by the graduation in question. 8 to 10 such operations can be made successively with the same tube in one hour.

F. S. K.

A New Form of Eudiometer. By W. MARCET (*Proc. Roy. Soc.*, **44**, 383—387).—A eudiometer tube, open at the lower end, plunges into mercury; at the upper end is a steel cap fitted with a three-way stopcock which allows the eudiometer and tubes to be washed, either with pure hydrogen from a gasholder or with the air to be analysed. Hydrogen is first introduced, and then air. Results obtained with this apparatus are given. H. K. T.

Calorimetric Bomb as a Combustion Furnace for Ultimate Analysis. By A. EILOART (*Chem. News*, **58**, 284).—The author suggests the possible adoption of the calorimetric bomb, filled with an atmosphere of dry oxygen under pressure, for quantitative combustion, small absorption vessels for estimating the water and carbonic acid formed being introduced inside the bomb. A bomb much smaller than that used for calorimetric purposes would do. D. A. L.

Estimation of Hydrogen Peroxide. By C. T. KINGZETT (*Analyst*, **13**, 62—63).—The author has shown (Trans., 1880, 803) that hydrogen peroxide can be determined by adding a sufficiency of potassium iodide and sulphuric acid and titrating the liberated iodine with thiosulphate. To titrate 10 c.c. of a 2-volume solution (to which strength stronger solutions should be diluted) there is required 20 c.c. of a 10 per cent, solution of potassium iodide and 20 c.c. of dilute sulphuric acid (1 to 5). If a stronger potassium iodide solution (10 c.c. of 20 per cent.) is used, half that quantity of acid is enough. With smaller quantities, either of iodide or of acid, less thiosulphate was consumed, and the colour returned on standing. M. J. S.

Estimation of Chlorine. By G. LINOSSIER and M. LIGNON (*Bull. Soc. Chim.*, **50**, 354—355).—The cold or slightly warm solution of the chloride is precipitated with mercury nitrate; the analysis is carried out in a manner similar to the other acids (this vol., pp. 75 and 308). Poirrier's orange is used as indicator. The method may be used in determining chlorine in urine. N. H. M.

Volumetric Estimation of Chlorine. By J. T. WHITE (*Chem. News*, **58**, 229—230).—About 45 c.c. of a solution containing chlorides is mixed with 1 gram of permanganate and 5 c.c. of sulphuric acid diluted with an equal volume of water; this is then gently heated in a current of carbonic anhydride free from acid, the liberated chlorine absorbed in a solution of potassium iodide, and the free iodine titrated with thiosulphate; the results obtained are good. If bromine and iodine are also present in the solution, the former is first separated by boiling with permanganate and aluminium sulphate (free from or containing a known quantity of chlorine); the chlorine may then be estimated in the above manner, and the iodine remains behind as iodate.

The iodine of an iodide may be distilled from mixtures containing chlorides and bromides by ferric chloride, chromic acid, and hydrogen peroxide. D. A. L.

A New Method of Estimating Free Hydrochloric Acid in the Contents of the Stomach. By J. SJÖQVIST (*Zeit. physiol. Chem.*, **13**, 1—11).—The oldest method is that of Bidder and Schmidt, who were the first to prove the existence of free hydrochloric acid in the gastric juice. Rabuteau's method, modified by Cahn and v. Mering (*Deut. Arch. klin. Med.*, **39**, 239), consists in distilling off the volatile acids and shaking the residue with a large excess of ether which takes up the lactic acid; this is separated, and cinchonine is added to the remainder until the reaction is neutral, then it is shaken four or five times with a large excess of chloroform, which takes up the cinchonine hydrochloride; the chloroform is distilled off, and the chlorine estimated in the residue. Another method devised by Cahn and v. Mering consists in distilling the contents of the stomach with water three times. The volatile fatty acids are estimated in the distillate. The residue is shaken six times with 500 c.c. of ether, and this is evaporated to dryness, and the lactic acid estimated by titration. The residue contains the hydrochloric acid, and this also can be estimated by titration.

Another method used by Seemann (*Zeit. klin. Med.*, **5**), and Hehner (*Zeit. anal. Chem.*, **17**, 236), consists in neutralising the stomach-contents by titrating with sodium hydroxide, evaporating to dryness, and carefully incinerating. The ash is extracted with water, and in the extract the alkali present is estimated by titrating with an acid; the difference between the amount of alkali added, and the amount of alkali found, gives the amount which must have combined with hydrochloric acid.

This method, however, gives too high results; and the other methods take too long, and too large a quantity of the necessary reagents to be available for clinical work.

The method now recommended gives absolutely accurate results, and is sufficiently simple to use clinically. The contents of the stomach are evaporated to dryness with barium carbonate and then incinerated; barium chloride remains unchanged, and the salts of the organic acids are burnt to barium carbonate. The barium chloride is then extracted with water, and the quantity of barium dissolved is a measure of the original amount of free hydrochloric acid. The barium may be estimated by Mohr's titration method. In this method, potassium dichromate is added to the barium solution, by which means a precipitate insoluble in water and acetic acid is formed; the indicator of the end of the reaction is the yellow colour which the smallest excess of the dichromate gives to the liquid which floats over the precipitate. A more delicate test for excess of the dichromate is, however, Wurster's tetramethylparaphenylenediamine paper. Potassium dichromate in an acetic acid solution acts in the same way as ozone, to test for which the paper was originally used; it turns it blue.

The titration is carried out as follows:—The solution of barium chloride is placed in a beaker, and a quarter of its volume of alcohol added, then a few c.c. of a 10 per cent. solution of sodium carbonate containing 10 per cent. of acetic acid. A standard solution of potassium dichromate is then added from a burette till the end-reaction is obtained. Directions are given for the preparation of the standard solution: the most convenient was found to be one of which each c.c. corresponded to 4·05 mgrms. of HCl.

The method was tested with known strengths of hydrochloric acid, and mixtures of hydrochloric and lactic acids, and with artificial gastric juice. The results obtained were exceedingly accurate. The paper concludes with the account of the results obtained from actual stomach-contents by the use of the method. These may be summarised as follows:—

Case.	Reactions for HCl.	Reactions for lactic acid.	Percentages.	
			Total acidity.	HCl.
1	Doubtful	Well marked	0·15	0·02
2	Positive	Positive	0·29	0·132
3	„	„	—	0·076
4	„	Doubtful	0·2	0·138

6	„	Weak	0·189	0·164
7	Negative	Positive	0·14	0·03

W. D. H.

Separation and Estimation of Chlorine, Bromine, Iodine, and Cyanogen. By G. Errera (*Gazzetta*, 18, 244—258).—Although it is but seldom in ordinary analytical work that cyanogen has to be determined in the presence of chlorine, bromine, and iodine, yet it frequently happens in determinations of the halogens in organic compounds by combustion with lime, that cyanogen is formed, and is precipitated along with haloïd silver salts. The method adopted by the author is founded on the successive action of the halogen acids on the mixed silver salts.

1. *Separation of Cyanogen from one of the three Halogens and of two Halogens from one another.*—In determining cyanogen and chlorine, the mixed silver salts, dried at 100° and weighed, may be treated with hydrochloric acid, but the action is slow; the increase in the weight of the precipitate multiplied by 14·23216 gives the weight of the silver cyanide present which has been decomposed, and the chloride originally present can be estimated by difference. It is, however, far better to treat the mixed salts with hydrobromic or hydriodic acids. In this case, both the cyanide and chloride are converted into silver bromide or iodide, as the case may be. The formulæ for the calculation are—

$$x = \frac{an + b(n + 1)}{n - m}, \qquad y = \frac{am - b(m + 1)}{m - n}.$$

where y is the cyanogen, x the chlorine, a the weight of the mixed silver cyanide and chloride, b that of the silver in these mixed salts (calculated from the weight of the final product, silver bromide or iodide), n the ratio of silver to cyanogen in silver cyanide, m the ratio of silver to chlorine in silver chloride. The same formulæ are applicable to the other halogens.

In estimating two halogens in the presence of one another, the ordinary process of treating the mixture with gaseous chlorine is the best.

2. *Separation of Cyanogen from two of the Halogens and of the three Halogens from one another.*—The mixture of silver cyanide with the silver halogen compounds is carefully dried at 100° and treated with fuming hydrochloric acid, this converts the silver cyanide into chloride, but leaves the other silver salts unacted on; the product is then

dried at 100°, heated until it fuses and weighed. It is then heated in a current of chlorine and again weighed.

Let x and y be the amount of the halogens, and v that of the cyanogen. Also a the weight of the original precipitate of mixed salts, c the weight after treatment with hydrochloric acid (or hydrobromic acid), and b the total weight of silver present, calculated from the silver chloride obtained as the final product.

The equations are as follows for the three mixtures:—

$$\begin{aligned}\mathrm{Cy} &= v = (c - a)\,2{\cdot}76679.\\ \mathrm{Br} &= y = c\,1{\cdot}79680 - b\,2{\cdot}38711.\\ \mathrm{Cl} &= x = a\,3{\cdot}76679 + b\,1{\cdot}38711 - c\,4{\cdot}56361.\end{aligned}$$

$$\begin{aligned}\mathrm{Cy} &= v = (c - a)\,2{\cdot}76679.\\ \mathrm{I} &= y = c\,1{\cdot}38796 - b\,1{\cdot}84395.\\ \mathrm{Cl} &= x = a\,3{\cdot}76679 + b\,0{\cdot}84395 - c\,4{\cdot}15476.\end{aligned}$$

In the case of a mixture of cyanide, bromide, and iodide it is better to treat with hydrobromic acid instead of hydrochloric acid. In this case the equations are—

$$\begin{aligned}\mathrm{Cy} &= v = (c - a)\,0{\cdot}48308.\\ \mathrm{I} &= y = c\,2{\cdot}70501 - b\,4{\cdot}70902.\\ \mathrm{Br} &= x = a\,1{\cdot}48308 + b\,3{\cdot}70902 - c\,3{\cdot}18810.\end{aligned}$$

With a mixture of the three halogens, the weighed silver precipitate is treated with hydrobromic acid, weighed, and then heated in a current of chlorine as above.

$$\begin{aligned}\mathrm{Cl} &= v = (c - a)\,0{\cdot}79680.\\ \mathrm{I} &= y = c\,2{\cdot}70501 - b\,4{\cdot}70902.\\ \mathrm{Br} &= x = a\,1{\cdot}79680 + b\,3{\cdot}70902 - c\,3{\cdot}50180.\end{aligned}$$

3. *Separation of Cyanogen from the Halogens when all three of the latter are present.*—The precipitate of mixed silver salts is dried at 100°, divided into two portions and weighed. One of these is treated with fuming hydrochloric acid, avoiding as far as possible any great excess of the acid, dried at 100°, heated until it fuses, and weighed. The second portion is treated with hydrobromic acid of sp. gr. 1·49 in precisely the same way, and the product after fusion and weighing is heated in a current of chlorine and again weighed. If x, y, z, and v be the quantities of chlorine, bromine, iodine, and cyanogen present, a the weight of the mixed silver salts, c the weight of these (calculated) after treatment with hydrochloric acid, d the same after treatment with hydrobromic acid, and b the total weight of silver present calculated from the silver chloride obtained as the final product, then

$$\begin{aligned}\mathrm{Cy} &= v = (c - a)\,2{\cdot}76679.\\ \mathrm{I} &= z = d\,2{\cdot}70501 - d\,4{\cdot}70902.\\ \mathrm{Br} &= y = b\,3{\cdot}70902 + c\,1{\cdot}79680 - d\,3{\cdot}50180.\\ \mathrm{Cl} &= x = (d - c)\,0{\cdot}79680 - (c - a)\,3{\cdot}76679.\end{aligned}$$

In the paper, full details are given of the way in which these equations are obtained, and also results obtained by the use of the methods described. C. E. G.

Estimation of Sulphur in Burnt Pyrites. By J. Watson (*J. Soc. Chem. Ind.*, 7, 305—307).—The following volumetric method for the estimation of total sulphur has been in daily use at the Newcastle Chemical Works for about nine years, and during that time has been introduced into other works where it appears to have displaced Pelouze's gravimetric method. 2 grams of sodium hydrogen carbonate of known alkalinity is mixed in a platinum crucible with 5·16 grams of the powdered sample of burnt ore, and heated gently over a low Bunsen flame for about five minutes, after which the mass is broken up with the end of a wire stirrer. The heating is then increased and continued for 10 or 15 minutes, when the mass is washed out with warm water into a beaker, boiled for 15 minutes, filtered, and washed. The filtrate is then titrated with standard hydrochloric acid, using methyl-orange as indicator.

The author has found this method useful also in ascertaining what proportion of the residual sulphur in burnt ore exists as sulphide, which should have been available for acid making with perfect combustion. He proposes to estimate the soluble sulphur and deduct this from the total sulphur found by the volumetric method just described, the difference being the sulphur existing as sulphide.

A convenient method of estimating the soluble sulphur is by boiling a weighed quantity of burnt ore with a known quantity of standard sodium carbonate, filtering, washing, and titrating the filtrate with standard acid. For green ore, the method is not satisfactory, although various modifications have been tried by the author. D. B.

Volumetric Estimation of Acids. By Engel (*Bull. Soc. Chim.*, 50, 197).—A claim to priority as regards the method for sulphuric acid described by Linossier (this vol., p. 75).

Volumetric Estimation of Sulphates. By D. Sidersky (*Chem. Centr.*, 1888, 1293, from *Mon. Sci.*, 32, 1132—1139).—The method depends on the double decomposition between sodium carbonate and barium chloride. To the solution containing sulphates, an excess of barium chloride is added, and this excess is determined by the addition of sodium carbonate until phenolphthaleïn shows the presence of the latter in excess, or the reaction becomes sharper still if, instead of titrating the excess of barium chloride with sodium carbonate, a quantity of sodium carbonate equivalent to the added barium chloride is added, and then the excess of the sodium carbonate titrated with barium chloride in the presence of phenolphthaleïn.

The solution must be perfectly neutral, and any sulphides, thiosulphates, or sulphites present must be removed. So also the presence of calcium or magnesium oxide and of phosphoric or oxalic acids must be avoided. J. W. L.

The true Rôle of Soda-lime in the Estimation of Nitrogen. By Quantin (*Bull. Soc. Chim.*, 50, 198—201).—The usual explanation of the action of the soda-lime in nitrogen determinations is that the water of the alkaline hydroxide being decomposed by the carbon of the organic substance, yields nascent hydrogen which combines with the nitrogen to form ammonia. Experiments were made in which calcined sand, calcium carbonate and sulphate, baryta, and lime were used instead of soda-lime; the nitrogen is still given off as ammonia, but there remained a carbonaceous residue containing nitrogen. The author considers that the action of the soda-lime is to convert this residue of nitrogen and carbon into sodium cyanide, and that this is transformed by water-vapour from the back part of the tube into sodium carbonate and ammonia; further, that a very high temperature is unnecessary. These views are supported by the results of experiments which are described. N. H. M.

New Method for the Estimation of Nitrogen. By J. H. SMITH (*J. Soc. Chem. Ind.*, **7**, 307—308).—The method, which is a modification of the process of estimating organic substances by oxidation with potassium permanganate (Abstr., 1888, 90), consists in attacking the nitrogenous product with a large excess of potassium permanganate and a small amount of potassium bromide—bromine being alternately liberated by the permanganate and reduced to hydrobromic acid whilst oxidising the organic substance and liberating or further oxidising its nitrogen, a small amount of bromide thus serving to oxidise a comparatively large amount of organic substance.

The author gives the results of experiments on the oxidation of ammonia, cyanides, and carbamide in acid bromide permanganate solution, which show, in the case of ammonia, an oxidation of 72 per cent. of the total nitrogen to nitric acid, with cyanides complete oxidation to carbonic anhydride and nitric acid, and with carbamide first oxidation, as in the well-known alkaline hypobromite reaction, and subsequently oxidation of the nitrogen as in the case of ammonia.

The investigation is being pursued with the view of ascertaining whether this oxidation of nitrogen is likely to vitiate determinations of organic matter by permanganate. D. B.

Estimation of Phosphoric Acid with Silver Nitrate. By J. CLARK (*J. Soc. Chem. Ind.*, **7**, 311—312).—The author has investigated the accuracy of Perrot's volumetric process for the estimation of phosphoric acid based on precipitation as silver phosphate (Abstr., 1882, 94). His experiments show that with pure materials the method is capable of yielding good results in the absence of iron and alumina; but when applied to manures and natural phosphates the following modifications are necessary:—(1.) The dissolution of the silver phosphate precipitate in nitric acid and titration of the silver with thiocyanate. (2.) The neutralisation of the acid solution with aqueous soda instead of ammonia to avoid the presence of an excessive quantity of ammoniacal salts which affects the results. (3.) The previous precipitation of the iron and alumina as phosphate by means of sodium acetate containing free acetic acid. D. B.

Estimation of Nitrogen in Vegetable Soils. By BERTHELOT and G. ANDRÉ (*Compt. rend.*, **107**, 852—854).—Vegetable soil carefully freed from occluded air by repeated treatment with carbonic anhydride, was enclosed in a well-stoppered flask filled with carbonic anhydride. Under these conditions, there can be no alteration in the total quantity of nitrogen present. The total nitrogen was determined before the soil was put into the flasks in May, 1888, and again in October, 1888. Three different varieties of soil were analysed, and the numbers represent the amount of nitrogen per kilo. of soil dried at 110°.

	May.		October.	
Kitchen garden	0·974	gram.	0·986	gram.
Garden	1·6551	,,	1·6552	,,
Field	1·744	,,	1·776	,,

These numbers indicate the magnitude of the experimental errors in independent determinations of nitrogen in homogeneous soils.

C. H. B.

Estimation of Nitrates by Kjeldahl's Method. By M. A. Scovell (*Bull. U.S. Dep. Agric.*, **16**, 51—54).—The results of Jodlbaur's phenolsulphonic acid modification (Abstr., 1886, 834) are apt to be somewhat low. The author, substituting 2 grams of salicylic acid for the phenolsulphonic acid, obtained numbers of almost theoretical accuracy, both with pure nitrates and with mixtures made to represent fertilisers.

M. J. S.

Estimation of Phosphoric Acid. By G. Linossier (*Bull. Soc. Chim.*, **50**, 353—354).—The solution of the phosphate acidified with nitric acid and free from hydrochloric and sulphuric acids, is heated nearly to boiling and treated with an excess of bismuth nitrate; the clear, supernatant liquid is decanted on to a filter and the precipitate washed several times with boiling water; the filter is washed with a saturated aqueous solution of hydrogen sulphide, the mass of the precipitate treated in the same manner, and well shaken with the saturated hydrogen sulphide solution; the clear liquid is filtered and the residue again treated with hydrogen sulphide. Finally the bismuth sulphide is put on to the filter and washed with the hydrogen sulphide solution until the filtrate no longer shows a reaction with Poirrier's orange. The filtrate is boiled and the phosphoric acid determined with decinormal soda solution, using Poirrier's orange 3 as indicator. For very exact determinations, a second flask of the same size and containing the same amount of water and indicator should be used for comparison. (Compare this vol., p. 75.)

N. H. M.

Estimation of Carbon in Iron, Steel, &c. By T. W. Hogg (*Chem. News*, **58**, 199).—The borings are covered to a depth of about half an inch with concentrated cupric chloride, considerable excess of strong ferric chloride added, the mixture stirred for five minutes, heated gently to boiling, and acidified with a few drops of hydrochloric acid; the carbonaceous residue is then collected and treated as usual. When silicon is also present, the carbon should be filtered as soon as the decomposition is complete. The cupric and ferric chloride solutions should be neutral; the latter is added to prevent the formation of cuprous chloride which is objectionable from the difficulty of keeping it in solution.

D. A. L.

Volumetric Estimation of Zinc Oxide. By R. BENEDIKT and M. CANTOR (*Zeit. angew. Chem.*, 1888, 236—237).—Contrary to the statement of Classen, zinc oxide and carbonate can be accurately titrated with standard acid and alkali, using methyl-orange as indicator, and zinc salts using phenolphthaleïn. The oxide or carbonate is dissolved in excess of acid and the excess titrated back by soda solution. Zinc salts are dissolved in water (50 c.c. to 0·1 gram ZnO), phenolphthaleïn is added, and then standard soda solution to intense red colour. A few more c.c. of soda is then added, the mixture is boiled for some minutes, and the excess of soda titrated. If either free acid or zinc oxide is present in the zinc salt, it is neutralised in presence of methyl-orange by alkali or acid, as the case may be.

M. J. S.

Estimation of the Percentage of Lead in Tin-Lead Alloys by taking the Specific Gravity. By C. WINKLER (*Chem. Zeit.*, **12**, 1229—1231).—The author describes a simple apparatus for measuring the water displaced by the immersion of the object when determining the sp. gr. He recommends the use of such determinations, when made with some hundreds of grams of material, for the estimation of the proportion of lead in tin-lead alloys. D. A. L.

Estimation of Copper by the Iodide Method. By R. WILLIAMS (*Chem. News*, **58**, 272).—The author finds this method both expeditious and accurate in the case of refined or of pure copper; but impurities such as lead, iron, and arsenic are prejudicial. Ferric acetate and nitrate liberate iodine from the potassium iodide; arsenic acid also quickly decomposes that salt. D. A. L.

Separation of Manganese and Allied Metals from the Sesquioxide-group and Phosphoric Acid. By C. MEINEKE (*Zeit. angew. Chem.*, 1888, 219—232).—In the analysis of ferruginous materials, the determination of manganese, calcium, and magnesium, as also of small quantities of copper, nickel, cobalt, zinc, and barium, is of frequent occurrence. It is usual to separate from these the iron, aluminium, and phosphoric acid in a single operation. As the bulkiness of the precipitate renders complete washing tedious, it is recommended to adopt partial filtration and to take a measured portion of the filtrate. If, as is usually the case, the liquid is filtered hot, the temperature must be taken at each measurement and the volumes corrected. Müller employs flasks with the necks so graduated as to measure off three-fourths of the original solution, allowing at the same time for the bulk of the precipitate and for a fall of temperature from 90° to 80°. Test analyses show that the corrections so made can be depended on.

Precipitation of the Iron, &c., by Alkaline Acetates.—The conditions for the successful separation of manganese from iron by a single precipitation, are the neutralisation of the solution as perfectly as possible, the use of only small quantities of acetates and acetic acid, and a rapid but short boiling. A little iron usually remains unprecipitated. Müller, for the analysis of spiegeleisen and ferromanganese, dissolves 1·92 grams in 16 c.c. of hydrochloric acid (1·12) and 5 c.c. of nitric acid (1·2), adds ammonium carbonate until a permanent precipitate is obtained, dissolves this by 10 drops of hydrochloric acid, adds 5 c.c. of ammonium acetate (glacial acetic acid neutralised with ammonia of 0·96 sp. gr.), with 1 c.c. of glacial acetic acid, dilutes to 500 c.c., and heats to boiling. Taking three-fourths of the solution as above, and precipitating the manganese by hydrogen dioxide, he weighs as manganoso-manganic oxide, of which 0·1 gram corresponds with 1 per cent. of manganese. By using these proportions, a rather large amount of iron remains unprecipitated, but it very exactly compensates for the loss due to the unexplained fact that three-fourths of the solution contains only on an average 73·7 per cent. of the manganese. The manganese precipitate always contains nickel and cobalt. As the amount of these is fairly constant, a deduction of 0·2 per cent. is made in the case of 10 per cent., and 0·24 for 20 per cent. of manganese. The determination can be completed in three-quarters of an hour.

Precipitation of the Iron by Neutralisation with Ammonium Carbonate and Boiling.—The solution must be free from sulphates. Ammonium carbonate is added until the liquid just loses its transparency, and it is then heated to boiling. Partial filtration of the hot liquid is advisable, as the precipitate cannot be completely washed without some iron dissolving. Copper, cobalt, nickel, manganese, zinc, calcium, magnesium, and barium are almost perfectly separated from iron and aluminium by this method. In the case of the three last, a little ammonia should be added after the boiling, and boiled out again; the basic ferric chloride is thus converted into hydroxide, which can be washed. In presence of copper, this addition is inadmissible, and it also occasions the loss of a trace of manganese. Without it, traces of iron remain in solution.

Precipitation by Alkaline Sulphates.—The liquid is neutralised with ammonia and ammonium carbonate until a small permanent precipitate forms, leaving the solution still of a deep brown colour and feebly acid. On now adding ammonium sulphate, the iron is thrown down at ordinary temperatures as basic sulphate. Manganese, copper, nickel, cobalt, and zinc remain entirely in solution. Aluminium is partially precipitated. To remove it completely, together with any traces of iron still in solution, a few drops of ammonium acetate should be added and the liquid boiled.

Fritzsche adds to the feebly acid solution a small quantity of sulphuric acid, and then sodium hydrogen carbonate so long as this produces a brown precipitate of basic ferric sulphate. Särnström omits the sulphuric acid, with the advantage that the liquid remains clear to within a few drops of complete neutralisation. The basic ferric chloride separates suddenly and completely, whilst manganese is not thrown down by an excess of the reagent as long as the liquid shows the faintest acidity. In the presence of more than traces of aluminium, this and Fritzsche's method are inapplicable. Calcium and magnesium can be perfectly separated from iron by this method; barium only when in small proportion. For preparing the manganese solution for volumetric determination, this method does not appear preferable to Volhardt's zinc oxide process (Abstr., 1880, 143), but for gravimetric analysis the author regards it as the most advantageous yet brought forward. To prevent the manganese precipitate from containing alkali, it should be heated with ammonia and ammonium chloride for some time before filtering. M. J. S.

Estimation of Chromium by Hydrogen Peroxide. By A. Carnot (*Compt. rend*, **107**, 948—949).—It is well known that with solutions of chromic acid, hydrogen peroxide produces a fugitive, deep blue colour, which according to Moissan has the composition CrO_3,H_2O_2. When decomposition takes place, the solution contains a quantity of sesquioxide equivalent to the hydrogen peroxide decomposed.

The chromate or chromic acid solution is diluted to about 50 c.c., and nearly neutralised, the reaction being left acid. Commercial hydrogen peroxide diluted with 5 to 20 volumes of water is run into the liquid from a burette. A dark coloration is produced which turns blue and then green. The titration is ended when the blue coloration is no longer produced as a drop of the peroxide falls into the liquid. The same operation is repeated with a standard solution of pure potassium dichromate. It is advisable that the conditions in the two titrations should be as nearly identical as possible. If the solution is too concentrated, the green colour of the reduced chromium masks the blue coloration. C. H. B.

Analysis of Commercial Scheelite. By K. Rusag (*Chem. Zeit.*, **12**, 1316).—The following method of decomposing scheelite is recommended, as by it all inconvenience from silica is avoided. The finely pulverised mineral is heated with hydrochloric and hydrofluoric acids until the silica and excess of hydrofluoric acid are removed, the residue is moistened with fuming hydrochloric acid, and after a little while heated with plenty of hot water. The precipitated tungstic acid is washed, dissolved in ammonia, ammonium chloride added, and the solution filtered. The filtrate is evaporated to dryness with ammonium chloride, redissolved, and again evaporated to dryness with ammonium chloride; these operations are then repeated once or twice more, and the residue is ultimately ignited, at first below a red heat, but finally strongly. The tungstic acid obtained in this manner is of a pure yellow colour, and although it dissolves incompletely and with difficulty in ammonia, it nevertheless yields a sodium tungstate completely soluble in water, and from which neither silica nor alumina are deposited when the solution is boiled with ammonium chloride.

D. A. L.

Volumetric Estimation of Antimonious and Arsenious Acids. By A. Jolles (*Zeit. angew. Chem.*, 1888, 160—163).—Antimonious acid is completely oxidised to antimonic acid by an alkaline solution of potassium manganate, according to the equation $Sb_2O_3 + 2K_2MnO_4 = Sb_2O_5 + 2K_2MnO_3$. The oxidation of arsenious to arsenic acid is precisely analogous. The manganate solution may contain 4 or 5 grams of potassium manganate and 8 or 10 grams of potash in the litre. It is standardised by a solution of tartar emetic containing 10 grams in a litre or by a solution of arsenious acid in dilute hydrochloric acid. The titration is performed by simply running in the antimony or arsenic solution to a measured volume (5 or 10 c.c.)

of the manganate, with shaking, until the green colour changes to a clear yellowish-brown. Only after a time does the solution become turbid from separation of manganese dioxide. Substances in which the antimonious acid is to be determined are dissolved in hydrochloric and tartaric acids, diluted to a known volume (200 c.c. to each gram), and employed in the same way, taking care to keep the mixture strongly alkaline. The manganate solution should be freshly prepared, as it does not keep well. M. J. S.

Volumetric Estimation of Antimonic Acid. By G. v. KNORRE (*Zeit. angew. Chem.*, 1888, 155—157).—Weil's method (Abstr., 1879, 276) is rapid, but only approximate, owing to the difficulty of ascertaining the exact point at which the green colour of the cupric chloride disappears. Weller's process is based on the reduction of antimony pentachloride to trichloride by heating with potassium iodide, and estimation of the liberated iodine. The antimonic acid or salt is boiled with hydrochloric acid and potassium iodide in Bunsen's chlorine distillation apparatus until the mixture becomes colourless, the iodine being received in cold potassium iodide. In the absence of other oxidising agents, the method yields good results.

Herroun (Abstr., 1882, 661) adopts the same reaction, but omits the distillation. The author finds, however, that in the cold the reaction is either incomplete or very slow, since after decolorisation with thiosulphate, free iodine again appears in the liquid. Neither can satisfactory results be obtained when antimonic acid is reduced by boiling with hydrochloric acid and potassium iodide until the free iodine is all expelled, and then titrating the solution with standard iodine after addition of sodium hydrogen carbonate. Fleischer (*Lehrb. der Titrirmethode*, 2nd ed., 306) recommends reduction with sulphurous acid and subsequent titration with iodine. Complete reduction could not be effected in an open basin. The following process is, however, satisfactory:—The antimonate, strongly acidified with hydrochloric acid, is treated in a roomy flask with strong solution of sodium sulphite added gradually in small portions. It is then vigorously boiled until the sulphurous acid is expelled. A drop of phenolphthaleïn is added and then potash until the red colour appears. This is removed by a small excess of tartaric acid; sodium hydrogen carbonate is then added, and the liquid is titrated with iodine.

M. J. S.

Estimation of Nitrates in Natural Waters. By S. C. HOOKER (*Ber.*, 21, 3302).—One part of nitric acid in two millions gives, under certain conditions, a green coloration with a sulphuric acid solution of carbazole (compare Gräbe and Glaser, this Journal, 1872, 302). This reaction can be employed for the estimation of nitrates in natural waters as follows:—A measured quantity of the water (2 c.c. or less according to circumstances) is mixed with about 4 c.c. of concentrated sulphuric acid, and a small quantity of a sulphuric acid solution of carbazole added to the cold mixture. The coloration is then compared under exactly similar conditions with that produced by various quantities of a solution of potassium nitrate of known strength.

This method, and the precautions to be observed in presence of chlorides, nitrites, &c., will be fully described in a subsequent paper.

F. S. K.

Estimation of Acetone in Methyl Alcohol. By J. MESSINGER (*Ber.*, **21**, 3366—3372).—Krämer's method of estimating acetone in methyl alcohol by weighing the iodoform obtained on treating the sample with aqueous potash and iodine solution (Abstr., 1880, 826) is not only somewhat tedious and troublesome, but also gives results which are too high when the quantity of acetone present is small. A rapid and trustworthy method has been devised by the author, who estimates volumetrically the amount of iodine required to convert the acetone into iodoform. 20 c.c., or, if much acetone is present, 30 c.c. of normal potassium hydroxide solution and 1 to 2 c.c. of the methyl alcohol are shaken together in a stoppered flask, and 20 to 30 c.c. of one-fifth normal iodine solution is run in, and the whole shaken for 15 to 30 seconds until the solution becomes clear; it is then acidified with hydrochloric acid (sp. gr. = 1·025), an excess of decinormal sodium thiosulphate added, and finally titrated back with the iodine solution, starch being used as an indicator. The calculation is based on the equation given by Orndorff and Jessel for the action of bleaching powder on acetone (this vol., p. 34), which when modified to represent the action of iodine in the presence of potassium hydroxide, indicates that 3 mols. of iodine are required to convert 1 mol. of acetone into 1 mol. of iodoform. Inasmuch as commercial potassium hydroxide almost invariably contains nitrite, it is necessary to correct for this, which can readily be done by adding a decigram or two of potassium iodide to 20 c.c. of the normal solution, and titrating the liberated iodine in the usual way. Results obtained by the use of the method are given in the paper. W. P. W.

Detection of Invert-sugar in the Presence of Cane-sugar by Means of Soldaini's Solution. By E. PARCUS (*Chem. Zeit.*, **12**, 1316).—For this purpose, 5 grams of sugar are directly dissolved in 50 c.c. of Soldaini's solution, or the latter is added to a solution containing 5 grams of sugar. To detect traces of invert-sugar, the second plan is the best, but the solution must not be too dilute; 10 grams of sugar are therefore dissolved in 50 c.c. of water, filtered, and 25 c.c. of the filtrate run into 50 c.c. of boiling hot Soldaini's solution, the mixture is then boiled over a naked flame for five minutes with frequent shaking, and filtered. If, however, clarification with lead acetate is desirable, 20 grams of sugar are dissolved in water, lead acetate is added, the whole made up to 50 c.c. and filtered. 25 c.c. of the filtrate is treated with sodium carbonate, to remove excess of lead, made up to 50 c.c., filtered, and then 25 c.c. of this filtrate is treated as in the above experiment. There is almost always a turbidity produced when the alkaline sugar solution is boiled with Soldaini's solution, therefore the filtered precipitate should be carefully examined for cuprous oxide to be sure that reduction has taken place. Fehling's solution gives no turbidity on boiling with solutions containing lime, but it is not suitable for the detection of small quantities of invert-sugar. D. A. L.

Indirect Analysis of the Sugar-beet. By D. Sidersky (*Ann. Agronom.*, **14**, 407—420).—The indirect analysis is usually made on the juice expressed after rasping, the chief determinations being made by taking the specific gravity of the juice, and determining the sugar in it by the polariscope after clarification with lead acetate. The sugar found is multiplied by the factor 0·95 to give the percentage existing in the root itself, but it is well known that the results so obtained do not always agree very well with direct estimations of the sugar in weighed samples of the root, made by the Scheibler-Soxhlet process. The indirect method, however, possesses so many points of convenience and advantage, that the author has sought carefully for the sources of error, with a view to make the results of the two methods harmonise. He shows from a number of sources that the factor 0·95 is very close to the truth, and that even in abnormal roots the proportion of juice to the total weight of root is not far enough from this to cause serious error. Next he shows that the optically active substances other than cane-sugar contained in the juice do not cause more than a very slight error, even if the positive and negative errors do not cancel each other. Next, that the precipitate caused by the lead acetate certainly augments the richness of the juice in sugar a little by diminishing its volume, but that to correct this it suffices to deduct 0·17 from the saccharine richness of the juice in the case of roots containing 12—15 per cent. of sugar. Finally, he traces the important source of error to the fact that the juice expressed from pulped or rasped roots is not the normal juice as it exists in the whole root, but that the torn cells easily yield up their juice at first, whilst the whole or closed cells retain theirs, and on increased pressure yield only an abnormal juice by extravasation through their walls. Accordingly, the expressed juice varies in composition both with the fineness of the rasping and with the amount of pressure used. As it is not possible to rasp so completely as to disintegrate every cell, nor on the other hand to press so strongly as to deprive every cell, torn or whole, of all its juice, the author proposes to rasp or pulp in the ordinary manner, and to extract the juice in a centrifugal machine without using any pressure. Much less juice is obtained, but this is of normal composition, as it comes from the torn cells only, and on taking its density with the Mohr-Westphal hydrostatic balance (the hydrometer is not sufficiently accurate), and its rotatory power in the polariscope after treatment with lead acetate, and applying the usual factors, results are obtained in close accordance with direct estimation of sugar made on the root. In 14 samples the greatest difference observed was 0·4 per cent. of sugar, whilst by the method of expression the differences ranged up to 1·4 per cent. Moreover, the "quotient of purity" of the juice obtained in the centrifugal extractor agrees much better with that of the juice actually obtained in the diffusion process than does that of the juice obtained by pressure.

J. M. H. M.

Estimation of Sugar in Beet by Digestion in Water. By L. Pellet, by J. Weisberg, by L. Battut, and by M. Clerc (*Bied. Centr.*, 1888, 777—786).—On a former occasion, Pellet recommended for the estimation of sugar by polarisation, that water be substituted for alcohol, as being simpler and cheaper; but in order to clear the liquid previous to polarisation, the addition of triplumbic acetate is necessary, and the influence of this addition on the rotatory power of the sugar, as also that of the alcohol as compared with water, is here discussed and experimented on by several writers.

J. Weisberg (*Oesterr. Ung. Zeit. Zucker-Ind*, 1887, 272) considers that pure aqueous solutions of saccharose may be mixed with much lead acetate without any effect on the rotation; this observation is confirmed by Muntz, who adds that no opacity is produced, whilst an alcoholic solution of sugar is affected by lead, the rotatory power being reduced 1° by the addition of 1 c.c. of lead solution. If, however, impure solutions of sugar (such as beet-juice) are examined, then the first portion of lead which precipitates impurities has no influence, but a further addition reduces the polarising power. In the case referred to, 2 c.c. of solution, added to 50 c.c. of root extract and alcohol, has no more effect than 0·55 c.c. in the polariscope, but 9 c.c. causes a reduction to the extent of 0·4°, consequently only so much lead should be added as is sufficient to precipitate all impurities, and to facilitate this result a definite solution of triplumbic must be employed; it is prepared as follows: 600 grams of lead acetate, and 200 grams of lead oxide are dissolved in water to 29° Baumé (Weisberg), or treated with 2 litres boiling water, filtered, and brought to 30° Baumé (Pellet).

As before stated, Pellet finds that the extraction of beetroot mash may be as well performed with water as with alcohol, and considers that the differences which have been observed by other experimenters is due to their having added too much lead solution to the alcoholic, and too little to the aqueous extract; moreover, he considers it necessary to destroy all alkalinity of the alcoholic extract by acetic acid; the same holds good for the aqueous extract. Pellet further states that the sugar may be all extracted by cold water and lead solution, but the roots must be very finely pulped; this process of extraction in the cold is termed by Pellet "the method of the future," and his directions are as follows: 26·048 grams of the finely pulped roots, the particles of which must not exceed $\frac{1}{2}$—$\frac{3}{4}$ mm., are mixed with water and 3—6 c.c. of the lead solution above referred to, and after a thorough shaking, and addition of 0·5—6 c.c. of ether, the whole is made up to 200·7 c.c., filtered, acidified with a few drops of acetic acid, and then polarised in a 400 mm. tube. Unripe or abnormal beets require more lead. This process only occupies three minutes. M. Clerc (*Deut. Zucker-Ind*, 1888, 1114) approves of Pellet's methods. L. Battut (*Suc. Belg.*, 1888, 458) recommends the substitution of milk of lime and carbonic anhydride for much of the lead, but the process is much more complicated than those given by Pellet. E. W. P.

Estimation of Milk-sugar in Milk by the Polariscope. By P. Vieth (*Analyst*, 13, 63—65).—The results are practically the same, whether the proteïds are precipitated by Schmoeger's basic lead acetate method, or by the simpler plan of adding mercuric nitrate and filtering. With the latter reagent, a clear whey is obtained, even from cream containing 50 per cent. of fat and only 2·25 of proteïds.

The following rule is given for making the calculation. To 50 c.c. of the milk, add 1·5 c.c. of the mercuric nitrate. As the precipitated proteïds occupy 1·5 c.c., the strength of the sugar solution remains unaltered. The formula $\frac{p(93-f)}{93s}$, in which p = percentage by volume of milk-sugar as shown by the polariscope, f = percentage by weight of fat, and s = sp. gr. of the milk (water = 1), then gives the percentage by weight of crystallised milk-sugar in the milk. From this is to be deducted one-twentieth for water of crystallisation.

M. J. S.

Compounds of Starch with the Alkaline Earths. By C. J. Lintner (*Zeit. angew. Chem.*, 1888, 232—236).—Starch is completely precipitated from a dilute solution by a solution of lime in sugar syrup. Dextrin is not so precipitated. The composition of the precipitate varies according to the quantity of lime added, the observed extremes being 0·3164 and 0·0952 of lime for 1 of starch, corresponding approximately with the formulæ $C_6H_{10}O_5,CaO$ and $(C_6H_{10}O_5)_4,CaO$ respectively. The behaviour of baryta-water is precisely similar. Whether with or without alcohol (in the former case following accurately the instructions given by Asboth, Abstr., 1887, 868) the larger the quantity of baryta added, the greater the proportion precipitated by the starch. The precipitate varied in composition from $(C_6H_{10}O_5)_2,BaO$ to $(C_6H_{10}O_5)_8,BaO$. Dextrin is also precipitated by baryta in presence of a little alcohol.

Strontia-water and solutions of strontia in syrup precipitate starch completely only on addition of alcohol. The composition of the precipitate is variable in this case also. Therefore, for quantitative determinations of starch, the alkaline earths cannot be employed directly with sufficient certainty. (Compare Spence, Abstr., 1888, 632; Monheim, 1888, 1134; also Seyfert, *ibid.*) M. J. S.

Adulteration of Vegetable Fatty Oils. By W. Peters (*Arch. Pharm.* [3], **26**, 857—893, and 905—918).—The paper gives a detailed survey of the methods proposed for the detection of mixtures of various fatty oils, and freely quotes numerical results obtained by previous investigators. The author then details his own experiments on some of the methods surveyed, and recommends the following course for the detection of adulteration:—(1.) The melting point should be determined of the fatty acids insoluble in water, separated by hydrochloric or dilute sulphuric acid after saponification. With pure olive oil, the end-point of the melting varies between 24° and 29°. If the melting point of an olive oil is above 29°, we may presume that cotton-seed oil is present; if under 24°, the admixture of linseed, castor, or poppy oil may be assumed. (2.) Sesame oil is easily detected in olive and almond oils, by the beautiful green coloration obtained when the oil is treated with a mixture of equal parts of concentrated nitric and sulphuric acids; or by mixing the oil with 23 to 24 per cent. hydrochloric acid, in which 2 per cent. of cane-sugar has been dissolved, when the mixture becomes reddish after a couple of minutes, gradually passing to dark cherry-red; or, according to Langlies, 3 grams of the oil is warmed with 1 gram of a mixture of

3 parts of nitric acid (sp. gr. 1·38) and 1 part of water; in presence of 5 per cent. of sesame oil, the mixture takes a characteristic red colour. Cotton-seed oil is detected by agitating with 2½ parts of colourless nitric acid (sp. gr. 1·4); on cooling a brown colour is produced; or 2 c.c. of the oil is treated with two or three drops of a syrupy solution of antimonious chloride, when cotton-seed oil becomes chocolate-coloured with evolution of much heat, and in a short time solidifies. Oils of the Cruciferæ are detected by the reduction of an alcoholic solution of silver nitrate. (3.) The elaïdin test detects the presence of cotton-seed, sesame, and peach-kernel oils in olive oil by the various colours produced. 10 c.c. of oil is placed in a stoppered flask with 1 c.c. of nitric acid (sp. gr. 1·4) and 0·4 gram of metallic copper in splinters; on shaking, the red vapours are absorbed, and when cooled to 10° or 20°, olive oil becomes a solid white mass within 30 minutes, sesame oil becomes red, and the other two red to brown; the time of solidification is less definite than the colour produced. (4.) After saponifying and treating with mineral acid, to separate the organic acids, the different solubility of these in an equal volume of 90 per cent. alcohol gives important information. The alcoholic solution obtained from olive and almond oil remains clear after evaporating off half the alcohol and cooling to 20°, whilst that of earth-nut oil becomes turbid and cotton-seed oil becomes solid. (5.) The "iodine number," as determined by Hübl (Abstr., 1884, 1435—1437), is important. J. T.

Action of Sulphur Chloride on Oils. By C. A. FAWSITT (*J. Soc. Chem. Ind.*, 7, 552—554).—The heat reaction between certain oils and sulphur chloride being more marked than that obtained when sulphuric acid is used, the author made a series of experiments to see if characteristic results could be obtained which might be turned to some account as a test for oils. 30 grams of oil was weighed in a small beaker, which was then placed in a larger beaker, and the intervening space filled with cotton-wool. The temperature of the oil having been taken, the chloride was added slowly during constant stirring, and the time having been noted, the thermometer was kept stationary until the temperature ceased to rise, when it was noted and also the time. No difficulty was experienced in carrying out the trials except in the case of castor oil, which, owing to its high viscosity, could not be mixed intimately and sufficiently rapidly with the sulphur chloride, to prevent local action.

The majority of the oils used in the trials were compounds of fatty acid with glycerol, on all of which the chloride acted. It was, however, found to have little or no action on glycerol and stearic acid, but with oleic acid it shows a heat reaction similar to that with olive oil. In some cases hydrogen chloride was liberated, for instance, with palm oil, cod-liver oil, castor oil, rosin oil, and mineral oils, whilst in others, such as seal oil, rape oil, and olive oil, no gas was given off. The evolution of gas had, in some cases, a marked effect in stopping the rise in temperature, notably in the case of mineral oils and rosin oil. In all cases, with the exception of palm oil, which appeared to turn thinner, the oils were thickened by the sulphur chloride treatment, and when the higher proportions were used the product was usually solid.

D. B.

Detection of Margarin in Butter. By V. PLANCHON (*J. Pharm.* [5], 18, 482—489).—The author has devised a process by which the whole work is done on one portion of the sample, and by which he determines the equivalent of saponification, the soluble acids and the insoluble acids. Three standard solutions are required for the process: a semi-normal sulphuric acid solution, a normal alcoholic sodium hydroxide solution, and a one-fifth normal aqueous solution of sodium hydroxide. The butter is heated to 50°, and 5 grams of the clear fatty matter is weighed off into a tared flask, capable of containing 150 c.c. of water, containing 15 per cent. alcohol when heated to 50—55°, and having the mark at the bottom of the neck. 25 c.c. of the alcoholic soda solution is added and boiled 20 minutes with a reflux condenser, when the saponification is almost complete; after cooling a little, about 60 c.c. of water is added, and some drops of phenolphthaleïn and standard acid is run in to neutralisation; the amount is noted. Then more acid is added until the exact equivalent of the soda taken has been used, and the flask is heated at 50—55°, when the fatty acids fuse, and after shaking a few times, warm water is added to bring the lower level of the acid layer up to the mark on the flask. After vigorously shaking, the flask is cooled, and 100 c.c. of the liquid passed through a tared filter dried at 100°, is titrated with the aqueous sodium solution; this gives the soluble acids. On adding boiling water to the tared flask, the fatty acids can be easily passed on to the tared filter and washed, after which the filter and its contents are dried at 100° for six or seven hours, when the loss of weight will not exceed 5 or 6 mgrms. per hour.

Calculation of results. 1. *Equivalent of saponification.*—The number of c.c. of acid equivalent to the sodium solution required for saponification, multiplied by 0·4, gives the weight in grams of sodium hydroxide required to saponify 100 grams of the sample. For pure butter this is about 16·12 to 16·4, and for margarin it is about 13·92 to 14·16. 2. *Soluble acids.*—The equivalent in butyric acid per 100 grams of sample is obtained by multiplying by the coefficient 0·528, the number of c.c. of one-fifth aqueous soda solution required to neutralise the 100 c.c. of solution obtained. For the samples of pure butter examined, this amounts to 3·85 to 4·41; and for margarin, 0·16 to 0·26. 3. *Insoluble acids.*—The weight of dried fatty acids is multiplied by 20. For pure butter this becomes 87·62 to 88·0; and for margarin 95·40 to 95·76.

The coefficient of saponification and the proportion of soluble acids can easily be determined in less than an hour, and this information is generally sufficient to show the degree of purity of the sample. A series of mixtures of butter and margarin, examined as above, gave results not more than 2 per cent. wide of the truth. J. T.

The Iodine Absorptions, combining Weights and Melting Points of some Fatty Acids. By R. WILLIAMS (*Analyst*, 13, 88—89).—The following are the average results from several samples of each kind of fat or oil:—

	Iodine absorption.	Combining weight.	Melting point.
	per cent.		
Tallow	41·3	276	119° F.
Lard	64·2	296	100
Cotton-seed oil	115·7	289	96
Olive oil	90·2	286	81
Linseed oil	178·5	283	75
Rape oil	105·6	307	71
Castor oil	93·9	292	—
Cocoanut oil	9·3	201	75
Palm oil	53·4	263	114
Sperm oil	88·1	305	56

M. J. S.

Detection of Cotton-seed Oil in Lard. By A. H. ALLEN (*Analyst*, **13**, 161—165).—Solid neutral fats and fatty acids from cotton-seed oil are used in the adulteration of lard. Their presence does not appreciably affect the melting and solidifying points. The specific gravities (at 99°) are as follows:—Cotton-seed fat, 0·8684; cotton-seed oil, 0·8725; acids from cotton oil, 0·8476; lard, 0·860—0·862; fatty acids from lard, 0·8372—0·8385.

The following are the percentage iodine absorptions (Hübl's method):—Cotton-seed fat, 89·8; cotton-seed oil, 108—110; acids from cotton oil, 115·8; lard, 55·4, 60·5, and 62 (Allen), 46·57, 51·2, 51·5, and 55 (other experimenters). Detection or determination by means of the difference in the iodine absorption may, however, be counteracted by the presence of beef suet, which has a much lower iodine absorption. Its sp. gr. is, however, identical with that of lard, so that an approximate determination can be effected by combining these two features. Milliau's modification of Bechi's silver nitrate test, appears to be valuable as a qualitative method (compare Abstr., 1888, 633, 1349). M. J. S.

Mixed Lard and the Detection of Cotton-seed Oil. By O. HEHNER (*Analyst*, **13**, 165—167).—The commission appointed by the Italian Government to investigate Bechi's method (Abstr., 1888, 301) reported that it is perfectly trustworthy, provided the reagent contains a little pure nitric acid, and the oil to be tested has been filtered. The reagents recommended are composed as follows:—(No. 1.) Silver nitrate, 1 gram; alcohol (98 per cent.), 200 grams; ether, 40 grams; nitric acid, 0·1 gram. (No. 2.) Amyl alcohol, 100 grams; colza oil, 15 grams. 10 c.c. of the oil is mixed with 1 c.c. of No. 1 and 12 c.c. of No. 2. The mixture is shaken and heated on the water-bath for a quarter to half an hour. In presence of cotton oil, it darkens from reduction of silver. With too little free acid present, reduction may occur in the absence of cotton oil; with too much, it may not take place even with cotton oil. The author sees no advantage in Milliau's modification, and omits the amylic solution of colza oil as unnecessary. He adds one volume of the silver solution to two volumes of the oil and heats for 15 minutes.

Maumené's reaction furnishes a quantitative method. 50 grams of pure lard mixed with 10 c.c. of strong sulphuric acid give a rise of 24° to 27·5°; cotton-oil a rise of about 70°. Mixtures with known proportions gave results agreeing closely with the calculated numbers.

Salkowski's phytosterin test (Abstr., 1888, 201) affords valuable corroboration. M. J. S.

Adulteration of Lard with Cotton-seed Oil. By R. WILLIAMS (*Analyst*, 168—169).—Koettstorfer's test is useless, since both fats require the same amount of alkali. The melting point of lard depends so much on the part from which the fat is taken as to be no criterion of purity. The sp. gr. can only furnish indications when the proportion of cotton-seed oil is large. Maumené's test has failed in the author's hands. The iodine absorbtion test is the most trustworthy; genuine American lards absorb 60 to 62 per cent.; a sample of leaf lard rendered by the author absorbed 51·8; whilst refined cotton oil absorbs 110, and beef stearin, on the other hand, only 21.

Milliau's silver nitrate test appears to be characteristic for cotton oil. Of numerous other oils and fats, none exerted a reducing action. M. J. S.

Lard Adulterated with Cotton-seed Oil. By E. W. T. JONES (*Analyst*, **13**, 170—171).—The sulphur chloride reaction will detect any important adulteration with cotton oil with certainty. 5 grams of the lard is melted in a porcelain basin, and just before it solidifies there is added to it ·2 c.c. of a mixture of equal volumes of carbon bisulphide and sulphur monochloride. This is well stirred in, and the mixture allowed to stand at the ordinary temperature. Pure lard thickens somewhat in the course of three hours, but mixtures containing cotton oil become quite hard in half that time (see also Warren, Abstr., 1888, 1348).

The author describes his mode of performing Hübl's test. The reagent is made by dissolving separately 5 grams of iodine and 6 grams of mercuric chloride, each in 100 c.c. of 95 per cent. alcohol, mixing and allowing to remain for 12 hours before use. About 0·5 gram of the fat is dissolved in 10 c.c. of chloroform in a stoppered bottle, 20 c.c. of Hübl's reagent is added, and the mixture left in the cold for three hours. The contents of the bottle are then rinsed into a beaker with potassium iodide solution, and the unabsorbed iodine is titrated by thiosulphate. The numbers reported for genuine commercial lard are:—Highest 61·31, lowest 56·47, average 58·9. The author adopts the number 60, and for cotton oil 105.

The average sp. gr. of the same samples of lard (at 100° F.) was 0·906, that of cotton oil was 0·9135. The percentage of adulteration calculated from the results of the two methods agreed closely. M. J. S.

Adulteration of Lard with Cocoa-nut Oil. By A. H. ALLEN (*Analyst*, **13**, 189—190).—The author has met with a specimen of lard adulterated with cocoa-nut oil. The following values are given:—

	Lard.	Cocoa-nut oil.	Suspected sample.
ORIGINAL FAT:—			
Plummet gravity at 99°	0·860—0·861	0·868—0·874	0·8666
Iodine absorption	55—61	9	37·4
Saponification equivalent	286—292	209—228	265·2
$\frac{N}{10}$ alkali required by distillate from 5 grams	0·5	7·0	3·3
SEPARATED FATTY ACIDS:—			
Plummet gravity at 99°	0·838—0·840	0·844	0·840
Iodine absorption	61—64	15·01	42·5
Mean combining weight	278	200	253·04

The volatile acids from the suspected sample had the odour of the distillate from cocoa-nut oil, and were in part insoluble. The silver nitrate test gave a negative result. The saponification equivalent furnishes the most accurate indications of the percentage adulteration, and would be unaffected by the presence of cotton-seed oil or tallow.

M. J. S.

Analysis of Grease. By L. ARCHBUTT (*J. Soc. Chem. Ind.*, 7, 494—495).—The method, which has for its object the separation and estimation of fatty acids in the presence of neutral fat and oil, consists in dissolving the mixture in ether and shaking with weak alcoholic soda, which extracts all substances of acid character, and leaves the mineral or other neutral oil dissolved in the ether.

The author has verified the method by experiment on tallow, palm oil, olive oil, and linseed oil. His trials with colophony were not, however, successful, and seem to confirm Allen's observation regarding the probable presence of either ethers or anhydrides in colophony, which do not react with caustic potash unless heated therewith.

D. B.

Estimation of the Oil and Water in Linseed Cake. By P. BAESSLER (*Landw. Versuchs-Stat.*, 35, 341—349).—In previous volumes of the *Landw. Versuchs-Stat.* (32, 1; 34, 420, 460), it has been stated that in determining the fat in foods, all water should first be expelled by drying at 100°, such treatment, however, in the case of linseed cake leads to serious error. Samples of two different cakes were taken, and the oil determinations in portions dried in a vacuum over sulphuric acid, namely, 7·69 per cent. in one cake and 9·96 per cent. in the other, were taken as correct; air-dried portions gave results 0·33 and 0·38 per cent. too high; portions dried at 100° for six hours gave results 3·95 and 2·26 per cent. too low; and portions dried at 105° for 10 hours gave results 5·13 and 4·55 per cent. too low. The following experiments showed that the error was caused by the absorption of oxygen by the oil of the cake with the formation of a substance insoluble in ether. Portions placed in a duck-shaped drying tube, immersed in boiling water, and connected with calcium chloride tubes were subjected to a current of dried air, and it was found that the loss of weight in the drying tube did not amount to as much as the gain in the calcium chloride tubes, showing that something had been absorbed from the air. Brownish-yellow oily drops condensed in the calcium chloride tubes, so that the gain in these is not water alone. On extraction with dry ether, the cakes thus treated gave lowered percentages of fat. On repeating the experiment, using hydrogen instead of air, the loss in the drying tube was equal to the gain in the calcium chloride tubes, and on extracting with ether, the percentage of oil was the same as when the cake had been dried in a vacuum. The oil in this case was greenish-yellow, whilst that from cake dried by heating in air was brownish-yellow. To prove that it was the oil that suffered oxidation, some oil from cake dried in a vacuum was mixed in the drying tube with pumice in small grains, and on heating at 100° in a current of dry air was found to gain in weight and to give the brownish-yellow oily substance in the calcium chloride tubes; on extracting with ether for six hours, only 26 per cent. of the oil was removed. The behaviour of the insoluble residue with dilute potash was studied, and the author concluded that the oxidised oil being insoluble in ether, coats and protects some unaltered oil. To obtain correct results, therefore, the amount of water in the cake should be determined by drying either in a vacuum over sulphuric acid or in a current of dry hydrogen, and the oil determination should be made in the sample thus dried.

H. H. R.

Analysis of Wax. By G. BUCHNER (*Chem. Zeit.*, **12**, 1276).—Allen has shown that chemically bleached wax differs from wax bleached by exposure to sunlight, in having a greater sp. gr. and higher melting and solidifying points; the author now shows that when examined by Hübl's method it also has a higher percentage of acid (mean 23·01) and a higher saponification equivalent (98·36), whilst the ratio (1·32) of these numbers is lowered, the corresponding numbers for sun-bleached wax being 20, 95, and 1·37 respectively.

D. A. L.

Chemical Examination of certain Gums and Resins. By R. WILLIAMS (*Chem. News*, **58**, 224—225).—The author has examined some gums, &c., for total potash absorption, saponification equivalent, potash required to neutralise free acid, iodine absorption, loss at 100°, and ash. The gums he examined were amber, animi, arabic, asphaltum, benzoïn, bone-pitch, copal, damar, dragon's blood, elimi, gamboge, kaurie, mastic, rosin, sandarac, senegal, shellac, and tragacanth. The data are tabulated in the paper.

D. A. L.

Detection of "Saccharin" in Beer. By A. H. ALLEN (*Analyst*, **13**, 105—106).—A pint of the beer is concentrated to about one-third, acidified with phosphoric acid, and shaken with ether. The residue from the ethereal solution is fused with alkali and tested for a sulphate. Beer to which less than half a grain of Fahlberg's "saccharin" had been added gave distinct indications. The original beer gave no trace. One part of barium sulphate corresponds with 0·785 of "saccharin." The simultaneous presence of salicylic acid does not affect this mode of detection. M. J. S.

Estimation of Alkaloïds in Nux-vomica. By A. KREMEL (*Arch. Pharm.* [3], **26**, 899, from *Pharm. Post*, **21**, 534).—5 grams of the finely powdered nux-vomica seeds is treated in an extraction apparatus with 40 c.c. of a mixture of three parts of chloroform and one part of alcohol for two to three hours. The extract is agitated with 25 c.c. of 10 per cent. sulphuric acid, and again with 15 c.c. of the same acid, the acid solution is separated from the chloroform in a separating funnel, and made alkaline with ammonia, after which the free alkaloïd is shaken with 25 c.c. of chloroform. The chloroform solution is evaporated in a tared glass dish, and the residue is weighed. Numerous results obtained during the year have varied from 1·84 to 2·76 per cent., the average being 2·5 per cent. J. T.

Estimation of Quinine by Kerner's Method. By E. A. RUDDIMAN (*Chem. News*, **58**, 202—204; 216—218; 226—227).—The author has investigated the version of Kerner's test for quinine given in the U.S. Pharmacopœia, and finds, firstly, that it is not applicable to samples containing more than 2 per cent. of cinchonidine sulphate, inasmuch as the final clearing of the solution is indistinct and uncertain, and, moreover, the water used in the first instance is insufficient to dissolve all the cinchonidine salt. The following test for commercial quinine gives better results, and would include all samples coming within the officinal test:—1 gram of the sample is dissolved in 30 c.c. of boiling water, cooled, and digested at 15° for two hours; 5·26 c.c. of this solution should be both precipitated and re-clarified by 7 c.c. of ammonia, sp. gr. 0·960. In order to ascertain the relation of such a solution to those prepared in the ordinary manner, 12 experiments were made, and it was found on the average that 5 c.c. of solutions prepared by digesting 1 gram of quinine with 10 c.c. of water at 15° for three hours, corresponded with 5·26 c.c. of solutions obtained by dissolving 1 gram in 30 c.c. of boiling water, and then digesting at 15° for three hours; although the amount of ammonia actually required varied for each sample.

In another series of test experiments, the author shows that as the temperature at which the titration is made rises, the quantity of ammonia required decreases, the average diminution per degree C. being 0·148 c.c. and 0·172 c.c. respectively for ammonia of sp. gr. 0·920 and 0·960. Further experiments with solutions containing cinchonine sulphate in quantities varying from 0·005 to 0·05 gram per 50 c.c. of standard quinine sulphate solution, indicate that each 0·001 gram of $(C_{19}H_{22}N_2O)_2,H_2SO_4 + 6H_2O$, requires 0·36 c.c. of ammonia, sp. gr. 0·920, for its precipitation and re-solution, and, therefore, in titrations, any excess of ammonia above that required by the standard quinine solution is readily calculated to cinchonidine. The proportions of water recommended in the officinal test of the different forms of quinine are not exactly the same as in Kerner's original test; to conform with the latter, the proportions of water should be, for the free alkaloïd 11·7, for the acid sulphate 8·07, for the hydrochloride 10·895, for the hydrobromide 10·2, and for the dried sulphate 10·144. D. A. L.

Detection of Cochineal in Alimentary Substances. By E. LAGORCE (*J. Pharm.* [5], 18, 489—492).—The substance being dissolved in water or weak alcohol, is slightly acidified if necessary with a drop or two of acetic acid, and the colouring matter is extracted by agitation with amyl alcohol; in presence of excess of acid, the reaction is not produced. The amyl alcohol is decanted and evaporated in presence of sufficient water. The aqueous solution thus obtained is treated with some drops of a 3 per cent. solution of uranium acetate, when a beautiful bluish-green coloration, or a precipitate of the same tint, is produced. Acids destroy this colour with the production of the orange tint of carminic acid. In the case of wines, the amyl alcohol is mixed with an equal volume of benzene, or, better still, toluene, otherwise œnolic acid is also taken up by the amyl alcohol, and the cochineal may be completely masked. Ammoniacal cochineal, which has occasionally been employed to colour wine, behaves differently with uranium oxide; the lake produced is rose-violet or violet-blue. Other substances, however, give coloured lakes with uranium oxide; so that if, in the process given above, a violet-lake is produced, it will be necessary to prove the absence of logwood before asserting the presence of cochineal; to this end it is only necessary to remember that ether extracts a yellow substance from logwood solutions which becomes rose to reddish-brown on addition of ammonia, and black with potassium dichromate. J. T.

Detection of Urobilin in Urine. By GRIMBERT (*J. Pharm.* [5], 18, 481—482).—The urine is mixed with an equal volume of fuming hydrochloric acid heated, until it begins to boil, and after cooling is agitated with ether. This takes a pale brownish-red colour with a decided green fluorescence. Examined by the spectroscope, the ethereal solution gives the absorption-band of urobilin; on evaporation, a garnet-red residue remains which is soluble with fluorescence in chloroform, and without fluorescence in alcohol, glycerol, and acetone, but less soluble in water. The ethereal solution shaken up with an alkali loses its colour, whilst the alkali becomes deep-red. On acidifying this in presence of fresh ether, a yellow slightly fluorescent solution is obtained, which, however, still gives the absorption-band of urobilin; on evaporation, an orange-yellow residue is left. This method of detecting urobilin tends to confirm Jaffé's view that urobilin does not exist as such in urine, but is produced under the action of oxidising agents from some chromogenic substance not yet isolated. J. T.

General and Physical Chemistry.

Invisible Lunar and Solar Spectra. By S. P. LANGLEY (*Phil. Mag.* [5], **26**, 505—520).—The author having detected heat of very low refrangibility in the spectrum of the sun-lit moon, has succeeded in isolating it in direct sunlight, the difficulty being greater here, owing to the preponderance of heat of moderate wave-length. The solar bands of low refrangibility are greatly affected by the altitude of the sun and the season. As they recede from the visible spectrum, they become broader, and beyond 5μ merge into one broad band. At $10{\cdot}2\mu$ a maximum is observed only in cold weather, succeeded by a minimum. The greatest maximum occurs at 13 or 14μ, a distance from the visible spectrum of over 20 times its length; this band is identical with that observed in the moon's spectrum, and corresponds with the maximum radiations of melting ice. The points of minima in the spectrum are identical with the absorption-bands obtained from a copper surface at 100°, at a distance of 100 m. The amount of radiation is excessively small, and there is not the great discrepancy between this part of the solar and lunar spectra which is observed in the visible spectra. This part of the solar spectrum is not hotter than that of melting ice; hence it appears that the earth's surface, even when at 0°, gives out radiations which permeate the atmosphere. H. K. T.

Absorption-spectra of Blue Solutions. By F. B. PITCHER (*Amer. J. Sci.*, **36**, 332—336).—By means of a modified Glan's spectrophotometer, the author has examined various blue pigments, including ultramarine, indigo, prussian blue, and some commercial mixtures. The resulting observations are mapped in curves, the various pigments absorbing the rays between A and G irregularly; nevertheless each individual pigment gives a characteristic curve, which may possibly serve for its identification in mixtures. The colours of these pigments are therefore not as pure or saturated as the approximate hues in the longer waved portions of the spectrum. Acid litmus solution examined in like manner was marked by brightness in the red, almost complete transparency for rays between B and C, and slight minima at D and F; with neutral litmus, the brightness in the red disappears, the absorption at D is much increased, whilst the whole spectrum is only half as bright as before neutralisation; in alkaline litmus solution, the absorption in the yellow increases and extends, and the brightness of the whole spectrum is again diminished, especially in the red portions. Copper sulphate solution absorbs slightly in the red, showing a maximum transparency between E and F, but absorbs again towards G. When, however, ammonia is added to the solution, there is strong absorption throughout the orange and yellow, whilst the absorption between F and G practically disappears. D. A. L.

Relation between Rotatory and Refractive Powers of Chemical Compounds. Part I. By I. KANONNIKOFF (*J. Russ. Chem. Soc.*, 20, 1888, 571—578).—The author has determined very accurately the rotatory powers (α) and refractive powers (ϕ) of several organic substances at different degrees of dilution, and finds $\frac{\alpha-\alpha'}{\phi-\phi'} = \text{A} = \text{const.}$ After differentiation and subsequent integration, the following relation is obtained: $\alpha = \text{A}\phi + \text{B}$. For cane-sugar, A = 11·40 and B = −268·23 (267·68 to 268·71).—It is found that the constants A and B are not identical for substances of the same chemical composition and function; for example, with cane-sugar, milk-sugar, and maltose, or with dextrose and galactose. But it is interesting to find that the relation A = constant obtains, at least in the case of the sugars investigated by the author, the constant varying from 23·52 to 23·60. How far this value varies with other compounds and different solvents is a subject for further investigation.

The following relation between the constant B and the specific rotatory power $[\alpha]_D$ is found by the author:—

	Saccharose.	Lactose.	Maltose.	Galactose.	Dextrose.	Mean.
$B/[\alpha]_D =$	4·18	4·37	4·19	3·98	4·33	4·20

from which $[\alpha]_D = B/4{\cdot}2$. The same is seen in the case of A, for—

	Saccharose.	Lactose.	Maltose.	Galactose.	Dextrose.	Mean.
$[\alpha]_D/A =$	5·62	5·39	5·62	5·92	5·45	5·60

from which $[\alpha]_D = 5{\cdot}6 \times A$.

The results obtained by the author with the carbohydrates are arranged in a table, and it is shown that the refractive power may be calculated, with close approximation, from the rotatory power of any of the compounds in question. The author is continuing his investigations.

B. B.

New Theory of Molecular Volume and Refraction. By E. KETTELER (*Zeit. physikal. Chem.*, 2, 905—919).—The author points out the unsatisfactory nature of the expressions proposed for the molecular refraction, and suggests an equation of the form $(n^2-1)(1-\beta d)/d = \text{M}$, or $(n^2-1)(v-\beta) = \text{M}$, where β is the volume actually occupied by the ponderable molecules, v that of the space in which they are contained, $(v-\beta)$ being therefore that of the intermolecular ether, and M is a molecular function depending on the constitution of the medium. In the case of gases, where β becomes so small in comparison with v that it may be neglected, the formula becomes $(n^2-1)v = \text{M}_g = \text{const.}$, which is Newton's law. If the pressure were infinitely great, v would in its turn vanish, and the value of the expression simply depend on β. The true molecular volume of the substance is given by $\text{P}\beta$, where P is the molecular weight; the expression at present accepted for the molecular volume Pv being only the apparent volume, and including the space between the molecules occupied by the ether. M may have one of two values, both of which are definite physical constants, the one M_f being for the liquid, and the other M_g for the gaseous state.

The value of β may be obtained in three ways: by varying the temperature, the pressure, or the constitution of the media examined. In the first two cases, if v be known or determined as a function of temperature or pressure, and then for two different temperatures or pressures observations of n be made, we get by elimination of M from the two observations—

$$\beta = \frac{(n_1^2 - 1)v_1 - (n_2^2 - 1)v_2}{n_1^2 - n_2^2}.$$

In the third case, the author shows how by mixing the substance, the constants for which are unknown, with one the constants for which have been previously determined by one of the above methods, the unknown constants may be deduced by observations on different mixtures.

Particular stress is laid on the importance of the constant β, as giving a means of determining the true molecular volume Pβ of a compound. Values of β calculated from Weegmann's observations are given. H. C.

Kinetics of Substances in Solution. By M. LOEB and W. NERNST (*Zeit. physikal. Chem.*, 2, 948—963).—From determinations of Hittorf's ratio of transference and the conductivity of a number of silver salts, the authors have calculated the ionic velocity of silver, according to the principles laid down by Kohlrausch, with the view of still further testing the truth of the modern views on electrolysis. The constancy of the value obtained from observations with eight different salts gives satisfactory evidence for the truth of the theory, the numbers varying only within very narrow limits from a mean value of 591×10^{-8} at 25°.

The calculated values for the velocities of the other ions are also given, and it further appears from a comparison with the temperature coefficients of the velocities, that the latter decrease as the velocity increases. H. C.

Determination of the Basicity of Acids from the Conductivity of their Sodium Salts. By W. OSTWALD (*Zeit. physikal. Chem.*, 2, 901—904).—The author has further tested the principle laid down by him for determining the basicity of an acid from the conductivity of its salts (Abstr., 1888, 331), with a number of pyridine- and quinoline- carboxylic acids of different basicity, the highest being the pentacarboxylic acid of pyridine. He finds in every case a confirmation of the law that the increase in the molecular conductivity of the salt with an increase in the dilution from 32 to 1024 litres is equal to $10 \times n$, where n is the basicity of the acid.

H. C.

Heat of Combustion of Terpilene, Terpin Hydrate, and Terpin. By W. Louguinine (*Compt. rend.*, **107**, 1165—1167).

	M. p.	B. p.	Rot. power.	Heat of combustion		Heat of formation.
				Per gram.	Per gram-molecule.	
(1.) Inactive terpilene...	33°	—	—	9530·4	1467682	113318
(2.) Caoutchene hydrate	33	—	—	9578·7	1475120	105880
(3.) Active terpilenol....	—	—	−80°	9597·0	1478077	102923
(4.) Active terpilenol....	—	—	−80	9575·2	1474581	106419
(5.) Synthetical borneol..	33	—	—	9551·0	1470854	110146
(6.) Eucalyptol	—	175°	—	9481·3	1460120	120880
(7.) Terpin hydrate	—	—	—	7621·1	1448009	270991
(8.) Terpin	—	—	—	8455·6	1454363	195637

(1), Obtained by the action of dilute acid on terpin; (2), by the action of glacial acetic acid on caoutchene; (3), by the action of formic acid on French terebenthene; (4), by the action of glacial acetic acid at 100° on French terebenthene; (5), by the action of glacial acetic acid at 200° on French terebenthene.

It would seem that the last molecule of water in terpin hydrate is very loosely combined, but the formation of terpin from water and the hydrocarbon corresponds with a very considerable development of heat.

C. H. B.

Heats of Combustion of Camphors and Borneols. By W. Louguinine (*Compt. rend.*, **107**, 1005—1008).

	Rot. power.	M. p.	Heat of combustion.		Heat of formation.
			Per gram.	Per gram-molecule.	
Laurel camphor, dextrogyrate	—	—	9225·1	1402215	109785
Feverfew camphor	−41° 6′	175°	9302·8	1414026	97975
Racemic camphor	—	178·8	9298·7	1413402	98598
Dryobalanops borneol......	—	—	9510·85	1464671	116329
Valerian camphol	−37 7	208·8	9561·6	1472486	108514
Racemic camphol	—	—	9570·3	1473826	107174

It is evident that physical isomerism is accompanied by very slight differences between the heats of formation. The heat of formation of laurel camphor is almost identical with that of cymene, and it is well known that camphor is readily converted into cymene. Conversion of camphor into borneol by the addition of H_2 corresponds with 6544 cal. The hypothetical conversion of borneol into menthol by the addition of H_2 would correspond with 24671 cal., and the magnitude of this number indicates a possibility of actually realising this conversion.

C. H. B.

Heat of Dissolution of Anhydrous Lithium Iodide. By A. Bodisco (*J. Russ. Chem. Soc.*, 1888, 500—503).—The anhydrous iodide was obtained from the salts $LiI + 3H_2O$ and $LiI + 2H_2O$ by heating them nearly to dull redness in a current of hydrogen. The heat of dissolution was found equal to 14,886 cal. According to Thomsen, the heat of formation of Li + I + aq = 76,100 cal., so that the formation of LiI from its elements = 61,214 cal. Now as the heat of formation of Li_2O = 140,000 (Beketoff), or of a quantity equivalent to LiI = 70,000; this value is by 8,786 cal. larger than the heat of formation of LiI, whereas in the case of the other alkali metals the reverse is always found to be the case. This shows that there is no constancy of modulus, but that the energy of chemical reaction accompanying the formation of a compound depends on the relation of masses of the constituents, as shown by Beketoff.

B. B.

Density and Expansion by Heat of Saline Solutions. By G. J. W. Bremer (*Rec. Trav. Chim.*, 7, 268—309).—The densities of calcium chloride and sodium carbonate solutions at different temperatures have been most carefully determined, for temperatures above that of the outside air by means of a specific gravity bottle, and for temperatures below by means of a dilatometer. It is found that between 0° and 100° the variation of the density with temperature may be expressed by $d = d_0(1 + at - bt^2)$. The following values for a, b, and d_0 have been calculated for calcium chloride solutions:—

Grams $CaCl_2$ in 100 grams water.	b.	a.	d_0.
4·4295	0·000003301	0·0001126	1·03619
7·4966	0·000002727	0·0001649	1·05948
7·4913	0·000002697	0·0001672	1·06036
11·8658	0·000002092	0·0002231	1·09085
13·6023	0·000001751	0·0002480	1·10704
20·9280	0·000001218	0·0003125	1·15373
28·5534	0·000000961	0·0003262	1·20597
31·5326	0·000000871	0·0003425	1·22005

For sodium carbonate solutions the following values are given:—

Grams Na_2CO_3 in 100 grams water.	b.	a.	d_0.
3·2430	0·000002797	0·0001766	1·03551
4·8122	0·000002578	0·0002046	1·05171
7·4587	0·000002306	0·0002342	1·07677
10·1400	0·000002041	0·0002732	1·11192

It will be noticed that in each case a increases and b decreases with the concentration of the solution. Hence the greater the concentration the more will the curve representing concentration approximate to a straight line. The different curves will also intersect very nearly at the same point.

It is found that d_0 is a function of the amount p of anhydrous salt dissolved in q grams of water, such that $d_0 = (p + q)\ (\alpha p + \beta)$, where α and β are constants. The equation $d_0 = 1 + \alpha p + \beta p^2$, is found to be in better agreement with the observations. β is negative for calcium chloride and equal to zero for sodium carbonate. The coefficients of dilatation a and b may be represented in similar manner as functions of the concentration.

Curves for sodium carbonate do not show any break in continuity at 36°, where the solubility of the salt abruptly changes. H. C.

Dilatation of Salt Solutions. By N. TSCHERNAY (*J. Russ. Chem. Soc.*, 1888, **20**, 486—497).—In a former paper (this vol., p. 204) the author has described his experiments with solutions of nitrates of alkalis and alkaline earths. In the present paper, the dilatation of solutions of chlorides of the same elements was determined. The following values were obtained :—

$HCl + 50H_2O\ \ V_t = 1 + 0{\cdot}0000652t + 0{\cdot}000004355t^2$ (Marignac).
$LiCl + 50H_2O$ „ $= 1 + 0{\cdot}0000557t + 0{\cdot}000004036t^2$
$NaCl + 50H_2O\ \ 1 + 0{\cdot}0002318(t - 9{\cdot}8) + 0{\cdot}000003093(t - 9{\cdot}8)^2$.
$KCl + 50H_2O = 1 + 0{\cdot}0001239t + 0{\cdot}000003611t^2$.
$RbCl + 50H_2O = 1 + 0{\cdot}0001267t + 0{\cdot}000003716t^2$.
$MgCl_2 + 50H_2O = 1 + 0{\cdot}0001394t + 0{\cdot}000002892t^2$.
$CaCl_2 + 50H_2O\ \ 1 + 0{\cdot}0001925t + 0{\cdot}000002647t^2$.
$SrCl_2 + 50H_2O$ „ $1 + 0{\cdot}0002204t + 0{\cdot}000002542t^2$.
$BaCl_2 + 50H_2O$ „ $= 1 + 0{\cdot}0002393t + 0{\cdot}000002456t^2$.

Sodium and potassium bromides gave—

$NaBr + 50H_2O\ \ V_t = 1 + 0{\cdot}0001714t + 0{\cdot}0000033512t^2$.
$KBr + 50H_2O$ „ $= 1 + 0{\cdot}0001412t + 0{\cdot}0000035252t^2$.

The following general results were arrived at in the above and the former series :—

The change of volume with temperature, as expressed in the above equations, holds good only between 0° and 50°, when values are obtained agreeing within 0·00015 with the direct results of experiment; but for temperatures above 50°, differences are found exceeding the possible experimental errors. For such calculations, analogous equations must be used starting from 50°, at which temperature the volume is assumed = 1.

The change of volume with rise of temperature is best expressed by the first quotient dv/dt, the coefficient of dilatation. Up to 50° the coefficients are found to approach each other, the values varying from 0·000147 (for $LiNO_3 + 50H_2O$) to 0·000214 (for $NaNO_3 + 50H_2O$). For the solutions of chlorides, the differences of the single values are much larger at 0°, but with increase of temperature up to 50° they become smaller, not exceeding 12 per cent. The same is seen in the case of bromides.

On comparing the mean values of dilatation-coefficients at 40° and

50°, it is seen that they approach each other for salts of similar constitution:—

Temperature.	40°.	50°.
Nitrates	0·00045	0·00052
Chlorides	0·00040	0·00047
Bromides	0·00043	0·00050

The *atomic weights of elements forming the molecules*, and the molecules themselves at temperatures above 50°, are without influence on the dilatation, as seen, for example, from the fact that the dilatation of nitric acid is nearly identical with that of silver nitrate; the same is seen in the case of some of the chlorides, whereas in others the dilatation-coefficient increases with the atomic weight of the metal:—

$MgCl_2 + 50H_2O = 0·000429$
$CaCl_2 + 50H_2O = 0·000457$
$SrCl_2 + 50H_2O = 0·000474$
$BaCl_2 + 50H_2O = 0·000485$

The values for monad metals do not differ much from those of dyad metals.

The relative proportion of the molecules of anhydrous salt and water is of the greatest influence on the dilatation, but for solutions of 1 mol. of salt in 50 mols. of water at 50°, the dilatation is nearly the same in all cases. The proportion of the number of molecules of the hydrate existing at that temperature in solution to the number of molecules of the solvent, seems to be one and the same for the salts in question, but at lower temperatures, this proportion varies considerably for every salt, and the difference between the corresponding dilatation-coefficients is far more considerable, and varies with the temperature.

Mendeléeff (see Trans., 1888, 357, foot-note) regards solutions as compounds of different hydrates of salts with water, the hydrates existing in a state of formation and dissociation, and the author (Tschernay) regards Mendeléeff's hypothesis as a very probable explanation of the fact that the coefficient of dilatation varies with varying temperature for each salt in a different manner. B. B.

Vapour-density Estimation under Diminished Pressure. By C. SCHALL (*Ber.*, **22**, 140—146).—The principle on which the apparatus is constructed is as follows:—The pressure of an amount of air, let into the bulb and measured under ordinary conditions, is compared with the pressure of the vapour evolved in the latter. The capacity is thus found for the normal pressure and temperature. The apparatus is described with sketch (compare Abstr., 1887, 695 and 882). N. H. M.

Water of Crystallisation of the Alums. By W. MÜLLER-ERZBACH (*Ber.*, **21**, 3538—3540).—A reply to Lescœur and Maturin (this vol., p. 7).

Selective Chemical Affinity. By N. Beketoff (*J. Russ. Chem. Soc.*, 1888, **20**, 525—533).—Chemical affinity, since the time of Newton, has been regarded by some as a manifestation of universal gravitation or as an inclination of matter to aggregation; by others, as a peculiar power of affinity, analogous to magnetic or electrical attraction, since it is selective, or behaves differently with different particles of matter. The author regards affinity not as a peculiar force, but as a peculiar manifestation of energy. As a typical example, take a mixture of different halogens and of alkali metals. The result will be the formation of alkali haloïds, that is, compounds of the halogens with the alkali metals, accompanied by development of heat, and not a combination of the halogens or of the metals among themselves, which would take place without appreciable development of heat. Moreover, an apparent change of volume and loss of the original properties of the substances takes place in the first case, but would not do so in the second. This instance of aggregation is at first sight different from the phenomena of gravitation, cohesion or adhesion. An analogous case would occur if the motion of planets round the sun were arrested, when they would fall into the sun, with development of heat; but if their original motion could be restored to them, the former state might be re-established. Something analogous takes place in the case of phenomena of selective affinity. The atoms may be assumed as gifted with a store of energy, for example, in the form of vortex motions. This motion hinders their close approach or union, which would result in the formation of chemical compounds; it is a repulsive force acting against aggregation. In order to unite, the atoms must lose this motion partly or entirely, but the energy cannot be taken away, even at the temperature of absolute zero, as seen from the fact that the product of heat capacity c and absolute temperature T, that is Tc, is only a part of the heat set free on combination. The only thing that is capable of taking away or annihilating this motion is the action of an element of opposite properties: then chemical combination ensues. An analogous case occurs when two masses moving in opposite directions meet each other. The author assumes that atoms of different elements are gifted with motions, different in form, velocity, and quantity, and that these dynamical attributes are greatest for elements placed at opposite ends of periods when arranged according to the natural system as represented by the periodic law. Atoms of the same element may combine to form a molecule comparatively stable towards physical influences, but this stability vanishes when an element of opposite properties enters the sphere of motion. The two opposite motions neutralise one another, and a new, more stable system, that is, a chemical combination, is formed, with a loss of energy. According to this view, the phenomena of selective affinity become intelligible, and it is seen that chemical affinity is different from the usual forms of attraction between masses and particles.

If we do not assume the *hypothesis of opposite motions*, the masses and particles of bodies might be expected to show the same inclination for combining, so that the most stable aggregates would be formed from atoms and molecules of identical and homogeneous substances. It is true that combination of identical or like atoms takes place comparatively easily, but the compounds formed, chloride of bromine, for example, or alloys, show no *chemical* change in their original properties, and their stability is physical merely, and not chemical.

The author shows that the proposed hypothesis is in complete accordance with the thermal phenomena and with the change of volume accompanying chemical processes. The following tables, I and II, show for many others that a great contraction corresponds with, and, in the case of nearly related elements, is even proportional to, the development of heat.

TABLE I.

Compounds.	Contraction per cent.	Heat of formation.	Contraction per cent.	Heat of formation.	Contraction per cent.	Heat of formation.

The same may be seen from Table III, representing phenomena of substitution. It would appear that the hypothesis of reciprocal annihilation of motion in chemical action is in accordance with the phenomena of contraction and of heat. But there is another cause on which the phenomena depend. The author showed, in 1859, that the distribution of the atoms of elements in a given system depends on the relative weight of the atoms acting on each other, and that the distribution proceeds in such a manner that smaller atoms combine with smaller, and larger atoms with larger ones. Such a distribution corresponds with the general inclination of matter to aggregation, and is accompanied by greater condensation and increased development of heat. This is apparent from the phenomena of double decomposition, but not in solutions, as the $\pm$ heat of dissolution obscures the phenomena. For, whereas, in solution, the "modulus" expressing the heat of substitution of one element by another is nearly constant (Favre and Silbermann), in the solid state this modulus changes from positive to negative values within wide limits. For example, when oxygen in oxides of alkali metals is displaced by chlorine, the heat developed decreases with decreasing weight of the metal, $\frac{K_2O}{2} + Cl = +57$; $\frac{Na_2O}{2} + Cl = 47{\cdot}5$; $\frac{Li_2O}{2} + Cl = 23{\cdot}2$. When oxygen is displaced by iodine there is at last a reversion of affinity, $\frac{K_2O}{2} + I = +32$; $\frac{Na_2O}{2} + I = +19$; $\frac{Li_2O}{2} + I = -10$; for in the case of lithium iodide the difference of atomic weights is very great, $\frac{Li = 7}{I = 127}$, and therefore the heat of formation of the oxide, $\frac{Li = 7}{O = 8} = 70$ Cal., is larger than that of the iodide. Lithium iodide is, therefore, easily decomposed by the oxygen of the air. A reversed action similar to that of oxygen and the halogens is seen in the case of hydrogen compounds; the formation of water, for instance, is accompanied by greater development of heat than that of hydrogen chloride, $H + \frac{O}{2} = 29$; $H + Cl = 22$; $\frac{H_2O}{2} + Cl = -7$. This difference is much larger for hydrogen bromide and iodide, the relation of the atomic weights $\frac{1}{80}, \frac{1}{127}$ being still more unfavourable for saturation than $\frac{1}{35{\cdot}5}$.

The influence of the relative weight of combining atoms or equivalents, in the case of different atomicity, is easily understood from the above point of view. The attraction of material particles increases with decreasing distance, and in the same way it increases as the acting masses become larger. Here we have another cause which promotes such a distribution; we can admit that the motions of atoms of nearly equal weight, if they are opposite in direction, will be most likely to completely neutralise each other. In the case of the formation of compounds with absorption of heat, the energy becomes greater, and the endothermic compounds formed will be less stable than the molecules of their simple constituents, so that under the influence of chemical or physical agents they will show an inclination to pass readily into more stable systems, in which the atoms possess a smaller store of energy. The physical stability of such compounds will depend mostly on the relative weight of the constituent atoms, that is, on the equal or nearly equal heat capacity. B. B.

Influence of Temperature on the Direction of Chemical Reactions. By A. POTILITZIN (*J. Russ. Chem. Soc.*, 1888, **20**, 503—506).—Claim of priority referring to Menschutkin's recent work, "Outlines of the Evolution of Chemical Views." B. B.

Formation of Amides from Ethereal Salts and Ammonia and the Reversal of the Reaction. By A. BONZ (*Zeit. physikal. Chem.*, **2**, 865—900).—The incomplete nature of the reactions for the formation of amides from ethereal salts and ammonia, led the author to suspect that the change was probably a reversible one. He found on experiment that this was the case, and that acid amides are, by the action of alcohol, partially converted into ethereal salt and ammonia. The two reactions were therefore further studied with a view of ascertaining the limits of each, and whether equilibrium exists between the two.

A large number of experiments were conducted which fully establish the reversible nature of both reactions, and show that the limits of each depend on molecular weight, temperature, and mass proportion. The higher the molecular weight of the ethereal salt, the less will be the quantity of amide formed and the greater will be the extent of the reverse reaction. Increase of temperature acts on the formation of the amide like increase of molecular weight, although at the same time the reaction is more rapid at high than at low temperatures. At high temperatures (above 100°), secondary reactions giving rise to the formation of amines also occur. H. C.

Dead Space in Chemical Reactions. By G. WATSON (*Chem. News*, **58**, 297).—The author attributes the dead space in chemical reactions observed by O. Liebreich (Abstr., 1888, 1242—1243) to the surface energy of the glass of the containing vessel. D. A. L.

Standard of Atomic Weights. By B. BRAUNER (*Chem. News*, **58**, 307—308).—The author points out how seriously the numbers representing the atomic weights are affected by the varying results obtained by different investigators for the ratio H : O, and suggests that instead of the atomic weights depending on this ratio, "the most difficult of all atomic ratios to determine accurately," it would be better to take O = 16, so as to make the atomic weights real Constants of Nature, and thus have to change these values only when a more exact determination replaces a less accurate predecessor.

D. A. L.

Apparatus for Determining the Reduction of the Freezing Point. By J. F. Eykman (*Zeit. physikal. Chem.*, **2**, 964—966).—A sketch of the apparatus, which is exceedingly simple, is given. It consists of a vessel of about 10 c.c. capacity, into which a small thermometer is so fitted as to act as a stopper. The whole can easily be weighed, and a stirrer is unnecessary as it can be taken in the hand and shaken. The details of a number of experiments with various plant substances in phenol show that it gives satisfactory results.

H. C.

Calculation of the Molecular Volumes of Benzene, Naphthalene, Anthracene, &c. By J. A. Groshans (*Rec. Trav. Chim.*, **7**, 263—267; compare this vol., p. 100).—For hydrocarbons containing two or three phenyl groups, 30 or 45 must be substituted for 15 in the formula $v_s = a - 15 + 2{\cdot}72$ B. For naphthalene, the value is 30, and for anthracene 45. If two substances belonging to the same series, fatty or aromatic, differ in their formulæ by 1 carbon-atom, their molecular volumes will differ by 14·72. H. C.

Lecture Experiments on Raoult's Law. By G. Ciamician (*Ber.*, **22**, 31—32).—The author describes, with the aid of a diagram, an apparatus suitable for lecture experiments on Raoult's law. It consists of an air-thermometer bent twice at right angles, the bulb of which, situated on the shorter limb, is placed in a large test-tube and encircled by a stirring-rod. The open and longer end dips into a beaker of coloured water and is provided with two bulbs, one near the extremity to prevent air being forced out of the thermometer, the other close to the bend serving to prevent the liquid from rushing back into the bulb. The solution is placed in the test-tube, the latter being surrounded by a beaker containing the cooling solution or freezing mixture. F. S. K.

Lecture Experiment: Volumetric Composition of certain Gaseous Compounds. By P. Hawkridge (*Chem. News*, **59**, 66—67).—The following arrangement serves for determining the composition of certain gases by heating with or by contact with a solid. A piece of wide glass tube is fitted into the tubulure of a 2-oz. retort by means of india-rubber tubing, the end of the tube inside the retort is plugged with asbestos, on this, sodium or any desired metal is packed, and a glass rod is fitted to the other end of the tube by means of india-rubber tubing. The retort is filled first with mercury, then with the gas to be examined, it is now stood upright with the end of the neck immersed in mercury. By pressing the rod, the metal is projected into the bulb of the retort, and may be heated; the contraction of the gas is measured by the rise of mercury in the neck of the retort.

D. A. L.

Blue Flame produced by Sodium Chloride in a Coal Fire. By N. Leonard (*Chem. News*, **59**, 15).—In connection with the blue flame produced when salt is thrown into a coal fire, the author points out that under similar circumstances the blue flame is produced equally well by potassium chloride, less readily by barium, calcium, and ammonium chlorides, also by chloroform, carbon tetrachloride, and ethylene dichloride, but that it is not produced by throwing sodium carbonate, phosphate, or sulphate into the fire, nor by dropping salt on red-hot platinum. These results support the view that the coloration is due to the chlorine of the salt. D. A. L.

Inorganic Chemistry.

Imperfect Combustion in Gaseous Explosions. By H. B. Dixon and H. W. Smith (*Chem. News*, **59**, 65—66).—The authors have observed that when mixtures of oxygen and hydrogen are exploded in a very long tube in proportions approximating to 2 vols. of the latter to 1 vol. of the former, an explosive residue always remains unburnt, even when the oxygen is in excess. In a number of experiments, the tube, after explosion, was filled with carbonic anhydride, until the internal pressure equalled that of the atmosphere, then a litre of gas was driven out of the other end of the tube, collected over soda and the unabsorbed gas analysed; the mean results of numerous analyses are given in the following table. It had been previously ascertained, that practically all the residual gas could be collected in the first litre expelled from the tube. The numbers under A are those obtained from the residue after the explosion of a mixture which contains a slight excess of hydrogen, whilst under B and C are given the mean results obtained from original mixtures containing excess of oxygen. The tube was 100 m. long, had a capacity of 8100 c.c., with a diameter of 9 mm. with an internal surface of 29,000 sq. cm.

	A.	B.	C.
Average residue..	150 c.c.	160 c.c.	220 c.c.
H..............	54·3 p. c.	29·5 p. c.	20·5 p. c.
CO..............		5·1 „	5·8 „
O..............	19·4 „	38·1 „	32·7 „
N..............	26·3 „	27·3 „	41·0 „

Other experiments show that the extent of surface of the vessel or tube employed does not exert any great influence on the explosion of the gases. Similar results were obtained in experiments with mixtures of carbon monoxide and oxygen. These results seem to confirm Mallard and Le Chatelier's observation, that the cooling in this method of combustion is more rapid than in ordinary combustion, and they also bear on Berthelot's theory of the mode of propagation of explosion waves. D. A. L.

Coefficients of Volatility for Aqueous Hydrochloric Acid. By R. B. Warder (*Amer. Chem. J.*, **10**, 458).—Expressing the strength of dilute hydrochloric acid by $H_2O + n$HCl, and the liquid which distils at any moment from such acid by $H_2O + v$HCl, the author tries to express the ratio existing between v and n by a constant factor as $v = 445n^3$ or $v = 3063n^4$, but as the values of v vary 10—30 per cent. with different conditions of boiling, no progress is made. H. B.

Rate of Decomposition by Heat of the Salts of the Halogen Oxy-acids and the Products obtained. By A. Potilitzin (*J. Russ. Chem. Soc.*, **20**, 1888, 541—570; compare Abstr., 1888, 219).—Lithium chlorate was prepared by the double decomposition of barium chlorate with lithium sulphate. It forms very hygroscopic needles of the formula $2LiClO_3 + H_2O$. It melts at about 50°, and the liquid, owing to superfusion, remains in that state at the ordinary temperature. On heating at 90° in a current of dry air, it becomes anhydrous, and then melts at 129°. On solidifying, two modifications separate, one in crystals and the other as a porcelain-like, white mass. The salt begins to decompose at 270°, but to a small extent only; at 323° the amount of decomposition varies from 0·19 to 0·63 per cent. in 20 minutes, or equals 2·85 per cent. in 3 hours 25 minutes. In order to study this decomposition, a weighed quantity of the dry salt was heated in a glass tube placed in a bath of Wood's alloy. The decomposition was as follows :—

Per cent.	17·10	34·08	37·10	36·54	41·11	41·60
Temp. ..	328°	338°	348°	358°	368°	383°
Time ...	7h. 20m.	8h. 40m.	8h. 20m.	3h. 30m.	5h. 50m.	2h. 30m.

The theoretical limit of total decomposition is 53·03 per cent., and the above rates of decomposition were calculated from a series of weighings after heating for 10 minutes at corresponding temperatures. It is seen that after some time, the amount of decomposition reaches its maximum, and then gradually decreases without reaching the theoretical limit. This maximum, moreover, is reached the sooner the higher temperature :—

Temperature	328°	338°	348°.	358°	368°	383°.
Maximum reached after........ .	5h. 40m.	2h. 20m.	1h. 20m.	40m.	10m.	<10m.
Limit of decomposition per cent..	—	—	37	—	40	41·6

The incomplete decomposition is due to the formation of some lithium perchlorate (by secondary reaction) which decomposes less easily than the chlorate (primary reaction) under the same conditions. The lithium perchlorate could be easily converted into the characteristic crystals of potassium perchlorate. The following equation represents the decomposition of lithium chlorate: $A\mathrm{LiClO_3} = m\mathrm{LiCl} + n\mathrm{LiClO_4} + p\mathrm{O}$. At the same time, some chlorine escapes, and some lithium oxide remains with the products of decomposition. In order to determine the amount of chloride and perchlorate formed in the different phases of the process, a weighed portion of the chlorate was heated as above, to 368°, weighed again, dissolved in water, and then in one part of the solution the chlorine of the chloride determined volumetrically with silver nitrate; in another part, the chlorine of the chlorate plus that of the chloride was determined in the same way, after evaporation to dryness with hydrochloric acid; the perchlorate is not acted on by the acid.

The result of a series of experiments is given in a table, and the theoretical facts deduced from it are the following:—The first period of the decomposition is represented by the equation: (*a*) $6LiClO_3 = 4LiCl + 2LiClO_4 + 5O_2$, whereas towards the end, the following reaction occurs: (*b*) $10LiClO_3 = 8LiCl + 2LiClO_4 + 11O_2$. It is seen from the numerical data, that the changes from the first to the second phase are not abrupt, but slow and continuous. The author shows in addition to this that lithium perchlorate is decomposed by heat into the chlorate and chloride, so that the reactions (*a* and *b*) are accompanied by a reversed reaction (*c*), $A LiClO_4 = n LiCl + m LiClO_3 + pO$. Both reactions are in contradiction to the principle of the maximum of work, and in fact the decomposition of lithium chlorate is not a simple one, representing a state of unstable equilibrium between the chlorate, perchlorate, chloride, and oxygen, the direction of the change depending on the temperature and the relative quantity of the substances present.

An analogous set of experiments was carried on with lithium perchlorate. This was prepared by dissolving pure lithium carbonate in perchloric acid, and purifying the salt by fractional precipitation with lithium carbonate, and treatment with absolute alcohol and recrystallisation. It forms either short prisms belonging to the hexagonal system or thin needles; it does not deliquesce on exposure to the air. The crystals are hexagonal-hemihedric with the forms R_1—R (which in an equilibrium form the pyramid P) ∞P and ∞P2. Axial ratio: $a : c = 1 : 0{\cdot}7039$. Optically monaxial. Bifraction negative. (A. Lagorio.) The crystals which have the composition $LiClO_4 + 3H_2O$ seem to be isomorphous with those of barium perchlorate; 2 mols. of H_2O are lost at 98—100°, and the third at 130—150°, the weight remaining constant up to 300°. The hydrated salt fuses at 95°, the anhydrous at 236°. It absorbs moisture, but does not deliquesce. At 380°, decomposition begins and increases rapidly with rise of temperature; at 415° the loss of oxygen is equal to 22—23 per cent. (theoretical limit 60·09 per cent.), this being the maximum. At higher temperatures, the amount of decomposition decreases. The greatest velocity of decomposition is more removed from the initial decomposition than in the case of the chlorate. The rate of decomposition is greatest at a moment when, at a certain temperature, the relative proportion of the chlorate and perchlorate which are mutually converted, is the greatest. This temperature lies about 368° when the mixture has the composition $3LiClO_3 + 2LiCl + LiClO_4$.

The phases of the decomposition of lithium chlorate and perchlorate, like those of barium bromate, cannot be foreseen and explained from the point of view of the "principle of maximum work," but are easily explained by the following rule of unstable equilibrium as shown by the author in 1880. In every case of chemical transformation, the equilibrium of the system of bodies depends on their atomic weights, their relative quantities (masses), and the store of internal and external energy. It is shown that the different phases of the reactions studied are in complete accordance with this law.

B. B.

Molecular Weight of Sulphur. By H. Biltz (*Zeit. physikal. Chem.*, 2, 920—947).—The author describes the details of his work on the molecular weight of sulphur, the results of which have been already given (Abstr., 1888, 1027).

Hydrazine. By T. Curtius and R. Jay (*J. pr. Chem.* [2], **39**, 27—58; compare Abstr., 1887, 715).—Hydrazine sulphate is best obtained when triazoacetic acid (250 grams in 2 litres of water, this vol., p. 369) is warmed with sulphuric acid (300 grams) until all effervescence ceases; the sulphate crystallises out on cooling. More may be extracted from the mother-liquor by shaking with small quantities of benzaldehyde, thus converting the hydrazine into benzalazine (see p. 393), which separates out; after recrystallisation this is decomposed with sulphuric acid, whereby hydrazine sulphate and benzaldehyde are reformed; the latter is then distilled off. The yield is 90 per cent. of that calculated. The same process will serve to extract the hydrazine contained in the mother-liquor from the preparation of triazoacetic acid (this vol., p. 369), and from the solution resulting from the reduction of ethyl diazoacetate in the presence of either acid or alkali.

The decomposition of triazoacetic acid by mineral acids is expressed by the equation $C_3H_3N_6(COOH)_3 + 6H_2O = 3N_2H_4 + 3C_2O_4H_2$, but during the reaction the oxalic acid splits up more or less completely into formic acid and carbonic anhydride. The authors observe that ammonium formate melts between 114° and 116°.

Hydrazine dihydrochloride (Abstr., 1887, 715) melts at 198° to a clear glass, evolving hydrogen chloride, and being converted into the *monohydrochloride* N_2H_4,HCl, which separates from hot absolute alcohol in long, white needles melting at 89°; it is decomposed at 240° into ammonium chloride, nitrogen, and water, and is very soluble in water. These hydrochlorides reduce platinic chloride in acid solution with evolution of nitrogen, no platinochloride being formed. *Hydrazine formate*, $N_2H_4,2H{\cdot}COOH$, is obtained by heating triazoacetic acid with water; it crystallises in rectangular tables melting at 128° with evolution of gas; the *carbonate*, *acetate*, *oxalate*, and *nitrate* have also been obtained.

Hydrazine itself is still unknown (compare Abstr., 1887, 715); its *hydrate*, N_2H_4,H_2O, is obtained, instead of the free base, when the hydrochloride is heated with caustic lime in a silver retort, and the resulting vapour passed through a silver tube containing caustic lime, and likewise heated: it is not dehydrated by barium oxide. It is a fuming, highly refractive, nearly odourless liquid, boiling at 119° unchanged; when hot it corrodes glass and destroys cork and rubber; it tastes alkaline and burns the tongue, and has most remarkable reducing powers. Some of its reactions with metallic salts are given. It is nearly destitute of odour. (For the remainder of this paper see p. 393.)

A. G. B.

Nitric Anhydride. By L. MEYER (*Ber.*, **22**, 23—24).—When phosphoric anhydride is mixed with almost anhydrous nitric acid, no heat is generated as stated by Weber (*J. pr. Chem.* [2], **6**, 342); the hissing noise and the evolution of brown fumes only take place when the acid contains more water than that obtained by distilling slowly with sulphuric acid.

Nitric anhydride has a more violent action on benzene than nitric acid, but the nitration does not proceed further than when the acid is employed. At 55° only dinitrobenzene is formed; trinitrobenzene is not produced until the dinitro-compound is heated with nitric anhydride and concentrated sulphuric acid at 160°. F. S. K.

Hypophosphoric Acid and its Salts. By P. DRAWE (*Ber.*, **21**, 3401—3404).—Hydrogen sodium hypophosphate is best prepared by allowing phosphorus to oxidise slowly in moist air as described by Salzer, and collecting the oxidation products in a 25 per cent. solution of sodium acetate. When a solution of nickel sulphate is added to a solution of hydrogen sodium hypophosphate in presence of sodium acetate, two salts are obtained, one of which, $Ni_2P_2O_6 + 12H_2O$, crystallises in prisms, the other, $NiNa_2P_2O_6 + 12H_2O$, in hexagonal plates. When the addition of sodium acetate is omitted, the prismatic crystals alone are formed, but when a solution of nickel sulphate is added to a solution of sodium hypophosphate both salts are produced. *Nickel hypophosphate*, $Ni_2P_2O_6 + 12H_2O$, is best prepared by adding a warm, dilute solution of sodium hypophosphate to excess of a warm solution of nickel sulphate, with constant stirring, and drying the precipitate in the air. *Nickel sodium hypophosphate*, $NiNa_2P_2O_6 + 12H_2O$, is obtained in the pure state by gradually adding a very dilute and well-cooled solution of nickel sulphate to excess of a very dilute and well-cooled solution of sodium hypophosphate, and drying the precipitate in the air.

The following salts, $Co_2P_2O_6 + 8H_2O$; $CoNa_2P_2O_6 + 1\frac{1}{2}H_2O$; $Cd_2P_2O_6 + 2H_2O$; $CdNa_2P_2O_6 + 6H_2O$; $Cu_2P_2O_6 + 6H_2O$; and $Zn_2P_2O_6 + 2H_2O$, were prepared as described above in the case of the corresponding nickel compounds. The salts are soluble in dilute acids, but almost insoluble in water; the double salts are decomposed by water. Some of the salts lose part of their water when heated at 110°, and their weight becomes constant, others are oxidised or decomposed. Cadmium hypophosphate is converted into the phosphide when ignited in the air, whereas nickel and cobalt hypophosphates are oxidised and become constant in weight, but the increase is less than what would correspond to a conversion into pyrophosphate.

F. S. K.

Arsenic in Glass and in Alkali Hydroxides. By J. MARSHALL and C. S. POTTS (*Amer. Chem. J.*, **10**, 425—430).—The amount of arsenious oxide in glass laboratory apparatus of American and German manufacture was found to vary from 0·095 to 0·446 per cent. All the samples of soda examined contained amounts of arsenic trioxide varying from 0·0028 to 0·0848 per cent.; a sample prepared by the Solvay process, however was free from arsenic. A 10 per cent. solution of soda readily dissolves arsenic from arsenical glass, but ammonia, and hydrochloric and sulphuric acids are without effect. Samples of potash were found to be free from arsenic, and sodium carbonate, although sometimes contaminated, was easily purified by recrystallisation. H. B.

Silicon and Boron. By L. GATTERMANN (*Ber.*, **22**, 186—197).—When quartz sand is heated with magnesium powder in a test-tube, a reaction takes place, and the whole glows intensely; if precipitated silica is used the reaction is very violent. Magnesium silicide is readily prepared by heating finely powdered, dry sand with powdered magnesium (1·5 part); the product is a bluish, half-fused substance which, when added to strong hydrochloric acid, at once gives rise to an evolution of silicon hydride. The residue has all the properties of the lower oxide of silicon; it burns when heated in air, reduces silver solutions, and reacts with alkalis with evolution of hydrogen. The experiments are very suitable for lecture experiments.

Silicon is best prepared by heating dry, finely powdered sand (40 grams) with magnesium (10 grams) in a not too thin test-tube; the whole tube is first heated moderately, and then a small portion is strongly heated, beginning at the lower end and continuing upwards. The product is greyish-black. The fragments of the test-tube, after the substance has been taken out, should be treated with acid, as the adherent substance will decompose in the moist air and evolve silicon hydride. Silicon is obtained by heating the substance in a closed crucible with zinc; on dissolving out the zinc, it is obtained in steel-blue needles.

Silicon tetrachloride is very readily prepared by gently heating the reduction-product in a tube in a stream of dry chlorine, and collecting in a receiver cooled with ice and salt. The product, which is greenish from dissolved chlorine, is purified by means of mercury. The yield is very good.

Silicon tetrabromide is prepared in a similar manner, but the receiver is merely cooled with water. The product is purified by distillation, and finally by shaking with mercury, and again distilling. The yield is not so good as in the case of the chloride, and the compound is more easily prepared from silicon and hydrogen bromide.

Silicon tetriodide is obtained by heating the reduction-product in a stream of dry carbonic anhydride and iodine vapour; a higher temperature has to be used than in the case of the chloride. The product is dissolved in carbon bisulphide, shaken with mercury until colourless, and the carbon bisulphide evaporated at a low temperature in a stream of carbonic anhydride. It is thus obtained in splendid, colourless crystals.

Silicon chloroform is readily prepared as follows:—The reduction-product is first freed from magnesia by keeping the powdered substance for some hours in contact with dilute hydrochloric acid (1 : 2); it is then washed well with water, dried, and heated in a stream of dry hydrogen chloride. It is preferable to first pass dry hydrogen over the heated substance to remove the last traces of water. The product is distilled in a distilling flask heated by means of a small vessel containing water at 90° which can be readily controlled. When a few drops of the compound are volatilised in a warm cylinder, and a slightly heated glass rod held at the opening, the substance ignites and explodes.

Silicoformic acid is easily obtained by connecting the receiver used in the preparation of silicon chloroform with a vessel containing ice-water. The uncondensed silicon chloroform on coming into contact with the water is decomposed, and flakes of silicoformic acid separate. It is filtered, washed with water, then with absolute alcohol, and finally with ether.

Silicon bromoform is prepared in a manner similar to silicon chloroform; a large amount of silicon tetrabromide is also obtained, so that it is better to prepare the tetrabromide by this method than by the method previously described. Silicon bromoform is spontaneously inflammable in the air, burning with a flame like that of zinc ethyl. It boils at 115—117°, sp. gr. = 2·7.

Silicon tetrachloride reacts with ammonia, yielding the compound $Si(NH)_2$ or $N\colon Si\cdot NH_2$; this is a white substance which does not melt. When silicon chloroform is treated with chlorobenzene and sodium, silicon tetraphenyl (m. p. 231°) is formed.

Boron is prepared by heating a mixture of magnesium (1 part) and dry borax (2 parts), covered with a layer of borax, to keep out the air, in a Hessian crucible for a short time. The product is powdered, extracted, first with hot water, and then with boiling hydrochloric acid. It is then washed, dried, and heated with aluminium in a crucible, when splendid hexagonal plates are obtained.

Boron trichloride is readily obtained by slightly heating the crude dried boron in chlorine. The greenish-yellow distillate is cooled in a freezing mixture, and shaken with mercury until colourless. 15 grams of the chloride were obtained when 8 grams of magnesium were used.

The author intends preparing aromatic derivatives of boron.

Lime, alumina, ferric oxide, chromic oxide, titanic and vanadic acids, &c., are also reduced by magnesium. N. H. M.

Graphite from Various Metals. By H. N. Warren (*Chem. News*, **59**, 29).—Cast iron, nickel, cobalt, ferromanganese, manganese, and chromium when treated with dilute acid leave scales of graphite differing in size, appearance, and combustibility in each case; but when some of the manganese graphite is added to molten iron, it is converted into the iron variety. D. A. L.

Decomposition of Potassium Chlorate in Contact with Metallic Oxides. By W. R. Hodgkinson and F. K. S. Lowndes (*Chem. News*, **58**, 309; **59**, 63—64).—When finely divided manganese dioxide is dropped into fused potassium chlorate, a sudden evolution of oxygen and chlorine ensues, the quantity of the latter gas depending on the fineness of the powdered oxide, at the same time some of the manganese enters into combination with the potassium. Oxides of cobalt, lead, iron, mercury, uranium, tungsten, molybdenum, and vanadium behave in a similar manner, the more acid oxides being most energetic, especially as regards the evolution of chlorine and formation of a potassium salt of the oxide. Platinum-black causes a temporary increase in the evolution of oxygen from fused potassium chlorate, but the action is purely mechanical.

Zinc, magnesium, bismuth, antimony, copper, and tin oxides, however, produce little or no effect when added to fused potassium chlorate. From a series of quantitative experiments, the authors are inclined to conclude that under the above circumstances the manganese dioxide suffers alternate reduction and re-oxidation, but the re-oxidation is rarely complete. In a similar way, Ag_2O is reduced to Ag and PbO_2 to Pb_3O_4. In other experiments, they show that the evolution of chlorine is due to the potassium forming manganates, uranates, vanadates, &c., as the case may be. Potassium chlorate is also decomposed by many salts, especially those of ammonia. D. A. L.

Extraction of Lithium from its Minerals. (*Pharm. J. Trans.* [3], **19**, 6.)—The method formerly in use for separating lithium from the other alkalis was based on the slight solubility of its carbonate. Schering now employs the following process for extracting lithium from *lepidolite* on the large scale. The finely ground mineral is digested with concentrated sulphuric acid, and the product is calcined and lixiviated with water. Potassium sulphate, sufficient to convert all the aluminium present into alum, is added, and after evaporation the alum which separates is removed, any portion remaining being afterwards decomposed by the addition of milk of lime. The filtrates are mixed with barium chloride, whereby all the bases are converted into chlorides. The whole is then evaporated to dryness, and extracted with absolute alcohol, which dissolves the calcium and lithium chlorides. The calcium chloride in the residue left on distilling off the alcohol is decomposed by ammonium oxalate; the filtrate is evaporated to dryness, and again extracted with absolute alcohol, which after evaporation leaves pure lithium chloride.

Solubility of Various Forms of Calcium Carbonate in Sea-water. By R. IRVINE and G. YOUNG (*Proc. Roy. Soc. Edin.*, **127**, 316—320).—The investigations were undertaken with the view of throwing additional light on Murray's theory as to the formation of coral island lagoons. The authors found a marked difference in the solubility of various corals, the porous kind being most easily dissolved by sea-water. This is due to the fact that porous corals present a larger surface to the action of sea-water, and also that the carbonate appears to be in a different molecular condition. Precipitated amorphous calcium carbonate dissolves in 1600 parts of sea-water, whilst of the same precipitate, when it has changed from the amorphous to the crystalline condition, 1 part requires 8000 of sea-water to dissolve it. Moreover, porous corals contain a large proportion of organic matter, which on oxidising produces carbonic anhydride, and so increases the solvent action of the water. The solution thus formed precipitates crystallised calcium carbonate, and this precipitation may be due either to loss of carbonic anhydride or to the formation of ammoniacal salts, which reduce the solubility. Once the crystalline form is produced, its greater insolubility protects it from further solution, and the protective influence of mud and sand and seaweed growth must also be considered. The action of sea-water on hard and soft corals is shown below.

Materials.	Temperature.	Exposure.	Average amount of $CaCO_3$ taken up.
	C.°	hours.	grams.
Dead corals, porites	27	12	0·395
Coral sand	27	12	0·032
Harbour mud (Bermuda)	27	12	0·041
Isophyllia dipsacea (Dana), Bermuda	—	—	0·041
Millepora ramosa (Pallas)	—	—	0·036
Madrepora asperosa (Dana), Mactan Isl., Zebu	—	—	0·073
Montipora foliosa (Pallas), Amboyna	—	—	0·043
Gomastræa multilobata (Quelch), Amboyna	10	—	0·073
Porites clavaria (Lamk), Bermuda	10	—	0·093

The effect of the presence of organic matter appears in the figures given below.

	Temp.	Hours.	Gram.
Weathered oyster shells	10° C.	12	0·331
Mussels allowed to rot in sea-water 7 days	17	168	0·384
Lobsters allowed to rot in sea-water 3 weeks	10	504	1·062
Shrimps allowed to rot in sea-water 3 weeks	—	504	1·047
Schizopoda allowed to rot in sea-water 3 weeks	—	504	0·782
a. Amorphous $CaCO_3$ (freshly prepared)	—	—	0·649
b. " " "	−1·66	—	0·610
Crystallised $CaCO_3$	10	12	0·123
Melobesia, Kilbrennan Sound, Scotland	10	12	0·089

In *a* and *b*, the $CaCO_3$ was added as long as it dissolved.

E. W. P.

Solubility of Strontium Nitrate in Alcohol. By J. R. HILL. (*Pharm. J. Trans.* [3], **19**, 420).—One part of strontium nitrate dissolves in 4189 parts of absolute alcohol, and in 199·87 parts of rectified spirit at 15·5°.

R. R.

Action of Ammonia on Metallic Magnesium. By H. N. WARREN (*Chem. News*, **58**, 297—298).—When magnesium is exposed to ammonia at a temperature below a red heat, although undergoing no apparent change, it becomes less fusible, and burns when ignited with violent decrepitations. At a dull red heat, the metal becomes yellow, with golden lustre; whilst at full redness it is converted into an orange-yellow powder, which evolves ammonia when its acidified solution is treated with sodium hydroxide. D. A. L.

Action of Hydrogen Sulphide on Zinc Sulphate. By H. Baubigny (*Compt. rend.*, **107**, 1148—1150).—A neutral solution of zinc sulphate, containing not more than 0·3 gram of salt in 100 c.c., is completely precipitated by hydrogen sulphide in the cold after several hours. With twice the quantity of zinc sulphate in the same volume of liquid, precipitation is less perfect, 0·004—0·006 gram remaining in solution. After three days, however, only 0·001 gram remained unprecipitated.

If the solution of zinc sulphate contains free acid, the phenomena are similar to those observed with nickel and cobalt. With 0·3 gram of salt in 100 c.c., the quantity of free acid required to prevent precipitation is 30 times the amount of combined acid in the salt. At a higher temperature, and a correspondingly higher tension of the hydrogen sulphide, decomposition proceeds further, and at 100° the quantity of free acid required is 90 to 100 times the quantity of combined acid. The more concentrated the solution, the smaller the quantity of free acid that must be added for a given weight of zinc salt in order to prevent precipitation. The decomposition is a function, not only of the ratio of free acid to water, but also of the ratio of free acid to the metal present in the form of a salt, just as in the cases of nickel and cobalt. C. H. B.

Mixed Double Sulphates of the Copper-magnesium Group. By Prafulla Chandra Ray (*Proc. Roy. Soc. Edin.*, **127**, 267—283). The accounts given of the constitution of these salts being conflicting, a large number were prepared and analysed. Of the mass of details of which this paper consists, it is impossible to make an abstract. It must suffice to say that "double-double" sulphates of definite composition do exist, and that the chemical affinity which determines the formation of such compounds is not indeed very powerful, but its influence is unmistakable if proper care is taken to avoid conditions under which it is necessarily obscured. The author believes that Aston and Pickering are completely mistaken in their views of these salts, and that their error is due to their methods of working, which brought about the formation of heterogeneous deposits. E. W. P.

Action of Sodium Hydroxide on Mercurous Salts. By C. Barfoed (*J. pr. Chem.* [2], **38**, 441—472).—The author has investigated the composition of the precipitate produced by the action of sodium hydroxide on mercurous salts, by treating it with gold chloride. He concludes that it is not, as previously believed, a mixture of mercury and mercuric oxide, but a mixture of mercurous oxide, mercury, and mercuric oxide in varying proportions; it sometimes contains as much as 81 per cent. of mercurous oxide. The mercurous oxide is oxidised by the air at the ordinary temperature both in the light and in the dark. In a limited volume of air, the precipitate retains its dark colour, but otherwise it becomes yellow as the mercury evaporates. At 100° these changes are more rapid, and there is less yellow oxide left, because a part only of the mercurous oxide is oxidised, the rest being split up. The finely divided mercury in the precipitate undergoes no oxidation in the air at the ordinary temperature, and in a small space much less of the mercury evaporates than would be expected from its accepted vapour-tension.

The reduction of gold chloride by mercury vapour forms a very delicate test, and occurs even at $-8°$. A. G. B.

Ammoniacal Mercury Compounds. By C. RAMMELSBERG (*J. pr. Chem.* [2], **38**, 558—569).—The author regards the pale-yellow product of the action of ammonia on mercuric oxide at the ordinary temperature, as a hydrate of mercurammonium hydroxide, $NHg_2{\cdot}OH,H_2O$, for it loses 4·1 per cent. of water over strong sulphuric acid. Millon's base is obtained when the pale-yellow compound is treated with either hot or cold aqueous ammonia; Millon gave it the formula $2HgO,NH_3,H_2O$, and Gerresheim (Abstr., 1879, 438) the formula $2(2HgO,NH_3),H_2O$, but the author's analyses show that it is $3(2HgO,NH_3) + 2H_2O$. By treating either of these compounds with dilute hydrochloric acid, the insoluble pale-yellow chloride which Kane formulates as Hg_2OClNH_2 is obtained; it loses water at 200°, and is the hydrate of mercurammonium chloride, NHg_2Cl,H_2O.

True "white precipitate" is infusible, but the officinal preparation, made by precipitating ammoniacal mercuric chloride by an alkaline carbonate, is fusible. The latter can be obtained from the former by boiling it with ammonium chloride; moreover, amorphous mercuric oxide at once yields the fusible precipitate when boiled with ammonium chloride solution; again, when the infusible precipitate is boiled with alkali it loses $\frac{1}{2}$ of its nitrogen as ammonia, whilst the fusible precipitate loses $\frac{3}{4}$ of its nitrogen as ammonia under the same circumstances. It would thus seem that they are both double compounds of ammonium chloride with mercurammonium chloride, the infusible being NHg_2Cl,NH_4Cl, and the fusible, $NHg_2Cl,3NH_4Cl$.

The author has obtained a whole series of mercurammonium salts by the direct action of acids on Millon's base. Of these the sulphate, nitrate, carbonate, phosphate, bromate, iodate, and periodate are described. A. G. B.

Action of Concentrated Sulphuric Acid on Solutions of Iron and Aluminium Sulphates. By F. A. EREMIN (*J. Russ. Chem. Soc.*, 1888, **20**, 468—477).—The author finds that the addition of sulphuric acid to a solution of aluminium sulphate throws down the salt, but as ferrous sulphate, if present, is also thrown down along with it, both salts were investigated in this respect. For this purpose the lower end of a separating funnel was plugged with glass-wool, a known volume of ferrous sulphate solution poured in, and then concentrated sulphuric acid of 66° B. was added from a burette. After 24 hours, the liquid was drawn off from the crystals formed and the amount of iron present in the solution determined volumetrically. This result was corrected for the amount of ferrous sulphate in the liquid adhering to the walls of the vessel employed, a determination having been previously made for that purpose. The first series of experiments was made with a concentrated solution containing 21 grams of $FeSO_4,7H_2O$ in 50 c.c., and it was found that the largest quantity of salt, 99·18 per cent., is precipitated when the solution is mixed with an equal volume of sulphuric acid, and that the percentage of salt precipitated is less whether the proportion of acid is greater or less than this. By using ferrous sulphate solutions of various degrees of concentration, the author finds that the amount of salt precipitated increases with increasing concentration of its solution, the volume of sulphuric acid added remaining constant. As regards the composition of the precipitate, it corresponds with the formula $FeSO_4,H_2O$, as long as for 5 c.c. of the solution, 5. 10, or 15 c.c. of sulphuric acid is added. When, however, 20 c.c. is added slowly, a mixture of monohydrated sulphate with a greenish-white, crystalline substance is precipitated, but the latter alone is formed if the sulphuric acid is added at once. These crystals have a brilliant lustre and are highly iridescent; their formula is $FeSO_4,5H_2SO_4,5H_2O$, but they are very unstable. At 95—97° they are decomposed as follows: $FeSO_4,5H_2SO_4,5H_2O = FeSO_4,H_2O + 5H_2SO_4,4H_2O$.

Chemically pure aluminium sulphate, containing no iron, was dissolved in water and its solution treated with sulphuric acid in precisely the same manner, but a very different result was obtained. Scarcely any precipitate is produced on adding an equal volume of sulphuric acid to a nearly concentrated solution of the aluminium salt, and the addition of two volumes of sulphuric acid produces no precipitate at all. But smaller quantities of sulphuric acid, which are without action on ferrous sulphate, give an abundant precipitate with the aluminium salt, so that the maximum precipitate is obtained on adding 1·5 c.c. of H_2SO_4 to 5 c.c. of aluminium sulphate solution. The precipitate thrown down on mixing equal volumes of the aluminium sulphate solution and sulphuric acid has the composition $Al_2(SO_4)_3,2H_2SO_4,16H_2O$; with 5 c.c. of the solution and 0·3 c.c. of sulphuric acid, the precipitate has the formula $Al_2(SO_4)_3,22H_2O$. The different behaviour of ferrous and aluminium sulphates towards sulphuric acid cannot be used, however, for their separation or for the preparation of pure aluminium sulphate, because some iron is always carried down mechanically with the latter. The author proposes to investigate the sulphates of the metals of the Third Group from the same point of view. B. B.

Solution for Depositing Metallic Cobalt. By H. N. WARREN (*Chem. News*, **59**, 64).—A concentrated solution of Rochelle salt is added to a solution of cobalt chloride until the precipitate first formed is redissolved; from this solution, the metal is readily deposited on any desired object attached to the negative electrode of a single cell battery. Nickel may be deposited in a similar manner, and when the solution contains nickel as well as cobalt, both metals are deposited in equal proportions and the deposit is darker and more durable than when cobalt alone is used. Zinc and several other metals may be deposited in a similar manner. D. A. L.

Nickel and Cobalt. By G. KRÜSS and F. W. SCHMIDT (*Ber.*, **22**, 11—15).—In the course of experiments which were commenced with the object of determining the atomic weights of nickel and cobalt, it was found that it was impossible to precipitate an equivalent quantity of pure gold from a neutral solution of auric chloride by means of metallic nickel or cobalt, because small quantities of these metals are again precipitated from the solutions of the chlorides which are produced. The precipitated gold was therefore washed, dried, ignited, and weighed, and then dissolved in aqua regia and precipitated with sulphurous acid. The metal thus purified weighed considerably less than the original precipitate, and although this difference was taken into account the results of various experiments were very discordant. In washing the gold precipitated by sulphurous acid from a solution of the powder which had originally been precipitated by cobalt, it was noticed that the filtrate gradually lost the red colour due to cobalt chloride and turned faintly green; on evaporating this portion of the washings, the slight residue which was obtained dissolved in warm, concentrated hydrochloric acid with a green coloration, but the solution became almost colourless on cooling. The same phenomenon was observed in washing the gold which had been precipitated by sulphurous acid from solutions of the metal obtained in similar experiments with nickel, but the quantity of the new chloride obtained was extremely small.

Nickel sulphide, prepared from the ordinary sulphate, was repeatedly treated with ammonium sulphide until the latter was no longer coloured brown; a bright-yellow residue was obtained and the relative quantity of the new substance present in this residue was far more than in the original sulphide. The chloride of this substance was also obtained from the mother-liquors of solutions containing equivalent quantities of mercuric chloride and nickel or cobaltous chloride, and by several other methods.

The pure oxide of this metal was obtained by making use of the fact that it is soluble in melted alkalis, nickel and cobalt oxides being insoluble.

Hydrogen sulphide produces no precipitate in acid solutions, but ammonium sulphide gives a blackish precipitate in neutral solutions of the chloride. Ammonia produces a white, very voluminous, flocculent precipitate in neutral solutions, and the precipitate is insoluble in excess of the reagent; potash also precipitates a white hydroxide insoluble in excess. When the oxide is moistened with cobalt solution, and heated, it becomes slightly brown; after having been strongly heated alone for a long time it is readily and completely soluble in cold, concentrated hydrochloric acid. Strongly acid solutions of the chloride have a peculiar greenish-yellow colour, but in the dry state, and when free from acid, the salt is white and dissolves in water, forming a colourless solution. When the vapour of hydrochloric acid is blown on to the white chloride, it turns greenish and then dissolves in water, forming a coloured solution. The oxide does not lose weight when heated in an atmosphere of hydrogen.

The metal can be obtained by the electrolysis of an aqueous solution of the chloride, or by heating the dry chloride in a stream of hydrogen.

It is black, but brownish-black in thin layers; it is readily soluble in acids when obtained by electrolysis in the cold, but when strongly heated in a stream of hydrogen it becomes much more sparingly soluble. F. S. K.

Interaction of Chromic Acid and Hydrogen Peroxide. By BERTHELOT (*Compt. rend.*, **108**, 24—31).—The blue compound to which Moissan (Abstr., 1884, 20) ascribes the formula CrO_3,H_2O_2, more probably has the composition $2HCrO_4,H_2O_2$. Both formulæ represent the same amount of available oxygen. The blue colour of the compound recalls the colour of permanganic acid, and the fact that it can be formed even in very dilute solutions distinguishes it from the ordinary compounds of hydrogen peroxide with acids, alkalis, &c.

When hydrogen peroxide reacts with permanganic acid, the action is reciprocal, and the volume of oxygen evolved is the same whether the peroxide is added to the permanganic acid, or *vice versâ*, a fact which indicates the formation of an intermediate compound. This is colourless and stable at a very low temperature. It probably has the composition H_2O_3, and decomposes into water and oxygen if the temperature rises.

With hydrogen peroxide and chromic acid, the phenomena are not quite similar, and the result varies with the mode of admixture, the temperature, and the concentration. When a very dilute solution of potassium dichromate acidified with hydrochloric acid is mixed with hydrogen peroxide, the ratio between the oxygen lost by the dichromate and that lost by the peroxide is 1 : 1·1, and the result is the same, whether the liquids are mixed gradually or rapidly. The difference is due to the intermediate formation of perchromic acid, and almost disappears in more dilute solutions.

If, on the other hand, with the same degree of concentration, the dichromate solution is added to the peroxide, the reaction takes place very slowly, and the end-point is very difficult to determine. The ratio between the oxygen evolved from the dichromate and that evolved from the peroxide is 1 : 1·52—1·63. With hydrogen peroxide containing barium chloride, the ratio obtained was 1 : 1·6. The formation of the intermediate compound could not, however, be detected in the calorimeter, the change taking place too rapidly. It is evident that the action of the peroxide on the chromic acid is not reciprocal, and it follows that in making titrations with these solutions (this vol., p. 311), the manner in which the liquids are mixed will influence the result.

The action of excess of chromic acid on hydrogen peroxide develops +45·6 Cals. for CrO_3. In presence of excess of the peroxide, the stability of the perchromic acid is greater, owing to the formation of the blue compound. The first stage of the reaction is represented by the equation $2CrO_3 + H_2O_2 = 2HCrO_4$, and the perchromic acid then interacts with a further quantity of the peroxide. Under the conditions described above, the reaction $2HCrO_4 + 4H_2O_2 + 6HCl = Cr_2Cl_6$ dil. $+ 4O_2 + 8H_2O$ develops +67·2 × 2. According to this

When brown ruthenic chloride is treated with so-called hyponitric acid, it is gradually converted into a non-crystallisable, violet-red liquid, which when mixed with alkaline chlorides yields the compounds just referred to. The reaction takes place only at a temperature at which the hyponitrous acid splits up into nitric acid and nitric oxide, and as a matter of fact the same product is obtained if ruthenic chloride is heated in nitric oxide. The salts are readily obtained by adding an alkaline nitrite to a warm solution of ruthenic chloride in hydrochloric acid.

If a mixture of ruthenium with potassium or sodium chloride is heated in chlorine gas, no rutheniochlorides are formed, and ruthenic chloride is the only product. It follows from these results that no true rutheniochlorides have yet been obtained, the salts described as such being really nitrosochlorides. Potassium chlorate, which removes all the metal from ruthenic chloride in the form of peroxide, has no action on the nitrosochlorides.

From analyses of these and other ruthenium compounds, the author is led to the conclusion that the atomic weight of ruthenium is 101·5. Debray's determination of the sp. gr. of gaseous ruthenium peroxide indicated that the atomic weight was less than 102. No details of the estimations are given. C. H. B.

Mineralogical Chemistry.

Fossil Resins from the Coal Measures. By W. I. Macadam (*Chem. News*, 59, 1—2).—The author has examined two samples of brown, resinous scales found in coals from the neighbourhood of Kilmarnock, and two samples obtained from the Chemise seam of the Methil district. These were treated first with ether, then with chloroform, and the respective resins analysed with the following results:—

	Kilmarnock coal, soluble in		Chemise seam coal, soluble in	
	Ether.	Chloroform.	Ether.	Chloroform.
Carbon	84·28	74·28	57·50	66·70
Hydrogen	9·36	6·52	7·53	7·32
Oxygen	6·36	19·20	34·97	25·98

The composition of the Kilmarnock resins approaches that of schlanite and anthracoxenite respectively. Attention is drawn to the fact that the resin soluble in ether is partially volatile much below 100°, probably due to its complex character or to decomposition; it is suggested that the gases obtained by Bedson from coals, probably arise from the decomposition of the resins in this manner. D. A. L.

Action of Cuprous Chloride on Potassium-iron Sulphide; Artificial Copper Pyrites. By R. SCHNEIDER (*J. pr. Chem.* [2], **38**, 569—582).—By shaking a faintly ammoniacal solution of cuprous chloride (equivalent to 0·455 gram of cuprous oxide) with potassium-iron sulphide, K_2S,Fe_2S_3 (1 gram), until the solution no longer contains copper, crystals are obtained which have the empirical formula $CuFeS_2$; but the quantity of the compound thus obtained and of the potassium chloride formed show that the formula of this sulphide is $Cu_2S.Fe_2S_3$, the equation for the reaction being $K_2S,Fe_2S_3 + Cu_2Cl_2 = 2KCl + Cu_2S,Fe_2S_3$.

These crystals behave almost identically with copper pyrites, and thus confirm the formula Cu_2S,Fe_2S_3 for copper pyrites, a view already adopted by the majority of chemists. A. G. B.

Artificial Production of Chromite. By S. MEUNIER (*Compt. rend.*, **107**, 1153—1154).—An intimate mixture of 148 grams of potassium dichromate, 58 grams of precipitated ferrous carbonate, and 56 grams of iron filings was heated to a very high temperature in a clay crucible for several hours. The following reaction takes place:— $FeCO_3 + 2Fe + K_2Cr_2O_7 = FeO,Cr_2O_3 + Fe_2O_3 + K_2CO_3$, and when the cooled product is treated first with water and then with concentrated acids, the chromite is left as a black, non-magnetic, granular residue. If the crucible is brasqued with a small quantity of cryolite, and the mixture is covered with a thin layer of the same mineral, the product shows distinct crystalline zones, one of which consists of specular hematite. The chromite is obtained in small octahedra, cubo-octahedra, and cubes. A small quantity of ferric chromate and of a double chromate of iron and potassium seems to be formed at the same time, and some lamellæ of chromic oxide are also observed. Similar results are obtained when powdered siderite is substituted for the precipitated ferrous carbonate. C. H. B.

Edisonite, a Fourth Form of Titanic Anhydride. By W. E. HIDDEN (*Amer. J. Sci.*, **36**, 272—274).—The original specimen of the mineral here described was discovered by the author in 1879 at the Whistnant gold mine, Polk Co., North Carolina. It was found in the concentrations of placer washings. The orthorhombic character of the mineral was easily proved with the hand-goniometer. The mineral has six cleavage planes, a hardness of 6, sp. gr. 4·26, resinous to adamantine lustre, bronze-yellow to golden-brown colour, and yellowish-white streak. It is insoluble in acids, unchanged before the blowpipe with sodium carbonate, but with borax gives a brownish bead. The axial ratio calculated by Des Cloizeaux is $\breve{a} : \bar{b} : c = 0·99275 : 1 : 0·92337$. On analysis, only titanic anhydride could be found. An analysis by S. L. Penfield has confirmed this conclusion. Owing to the scarcity of material, an equal weight of rutile was analysed by the same method as a check. The results were as follows:—

	Rutile.	Edisonite.
TiO_2 precipitated by boiling	0·0756	0·0744
Trace of oxide from the filtrate	0·0022	0·0033
Loss on ignition	0·0002	0·0001
Totals..................	0·0780	0·0778
Weight of mineral taken	0·0780	0·0770

These results show that edisonite is a nearly pure titanic anhydride like rutile. The author thinks he has recently identified this mineral on the Pilot Mountain, Burke Co., North Carolina, and proposes for it the name of edisonite, after T. A. Edison. B. H. B.

Artificial Production of Zircon. By P. HAUTEFEUILLE and A. PERREY (*Compt. rend.*, **107**, 1000—1001).—Zircon was obtained by Deville and Claron by the action of zirconium fluoride on silica, or of silicon fluoride on zirconia, at a very high temperature. It can, however, be prepared at a temperature which need not exceed 700° by heating 11·88 grams of zirconia with 5·84 grams of silica and 100 grams of lithium bimolybdate. The same crystals are obtained at all temperatures between 700° and 1000°; they are hyaline, quadratic prisms with a brilliant lustre; sp. gr. = 4·6. If zirconia is in excess, the crystals are long: if silica is in excess, they are short.

Levy and Bourgeois used sodium carbonate at a very high temperature as a reagent for the detection of zirconium, zirconia being obtained in hexagonal prisms. With lithium molybdate and silica, easily recognisable crystals of zircon are obtained in a few hours at a temperature not necessarily exceeding 700°. C. H. B.

Beryllonite, a New Mineral. By E. S. DANA (*Amer. J. Sci.*, **36**, 290—291).—The author gives a preliminary notice of a new mineral, the locality of which is withheld for the present. The crystals belong to the orthorhombic system, the approximate axial ratio being $a : b : c = 0·57 : 1 : 0·94$. The mineral is white to colourless, transparent to translucent, and has a hardness of 5·5 to 6, sp. gr. 2·84, conchoidal fracture, and vitreous lustre. A preliminary analysis has shown the mineral to be an anhydrous phosphate of beryllium and sodium. B. H. B.

Xenotime. By W. E. HIDDEN (*Amer. J. Sci.*, **36**, 380—383).—The author describes crystals of xenotime found in the vicinity of 155th Street and 11th Avenue, New York City, in a coarse pegmatite vein; in some concentrations of vein material at Milholland's Mill, Alexander Co., North Carolina, and at Dysartsville, McDowell Co., North Carolina. He also describes xenotime-zircon from a new locality, namely, the Davis Land, Henderson Co., North Carolina. Of the 17 crystals of xenotime found at this locality, seven had zircons enclosed in parallel position. These symmetrically-compounded crystals of zircon and xenotime were first noticed by Zschau on specimens from Hitterö, Norway. Similar crystals have been found by the author at the Mills' gold mine, Burke Co., North Carolina, and at Deake tin mine, Mitchell Co., North Carolina. B. H. B.

Mineralogical Notes. By S. L. PENFIELD and E. S. SPERRY (*Amer. J. Sci.*, **36**, 317—331).—1. *Beryl.*—In order to prove the correctness of the assumption formerly made by the authors, that the alkalis, when present, replace the beryllium, analyses have been made of (I) the cæsium beryl from Norway, Maine; (II) a transparent yellow beryl, known as golden beryl, from Litchfield Co., Connecticut; and (III) a transparent, glassy variety from Willimantic, Connecticut, with very unusual crystalline habit. The results were as follows:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	BeO.	Cs_2O.	K_2O.
I.	64·12	17·89	—	0·16	—	12·13	1·61	0·10
II.	65·62	17·86	0·37	0·18	—	13·50	0·03	—
III.	65·72	18·40	—	0·26	0·12	13·08	—	0·12

	Na_2O.	Li_2O.	Ignition.	Total.	Sp. gr.
I.	1·21	0·75	2·24	100·21	2·747
II.	0·54	0·10	2·34	100·54	2·716
III.	0·75	0·28	2·06	100·79	2·725

The results of analysis I afford the necessary proof of the correctness of the assumption that the alkalis in beryl are isomorphous with the BeO.

2. *Phenacite.*—Analysis of colourless phenacite from Topaz Butte, Pike's Peak region, Colorado, gave—

SiO_2.	BeO.	Na_2O.	Li_2O.	Ignition.	Total.
54·44	45·58	0·21	trace	0·26	100·49

3. *Monazite.*—Crystals of this mineral from a locality 3 miles east of the Emerald and Hiddenite mine, Alexander Co., North Carolina, gave, on analysis, the following results:—

P_2O_5.	Ce_2O_3.	$(LaDi)_2O_3$.	ThO_2.	SiO_2.	Ignition.	Total.	Sp. gr.
29·32	37·26	31·60	1·48	0·32	0·17	100·15	5·203

In opposition to the views of C. W. Blomstrand (this vol., p. 217), the authors do not regard the ThO_2 as an essential constituent of monazite, as it occurs in varying proportions, although almost always present in the different varieties.

4. *Sussexite.*—A new analysis of this rare mineral from Maine Hill, Franklin, New Jersey, fully substantiates the formula $H(Mn,Mg,Zn)BO_3$, determined by G. J. Brush, who first described the mineral.

The authors also describe (5) twin crystals of quartz with inclined axes, said to be from Madagascar, and give long descriptions and analyses of (6) oligoclase from Bakersville, North Carolina, with abnormal optical properties; (7) barium felspar from Blue Hill, Delaware Co., Pennsylvania; and (8) a very pure magnesia mica, phlogopite, from Edwards, St. Lawrence Co., New York.

B. H. B.

Ferric Orthoclase. By P. HAUTEFEUILLE and A. PERREY (*Compt. rend.*, **107**, 1150—1152).—A mixture of 78 parts of normal potassium vanadate and 10 parts of potassium nitrate is fused at 700°, and a mixture of 18 parts of silica and 8 parts of ferric oxide is gradually added and well mixed by means of a platinum wire. Mineralisation is very soon complete, and the first product is a ferric leucite, but if the mixture is kept at 700° for about a month, crystals separate in the fused mass. After cooling, the product is extracted with water and the residue is treated with cold concentrated potash. Ferric orthoclase, $K_2O,Fe_2O_3,6SiO_2$, is thus obtained in monoclinic prisms, frequently macled in the same way as orthoclase, and with the same optical properties. They show the faces p, m, g', a', $a^{\frac{1}{2}}$, $o^{\frac{1}{2}}$, $b^{\frac{1}{2}}$, the angles m/m 118° 58′ and p/m 112° 44′, being practically identical with those of orthoclase. Some ferric microcline seems to be formed at the same time.

C. H. B.

Geology of the District of Ričan. By F. KATZER (*Chem. Centr.*, 1888, 1493, from *Jahrb. geol. Reichsanst. Wien.*, **38**, 355—415).—The district of Ričan, south-east of Prague, consists of granite and clay-slate of the Cambrian formation. The granite, principally porphyritic, contains partly white, partly red orthoclase crystals (containing calcium) 8—10 cm. long, with biotite, and a little plagioclase and accessory apatite, tourmaline and titanite. As the clay formation nears the granite, it becomes harder and more crystalline, whilst, on the other hand, the granite near the juncture with the clay becomes more porphyritic. Close to the granite is a massive layer of chert. This is rich in quartz with liquid inclusions. The following analyses are given by the author:—

	Normal clay-slate.	Blackened slate.	Chert.
SiO_2	54·97	61·35	84·19
H_2O	4·22	3·07	1·70

The author subdivides the strata as follows:—(*a.*) Contact zone, containing little mica and no tourmaline; (*b*) granitic pegmatite, rich in tourmaline; (*c*) porphyritic granite, containing biotite, felspar, and granitic tourmaline. The latter is 100 m. thick in places; the pegmatite is regular, and measures 6 metres throughout. The following further analyses were made:—(1.) Biotitic granite, 8 cm. from the juncture; (2) tourmalinic pegmatite, 3 metres from the contact; (3) normal granite of Zeruovka.

	SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	CaO.	MgO.	K_2O.	Na_2O.	B_2O_3.	H_2O.
I.	74·29	15·95		trace	0·78	0·66	5·31	2·66	—	0·66
II.	75·27	12·92	1·89	0·29	0·32	0·47	6·48	1·14	1·24	0·61
III.	71·13	18·53		trace	0·96	0·58	7·26		—	0·74

J. W. L.

Two New Masses of Meteoric Iron. By G. F. KUNZ (*Amer. J. Sci.*, **36**, 275–277).—1. A mass of meteoric iron was found in 1882 on Linville Mountain, Burke Co., North Carolina. The meteorite weighs 428 grams, the original weight having been 442 grams. It is 2⅗ inches long, 1⅗ inch high, and 2½ inches wide. One side is rather rough, and the other covered with very shallow pittings. Traces of the black crust of magnetic oxide are still visible. The iron admits of a very high polish, and, under the glass and by reflected light, appears to be a network of two distinct bodies. On analysis, it gave the following results:—

Fe.	Ni.	Co.	S.	C.	P.	Total.
84·56	14·95	0·33	0·12	trace	trace	99·96

It most closely resembles the Tazewell (Claiborne Co.) and Bear Creek meteorites in composition.

2. In 1887, a mass of meteoric iron was found in the Silver Crown district, Laramie Co., Wyoming. When found, it was half buried in decomposed granite and earth. In shape, it somewhat resembles an anvil. It weighs 25·61 lbs. The surface is still covered with the original crust of magnetic oxide, and is irregularly pitted. This iron belongs to the braunite group of Meunier. Analysis gave the following results:—

Fe.	Ni.	Co.	P.	C.	Total.	Sp. gr.
91·57	8·31	trace	0·07	trace	99·95	7·63

In composition it most closely resembles the Rowton, Charlotte, and Jewel Hill meteorites. B. H. B.

Meteorite from Ochansk. By TICHONRAVOFF, PETROFF, and others (*J. Russ. Chem. Soc.*, 1888, **20**, 513—518).—This meteorite, together with other smaller ones, fell on April 18 (old style), 1887, near Tabory, Ochansk, in the Government of Perm. Its original weight was about 120 lbs., and it was found in a very hot state about 2 yards in the ground. The meteorite was covered with a black, glistening crust, and its mass was ash-grey; structure crystalline. It dissolves in hydrochloric acid with evolution of hydrogen and hydrogen sulphide, owing to the presence of free nickel-iron and troïlite (magnetic pyrites). The glistening black grains were found to be meteoric iron, containing Fe = 79·10—74·19, Ni 20·9—25·81 per cent.

It contains only 0·05 per cent. phosphorus, probably in the form of schriebersite (Fe_4Ni_2P). Its percentage in the meteorite varies from 20·54 to 25·02 per cent., owing to the non-homogeneity of the mass of the meteorite. The mean composition of the meteorite, according to four analyses, is—

SiO_2.	FeO.	MgO.	CaO.	Fe.	Ni.	S.
37·36	13·80	18·54	3·00	19·80	5·55	2·30

P.	C amorphous.	Cu + Sn.	Mn, Co, Na.
0·05	0·08	0·52	traces

Assuming that all the sulphur is present as Fe_7S_8, the amount would be 8·17 per cent., and that of the FeO only 7·41 per cent.

The Chemical Composition of the Water composing the Clyde Sea Area. By A. DICKIE (*Proc. Roy. Soc. Edin.*, **127**, 283—286).

Organic Chemistry.

Action of Mercuric Cyanide on Cupric Salts. By R. VARET (*Compt. rend.*, **107**, 1001—1002).—When an aqueous solution of mercuric cyanide is boiled with an equivalent quantity of any oxy-salt of copper, no cyanogen is evolved, and no cuprous cyanide is precipitated. Double salts are formed, and crystallise on cooling.

If a concentrated solution of mercuric cyanide is mixed with half the equivalent quantity of cupric chloride below 25°, and the saturated solution is cooled in a freezing mixture, it very slowly deposits small, transparent, blue needles, of the composition

$$2HgCy_2,CuCl_2 + 6H_2O.$$

They are very deliquescent, and dissolve readily in water and ammonia solution. Above 30° the mixture of mercuric cyanide and cupric chloride evolves cyanogen, and, if the solution is dilute, cuprous cyanide is precipitated, but if it is concentrated, a double cyanide of copper and mercury is obtained.

A concentrated solution of mercuric cyanide and cupric chloride in equivalent proportions deposits hard, green, efflorescent crystals of the compound $HgCy_2,CuCl_2 + 6H_2O$, less soluble in water than the preceding compound, but readily soluble in ammonia. At 35°, the solution evolves cyanogen, and yields a precipitate of the composition $Cu_2Cy_2,CuCy_2 + H_2O$, which at a higher temperature is converted into cuprous cyanide.

Hot solutions of haloïd cupric salts are decomposed by mercuric cyanide, with evolution of cyanogen, and formation of compounds of mercuric salts and cuprous cyanide which will be described subsequently. The same compounds are obtained without evolution of cyanogen, by the direct action of mercuric salts on cuprous cyanide.

C. H. B.

A New Potassium Iron Cyanogen Compound. By F. MAHLA (*Ber.*, **22**, 111—114).—When a cold, aqueous extract of the substance (?) used in the purification of gas is fractionally precipitated with ferric chloride, a dark-violet substance is at last obtained, which differs from Prussian blue in many of its properties. It is decomposed by alkalis with separation of ferric hydroxide, and on adding acid to the yellow solution, the substance again separates as a splendid violet precipitate, and when the solution is not too dilute, the whole solidifies to a gelatinous mass. The *potassium salt*, which is prepared by treating the well-washed violet precipitate with potash free from chloride, keeping the solution neutral, crystallises in indistinct, bright-yellow, tabular crystals, resembling potassium ferrocyanide; it is almost insoluble in ether, very sparingly soluble in alcohol. The crystals contain water of crystallisation, the whole of which cannot be removed without decomposition of the salt. Dilute sulphuric acid decomposes it with evolution of hydrogen cyanide; when heated with strong sulphuric acid, it is converted into ammonium sulphate and carbon monoxide. The aqueous solution yields with ferric chloride a violet, with copper salts a parrot-green, and with silver salts, stannous chloride, lead acetate and mercuric chloride white precipitates. Analyses of the potassium salt pointed to the formula $K_2\!:\!C_3N_3\cdot Fe\cdot C_2N_2\cdot K$.

In determining the carbon in the potassium salt, the substance was mixed with alumina, which combines with potash, so that the whole of the carbonic anhydride passes off. N. H. M.

New Method of Obtaining Cyanethine and Similar Bases. By E. v. MEYER (*J. pr. Chem.* [2], **38**, 584).—Ethyl cyanide is heated with dry sodium ethoxide in a tube at 140°, and the product treated with water; the ethyl cyanide is thereby mostly converted into cyanethine. The subject is under investigation. A. G. B.

Action of Alcoholic Potash on Allylene. By A. FAVORSKY (*J. Russ. Chem. Soc.*, 1888, **20**, 518—523).—In previous papers (Abstr., 1888, 798 and 1168), the author has shown that monosubstituted acetylenes when acted on by alcoholic solution of the alkalis are converted into disubstituted acetylenes or non-symmetrical allenes. It was, however, impossible to prove the existence of intermediate mixed tertiary ethers of the general formula $CHR\!:\!C(OEt)\cdot CH_3$ or $R_2CH\cdot C(OEt)\!:\!CH_2$. In this respect it was interesting to investigate allylene as the simplest of the monosubstituted acetylenes. Allylene was prepared by the action of alcoholic potash on propylene bromide, using a reflux condenser, and the gas absorbed in ice-cold absolute alcohol. The saturated solution was then heated in sealed tubes with solid potash for 12 hours at 170—180°. On opening the tubes, much of the allylene was found to be unchanged, and on addition of water, an oily layer separated, which was found to distil between 62° and 63°. Its sp. gr. is 0·790 at 0° and 0·769 at 20°. It consisted of ethyl isopropenyl ether, $CH_3\cdot C(OEt)\!:\!CH_2$. The same compound is obtained directly by the action of alcoholic potash on propylene bromide at 170—180°. When treated with concentrated hydriodic acid, it is completely resinified. With sulphuric acid of 2, or better, of 1 per cent., the ether even at the ordinary temperature yields acetone and ethyl alcohol. By this behaviour it is distinguished from ethyl allyl ether (b. p. 62·5°), which with hydriodic acid yields ethyl and allyl iodides (Oppenheim), and with sulphuric acid of 2 per cent. ethyl and allyl alcohols (Eltekoff). The ether is formed by the direct addition of allylene and alcohol, and represents an intermediate product, as was expected by the author. The intermediate product was not isolated in other cases quoted above, as the temperature (130—140°) was sufficient for the decomposition of the analogous compounds produced. Further investigations will show whether the tertiary ethyl isopropyl ether is stable, and whether, like its homologues, it decomposes into alcohol and allene. B. B.

Butines. By L. M. NORTON and A. A. NOYES (*Amer. Chem. J.*, **10**, 430—433).—The fourth possible butine, *methylisoallylene*, $CH_3\cdot CH\dot{:}C\dot{:}CH_2$, is prepared from butyric chloral, itself prepared from croton chloral hydrate. The butyric chloral, $CH_3\cdot CHCl\cdot CCl_2\cdot CHO$, was treated in the cold with zinc ethyl, and the product when decomposed by dilute acid gave trichlorobutyl alcohol, which by heating with phosphorus pentachloride yields methylisoallylene tetrachloride, $CH_3\cdot CHCl\cdot CCl_2\cdot CH_2Cl$, and also $\alpha\alpha\beta$-trichlorbutyl phosphate, a substance crystallising from alcohol and melting at 85·3°. The former substance, when treated in alcoholic solution with the copper-zinc couple, yields methylisoallylene, a colourless liquid boiling at 18—19°; it does not precipitate an ammoniacal cuprous solution, and with bromine yields first a dibromide and then a tetrabromide, both being liquids. H. B.

Heptine from Perseitol. By MAQUENNE (*Compt. rend.*, **108**, 101—103).—The heptine obtained from perseitol by the action of hydriodic acid (this vol., p. 32) is attacked by sulphuric acid even at 0°, when it becomes brown, and is partially converted into a polymeride, $C_{14}H_{24}$, and partially into a resin which gives a green solution with alcohol. Concentrated hydriodic acid at the ordinary temperature yields a crystallisable hydriodide, $C_7H_{13}I$, which can be distilled in a vacuum, and yields the original hydrocarbon on treatment with potash; at 150° it is converted into complex polymerides. Chlorine acts destructively on the hydrocarbon, and bromine acts violently in the cold with formation of a dibromide, $C_7H_{12}Br_2$, which soon decomposes and becomes green. Mercuric chloride is slowly attacked with formation of a rose-grey precipitate changing to black, but ammoniacal silver and cuprous solutions are not affected. Nitric acid acts violently, and produces resinous products and acetic and butyric acids. When exposed to air, the hydrocarbon oxidises, and in 10 days will absorb 100 times its volume of oxygen. If the product is distilled, it yields a hydrate, $C_7H_{14}O_2$, which crystallises from water in long, white, seemingly quadratic needles. The same product is obtained by allowing the hydrocarbon to remain in contact with a small quantity of water in a loosely corked flask.

The heptine obtained from perseitol is identical with that obtained by Renard (*Ann. Chem. Phys.* [6], 1, 223) and by Morris from resin (Trans., 1882, 174). With concentrated hydrochloric acid at 150°, both products yield a crystalline hydrochloride, $C_7H_{13}Cl$, which boils at 55° in a vacuum, and yields the original heptine when treated with potash, alcoholic ammonia, acetates, or zinc ethyl. It is at once coloured by bromine, but can only be attacked by substitution.

The properties of this heptine indicate that it has a closed chain nucleus, and is not methylpropylallylene, as supposed by Morris.

The tendency to oxidise, form a hydrate, and polymerise indicates that it is related to the terpenes, whilst the formation of green compounds on oxidation points to a relationship with furfuran. It would seem, therefore, that heptine from perseitol is a non-saturated hydrocarbon with a tetramethylene nucleus. The relation between this heptine and the terpenes, and the fact that it is obtained both from resin and from perseitol, seems to point to a connection between the sugars and the resins. C. H. B.

Diisocrotyl and several of its Derivatives. By S. PŘIBYTEK (*J. Russ. Chem. Soc.*, 1888, **20**, 506—512).—*Diisocrotyl*, a hydrocarbon, C_8H_{14}, of the diallyl series, is obtained by the action of sodium on isocrotyl bromide, $CMe_2{:}CHBr$, in the following manner. Isobutylene is converted into its dibromide, and this, on treatment with alcoholic potash, yields isocrotyl bromide (b. p. 91—96°); the latter is poured on to metallic sodium covered with a layer of ether and contained in tubes, but as a violent reaction takes place after the lapse of 15—20 minutes, the tubes have to be carefully cooled before sealing up. The sealed tubes are then placed for five days in water of the ordinary temperature, and are afterwards exposed to the temperature of 30—40° for 10 days, until no further diminution of volume (amounting to one-fifth of the whole liquid) is found to take place. On opening the tubes, a gas, consisting chiefly of isobutylene, escapes under great pressure. After separating the sodium and sodium bromide by filtration, and the ether by distillation, the liquid product of the reaction boils between 120° and 150°, leaving a resinous mass containing sodium. It is difficult to obtain a product of constant boiling point, as the hydrocarbon shows an inclination to polymerisation; so that on repeating the distillation several times, the boiling point becomes lower, and after a lapse of some time it again becomes higher. The same is the case as regards the melting point. The freshly distilled hydrocarbon boils at 125—130°, solidifies at 0°, and the crystals melt at 4° to 5°, but after several months the melting point becomes 12° to 22°. The hydrocarbon absorbs oxygen very eagerly; 1 c.c. was found to absorb 17·7 c.c. of oxygen over mercury. The molecular formula is C_8H_{14}, sp. gr. = 0·7726 at 18°. By treating it with bromine, a liquid tetrabromide, $C_8H_{18}Br_4$, was obtained. From this, as well as from the formation of an oxychlorhydrin by the addition of hypochlorous acid and oxygen, the structure $CMe_2{:}CH{\cdot}CH{:}CMe_2$ is derived.

The chlorhydrin, $C_8H_{14}OCl{\cdot}OH$, is a colourless liquid, soluble in ether; the solution in ether, on treatment with dry potassium hydroxide, yields the impure dioxide, $C_8H_{14}O_2$, and this with water forms a crystalline tetrahydroxide, $C_8H_{14}(OH)_4$—the erythrol of the octyl series. The same erythrol was obtained on heating the diisocrotyl chlorhydrin with water and lead oxide at 100° in sealed tubes. Its melting point is 152—154°. B. B

Action of Iodine, Iodoform, and Methylene Iodide on Sodium Ethoxide and that of Iodine on Ethyl Sodium Carbamate. By E. Mulder (*Rec. Trav. Chim.*, **7**, 310—333).—The action of iodine on sodium ethoxide was studied by Butlerow, who found, as chief products, iodoform and methylene iodide. The author has further investigated the nature of the reaction, and finds that it may be represented by the following stages:—(A) $C_2H_5{\cdot}ONa + I_2 = C_2H_5{\cdot}OI + NaI$; (B) $C_2H_5{\cdot}OI = CH_3{\cdot}COH + HI$; (C) $C_2H_5{\cdot}ONa + HI = C_2H_5{\cdot}OH + NaI$; (D) $CH_3{\cdot}COH + 3C_2H_5{\cdot}OI = CI_3{\cdot}COH + 3C_2H_5{\cdot}OH$. The iodal is then decomposed by the sodium ethoxide with formation of iodoform and ethyl formate. By the action of iodoform on sodium ethoxide, methylene iodide and other secondary products are produced. Methylene iodide has no appreciable action on sodium ethoxide at the ordinary temperature.

The products of the reaction of iodine with ethyl sodium carbamate are found to be iodoform and urethane. The iodoform has no further action in alcoholic solution, and secondary products are therefore not produced.

It is found that iodoform is dissolved by hydriodic acid in appreciable quantity in alcoholic, but not in aqueous solution. The maximum amount of iodoform is obtained from sodium ethoxide with $1\frac{3}{10}$ mol. I to 1 mol. of the ethoxide. H. C.

Action of Methyl Iodide on Sodium Arsenite. By H. Klinger and A. Kreutz (*Annalen*, **249**, 147—155).—The authors confirm the accuracy of G. Meyer's statement (Abstr., 1883, 1078) that the products of the action of methyl iodide on sodium arsenite are sodium iodide and sodium methyl arsenate. *Methylarsendisulphide*, $AsMeS_2$, is obtained by passing hydrogen sulphide through the hot acid solution of the sodium salt. It is a thick, gum-like mass having a disagreeable smell, and is decomposed by heat into methyl sulphide and arsenic sulphide. Nitric acid oxidises it to methylarsenic acid, and sulphur is liberated. W. C. W.

Ethyl Fluoride. By H. Moissan (*Compt. rend.*, **107**, 992—994).—When dry ethyl fluoride is heated to dull redness in a glass bulb for several hours, it yields a complex mixture of hydrocarbons containing only traces of silicon fluoride. A feeble induction spark causes considerable expansion, and the products are hydrogen fluoride, ethylene, and a small quantity of acetylene, but no free carbon. Strong induction sparks produce a deposit of free carbon and a gaseous mixture of acetylene, ethylene, propylene, &c. If the ethyl fluoride is passed slowly through a platinum tube heated to dull redness, it yields hydrogen fluoride, and hydrocarbons which are partly soluble in concentrated sulphuric acid, whilst those not absorbed by the acid are partly absorbed by bromine-water. Inside the tube there is a deposit of a small quantity of carbon, readily soluble in nitric acid and potassium chlorate.

Inhalation of ethyl fluoride by a guinea-pig, produces at first a period of excitement, but this is soon followed by death.

The fluoride was analysed by burning it in a metal tube by means of a mixture of cupric oxide and lead oxide. Dry ethyl fluoride does not attack glass, but it dissolves in concentrated sulphuric acid, and this solution acts on the glass with formation of an equivalent quantity of silicon fluoride. The latter is insoluble in sulphuric acid, and measurement of its volume determines the quantity of fluorine in the original compound. The results agree with the formula C_2H_5F.

C. H. B.

Methyl and Isobutyl Fluorides. By H. MOISSAN and M. MESLANS (*Compt. rend.*, **107**, 1155—1157).—Dumas and Peligot obtained methyl fluoride by the action of methyl hydrogen sulphate on potassium fluoride, but the authors find that the product of this reaction is a mixture of methyl fluoride and methyl oxide, which can be separated by their difference in solubility. Better results are obtained by the action of methyl iodide on silver fluoride, the gas being passed through a lead tube cooled at —50°, and over silver fluoride heated at 90°. Methyl fluoride is not formed by the action of phosphorus pentafluoride or hydrofluoric acid on methyl hydroxide. The properties of the compound agree with the description given by Dumas and Peligot. Its sp. gr. is 1·22 (calc. 1·19), it liquefies under 30 atmos. at the ordinary temperature, and is only slightly soluble in water, but more soluble in methyl alcohol and methyl iodide. It is very stable, and is only very slowly saponified by water or dilute potash in sealed tubes at 120°. (Compare Collie, Trans., 1889, 110.)

Isobutyl fluoride is obtained in a similar manner; it is a liquid which boils at 16° under atmospheric pressure. The gas burns with a very smoky flame with formation of hydrogen fluoride. When dry, it does not attack glass; it is very soluble in alcohols and ethers; sp. gr. at 21° = 2·58 (calc. 2·66). Below 16°, it condenses to a colourless, very mobile liquid, which has not a pleasant odour, does not attack glass if quite dry, and dissolves small quantities of sulphur and phosphorus, and considerable quantities of iodine and bromine.

All these fluorine-derivatives are more stable than the corresponding chlorine-derivatives, and boil at a lower temperature.

C. H. B.

Isobutyl Nitrite. By W. R. DUNSTAN and E. J. WOOLEY (*Pharm. J. Trans.* [3], **19**, 487).—Isobutyl nitrite was prepared by gradually mixing isobutyl alcohol with sulphuric acid; when cold, the mixture was poured, in small quantities at a time, to the bottom of an aqueous solution of sodium nitrite (1 : 3), the whole being kept cool. Isobutyl nitrite immediately separated as an ethereal layer, and was decanted, washed with solution of potassium carbonate, and digested with fused potassium carbonate. It is a pale-yellow, slightly fragrant liquid, sp. gr. 0·876 at 15° (water at 15° = 1), and boils at 67°. It is apt to become acid when kept, especially in presence of moisture, and when acid is once formed, decomposition ensues rapidly. This, however, is greatly retarded by keeping a fragment of sodium hydrogen carbonate in the liquid. Administered to animals, isobutyl nitrite brings about a rapid fall of blood-pressure, an acceleration of the pulse, and a powerful respiratory paralysis.

R. R.

The Metameric Amyl Nitrites. By W. R. DUNSTAN and W. L. WILLIAMS (*Pharm. J. Trans.* [3], **19**, 487—489).—The liquid hitherto known as amyl nitrite is a mixture of metameric nitrites corresponding respectively with the isobutyl carbinol (α-amyl alcohol) and the secondary butyl carbinol (β-amyl alcohol) contained in various proportions in the "amyl alcohol" from which it has been prepared. The authors describe the process by which they obtained from the 127—132° fraction of fusel oil, a mixture of these two amyl alcohols free from other substances. This mixture had a lævorotatory power that indicated the presence of 15·4 per cent. of secondary butyl carbinol, the other alcohol being optically inactive. A mixture of the two nitrites obtained from this was, however, dextrorotatory from the action of the β-amyl nitrite, and its physiological effect was like that of isobutyl nitrite, but less powerful. These nitrites could be obtained separately only by previous isolation of the corresponding alcohols, and this was effected by converting the mixture into barium amyl sulphates and taking advantage of the smaller solubility of the α-amyl salt. It was only after 35 recrystallisations, that, on regenerating the alcohol from the barium salt, practically pure isobutyl carbinol was obtained. The nitrite prepared from this was an optically inactive, pale-yellow liquid of sp. gr. 0·880, b. p. 97°. It had a not disagreeable odour, and when inhaled, produced the characteristic nitrite effect. Its exact physiological action is under further investigation. R. R.

Action of Alkalis on the Nitro-compounds of Alkyl Radicles. By N. SOKOLOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 498—500).—In reference to the interesting reaction which takes place between nitroethane and soda or ammonia, the author has investigated its homologues from the same point of view. Nitromethane was heated with ammonia in sealed tubes at 100°, when the mixture became brown. Nitrous acid was found to be present in the liquid, but no other definite products of the reaction could be isolated. As the reaction between nitropropane and alkalis is far more feeble, it was heated with alcoholic potash for 4—5 hours at 140°. The product is a liquid, $C_9H_{15}NO$, of sp. gr. 0·961, boiling at 217—220°. Nitro-isopropane enters more easily into reaction with ammonia or soda, and the product consists chiefly of pseudopropylnitrol, together with much nitrite, but no compound analogous to $C_9H_{15}NO$ is formed.

B. B.

Action of Alkyl Iodides on Sodium Nitroethane. By N. SOKOLOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 579—582).—In former papers (*J. Russ. Chem. Soc.*, 1886, 274, and 1887, 384), the author has shown that the following reactions take place between nitroethane and alkaline hydroxides or carbonates in alcoholic or aqueous solutions: (1) $3C_2H_5NO_2 + NaOH + 2C_2H_6O = C_6H_9NO + NaNO_2 + 2C_2H_4O + NH_3 + 4H_2O$, and (2) $6C_2H_5NO_2 + 3NaOH = 2C_6H_9NO + 3NaNO_2 + NH_3O + 6H_2O$. The equations were confirmed by the quantitative determination of the products of reaction. As the compound C_6H_9NO and its homologues C_4H_5NO, C_5H_7NO, and $C_7H_{11}NO$ were obtained by Götting (Abstr., 1888, 355) by the action of alkyl iodides on sodium nitroethane in alcoholic solution, the author has repeated these experiments, employing V. Meyer's and Wurster's methods. The iodides of methyl, ethyl, propyl, and isobutyl were heated with dry sodium nitroethane in closed vessels in a water-bath, but it was found that no action took place. After treatment with water and boiling the aqueous solution, the compound C_6H_9NO could be extracted with chloroform. With other alkyl iodides, it was also found that there was no change. The same experiments were repeated in the presence of alcohol of 90—99 per cent., and then a reaction took place. The same was observed when sodium ethoxide was heated with nitroethane and the alkyl iodide. After dilution with water, the compound C_6H_9NO was extracted with chloroform and purified by distillation with steam. It is a yellow, oily liquid, boiling at 171°, whereas the pure substance obtained from sodium nitroethane and alcohol or water boils at 175°. Sp. gr. = 1·00023 at 0°. From methyl iodide or ethyl iodide, one and the same compound, C_6H_9NO, was obtained. The author concludes that: (1) alkyl iodides gives no reaction with sodium nitroethane; (2) the reaction described by Götting is due to the presence of ethyl alcohol, the alkyl iodides have only a disturbing action; (3) the compound C_6H_9NO obstinately retains water and alcohol, with which it parts near its own boiling point only; to this cause may be due the fact that Götting, on analysing such mixtures, obtained results agreeing with the formulæ C_4H_5NO, C_5H_7NO, and $C_7H_{11}NO$. The author claims priority in the discovery of the compound C_6H_9NO (see Abstr., 1888, 797). B. B.

Nitroethyl Alcohol. By R. Demuth and V. Meyer (*Ber.*, **21**, 3529—3530).—*Nitroethyl alcohol*, $NO_2{\cdot}CH_2{\cdot}CH_2{\cdot}OH$, is prepared by the action of silver nitrite on ethylene iodohydrin, and is purified by means of the sodium salt; this is dissolved in water, treated with sulphuric acid, and extracted with ether. The compound behaves like an alcohol, and is miscible with water. It yields azo-dyes; the compounds $N_2Ph{\cdot}CH(NO_2){\cdot}CH_2{\cdot}OH$ and $SO_3Na{\cdot}C_6H_4{\cdot}N_2{\cdot}CH(NO_2){\cdot}CH_2{\cdot}OH$ were prepared and analysed. The *sodium salt*, $NO_2{\cdot}CH_2{\cdot}CH_2{\cdot}ONa$, is an explosive substance insoluble in water. N. H. M.

Butyric Ethers. By E. Reboul (*Compt. rend.*, **108**, 39—43).—The four butyl alcohols were converted into sodium-derivatives in the usual way, care being taken to avoid access of air. With the tertiary alcohol, the reaction takes place slowly, and the liquid must be heated for some time. All four compounds separate in crystals containing 2 mols. of the particular alcohol, which is expelled by heating at 200—220°, or by placing the crystals in a vacuum over sulphuric acid, or by subjecting them to a current of purified and dry hydrogen or air. The dried sodium-alkyl oxides are decomposed by water into the corresponding alcohol and sodium hydroxide, but even when the compounds have been heated to 220° they have experienced no isomeric change, and the alcohol which they yield on treatment with water is identical with that from which they were formed. At 210—220°, the tertiary compound sublimes in bulky, slender, white needles, and the secondary compound shows signs of sublimation.

The ethers were prepared by the action of butyl bromides on a slight excess of the sodium-derivatives. In addition to the ether and sodium bromide, a butyl alcohol and butylene are formed, and this secondary reaction, which is comparatively slight in six cases, becomes the predominant if not the only reaction in the other four cases. The following ethers were obtained in this way :—

	B. p.	Sp. gr.
$O(CH_2{\cdot}CH_2{\cdot}CH_2Me)_2$	141°	0·784 at 0·0°
$CH_2Me{\cdot}CH_2{\cdot}CH_2{\cdot}O\ CH_2{\cdot}CHMe_2$ ..	131·5—132°	0·763 at 15·5
$CH_2Me{\cdot}CH_2{\cdot}CH_2{\cdot}O{\cdot}CHMe{\cdot}CH_2Me$	131·0—131·5	0·7687 at 15·0
$CH_2Me{\cdot}CH_2{\cdot}CH_2{\cdot}O{\cdot}CMe_3$	124·0—125·0	

With hydrobromic acid, all the ethers yield water and the bromobutanes corresponding with the alcohols from which they were formed. The boiling point of the last ether in the list differs from that of the normal ether by only 16—17°, whilst the difference in the case of the alcohols is 33°, and in the case of the bromobutanes 30°.

C. H. B.

Compound of Monosodium Glycol with Glycol. By De Forcrand (*Compt. rend.*, **107**, 1160—1162).—23 grams of sodium is added very gradually to 124 grams of glycol, and when the reaction is nearly complete the liquid is heated at 150° until all the sodium dissolves. When the liquid cools, it forms a mass of dry, colourless, very brilliant crystals of the composition $C_2H_5NaO_2,C_2H_6O_2$. Heat of dissolution in water at 20° = +0·70, and from the thermal data obtained by the action of sodium on glycol—

$2C_2H_6O_2$ liq. + $\frac{1}{2}Na_2O$ sol. = $\frac{1}{2}H_2O$ sol. + $C_2H_5NaO_2,C_2H_6O_2$ sol. .... develops +31·245 Cal.

$C_2H_5NaO_2$ solid + $C_2H_6O_2$ liquid = $C_2H_5NaO_2,C_2H_6O_2$ sol................ „ +7·025 „

The heat of formation of this compound from its proximate constituents is higher than that of any alcoholate except the methyl alcoholate of sodium methoxide.

C. H. B.

Molecular Weight of Arabinose and Xylose. By B. Tollens, F. Mayer, and H. Wheeler (*Ber.*, **21**, 3508—3510).—The following results were obtained by Raoult's method: for dextrose, 188·7; for arabinose, 155·1; for xylose (wood-sugar), 154·1. In determining the molecular weight, very uniform results are obtained if the vessel when taken out of the freezing mixture is dried and surrounded with cotton-wool.

N. H. M.

Platinum Compounds of Propyl and Isopropyl Sulphides. By C. Rudelius (*J. pr. Chem.* [2], **38**, 497—512; compare this vol., p. 230).—*Platosopropylsulphine α-chloride*, $PtCl{\cdot}SPr_2{\cdot}SPr_2Cl$, is obtained by the action of propyl sulphide on a solution of potassium platinosochloride; it is soluble in chloroform, ether, and absolute alcohol (6·5 parts at 15°), and crystallises in large, yellowish-red crystals melting at 46°. The *β-chloride*, $Pt(SPr_2Cl)_2$, crystallises in pale yellow, monosymmetrical prisms soluble in alcohol, and melting at 86°. The γ-*chloride* forms pale-yellow, thin, rhombic laminæ, soluble in the usual solvents and melting at 63°.

Platosethylpropylsulphine iodide, $SEt_2I \cdot Pt \cdot SPr_2I$, forms red, rhombic prisms [$a : b : c = 1 \cdot 7270 : 1 : 4 \cdot 1729$], melting at 115°. *Platosopropylisopropylsulphine iodide* forms long, slender, rhombic crystals melting at 131°. *Platosethylisopropylsulphine iodide* crystallises in short, thick crystals.

Platosopropylsulphine α-hydroxychloride, $PtCl \cdot SPr_2 \cdot SPr_2 \cdot OH$, is obtained by the action of alcoholic potash (1 mol.) on the α-chloride; it forms a semi-solid mass which gradually crystallises. The *α-iodochloride* forms long, prismatic crystals, soluble in chloroform and alcohol. The *bromide*, $Pt(SPr_2Br)_2$, forms long, yellowish-brown, rhombic prisms, soluble in ether, chloroform, and alcohol, and melting at 105°; the *iodide* forms long, red, rhombic prisms melting at 133°. The *α-* and *β-nitrites*, the *α-nitrate*, *basic α-nitrate*, *β-nitrate*, *β-sulphate*, *β-chromate*, *β-oxalate*, and *β-thiocyanate* are also described.

Of double salts, the author describes *platosopropylsulphine platinosochloride*, the *platinoso-iodide* and *mercurochloride*.

Platinipropylsulphine chloride, $PtCl_2(SPr_2Cl)_2$, is obtained from the platoso-α-chloride and chlorine; it crystallises in long, bright yellow, monoclinic prisms, soluble in alcohol and chloroform, and melting at 139°. The *bromide* forms long, dark red, monoclinic prisms melting at 141°. The *bromochloride* forms yellowish-red, prismatic crystals melting at 129°; the *iodide* and *hydroxy-nitrate* are also described.

Platosoisopropylsulphine chloride, $Pt(SPr^{\beta}_2Cl)_2$, forms long, yellow, triclinic crystals melting at 163°, and soluble in chloroform, ether, and alcohol. The *bromide*, *iodide*, *thiocyanate*, and *nitrite* are described.

Platinisopropylsulphine iodide, $PtI_2(SPr^{\beta}_2I)_2$, forms dichroic crystals, soluble in chloroform and alcohol and melting at 139°.

A. G. B.

Platinum Compounds of Butyl, Isobutyl, and Benzyl Sulphides. By H. LÖNDAHL (*J. pr. Chem.* [2], **38**, 512—523).—*Platosobutylsulphine α-chloride*, $PtCl \cdot SBu_2 \cdot SBu_2Cl$, forms large, orange-yellow, asymmetrical crystals, soluble in alcohol and ether and melting at 40°. The *β-chloride*, $Pt(SBu_2Cl)_2$, forms greenish-yellow, four-sided, asymmetrical tables melting at 77°. The γ-*chloride* is semi-solid at the ordinary temperature, and melts at 17—20°. The *bromide*, $Pt(SBu_2Br)_2$, crystallises in brownish-yellow, rhombic tables melting at 65°, and the *iodide* in dark red, rhombic tables melting at 65°. The *nitrite* and *nitrate* are described.

Platinibutylsulphine chloride, $PtCl_2(SBu_2Cl)_2$, is obtained by the action of chlorine on the platoso-α-chloride, and forms small, yellow crystals.

Platosoisobutylsulphine α-chloride crystallises in thin, four-sided, rhombic tables melting at 83°. The *β-chloride* forms oblique, four-sided, greenish-yellow, monoclinic tables, soluble in alcohol and ether and melting at 139°. The *bromide* crystallises in thin, hexagonal tables melting at 143—144°, and the *iodide* in hexagonal, rhombic tables melting at 187°. The *α-nitrite*, *β-nitrite*, *α-chloronitrate*, *β-nitrate*, *β-sulphate*, and *β-chromate* are also described. The *hydroxide*, $Pt(SBu^{\beta}_2 \cdot OH)_2$, is obtained as a viscous substance by the action of barium hydroxide on a sulphuric acid solution of the β-sulphate; its solution is alkaline.

Platinisobutylsulphine chloride, $PtCl_2(SBu^{\beta}_2Cl)_2$, crystallises in thick, yellow, hexagonal tables melting at 162°. The *bromide* forms red, monoclinic prisms or tables melting at 184°. The *bromochloride* and *chlorobromide* are described. A *periodide*, $PtI_2(SBu^{\beta}_2I)_2,I_2$, is obtained by the action of iodine on a chloroform solution of the β-iodide; it forms large, dark prisms and is converted into the β-iodide at 110°. A similar *periodochloride* is described. *Diplatinisobutylsulphine iodochloride*, $PtI(SBu^{\beta}_2Cl)_2,PtI(SBu^{\beta}_2Cl)_2$, is deposited from a chloroform solution of the β-chloride, containing iodine, as a reddish-yellow, crystalline powder insoluble in ether; it crystallises in large, hexagonal tables.

Platosobenzylsulphine chloride, $Pt(S(C_7H_7)_2Cl)_2$, forms greenish-yellow crystals containing 1 mol. of chloroform; it melts at 159°. The *bromide* crystallises from mixed chloroform and alcohol in crystals containing 1 mol. of chloroform and 1 mol. of alcohol; it melts at 139°. The *iodide* forms red, oblique, four-sided prisms melting at 129°. The *basic nitrate*, *nitrite*, and *sulphate* are described.

Platinibenzylsulphine chloride, $PtCl_2(S(C_7H_7)_2Cl)_2$, forms bright yellow prisms melting at 172° with decomposition. A. G. B.

Metallic Diamine Compounds. By S. M. Jörgensen (*J. pr. Chem.* [2], **39**, 1—26. See p. 351).

Determination of the Molecular Weight of Paraformaldehyde by Raoult's Method. By B. Tollens and F. Mayer (*Ber.*, **21**, 3503—3507).—Solutions of formaldehyde prepared from oxymethylene were kept in closed tubes for six months, and the molecular weight again determined with the same results as before (Abstr., 1888, 809), so that there had been no polymerisation in this time.

Paraformaldehyde, $(CH_2O)_2$, separates as a soft substance when a solution of formaldehyde is evaporated over sulphuric acid; it is readily soluble in water. The molecular weight was determined by Raoult's method. When the concentrated solution is diluted with water, formaldehyde is again formed.

Metaformaldehyde, or oxymethylene, has probably the formula $(CH_2O)_3$. The compound was previously shown to melt at temperatures varying from 142° to 171° (Abstr., 1884, 293); when freshly prepared and not sublimed, it melts gradually at 100°.

N. H. M.

Triazo-derivatives. By T. Curtius and J. Lang (*J. pr. Chem.* [2], **38**, 531—558).—The new azo-acid obtained by the action of hot concentrated aqueous alkali on ethyl diazoacetate (Abstr., 1887, 715) is *triazoacetic acid*, $C_3H_3N_6(COOH)_3$. It is best prepared as follows:—An aqueous solution of sodium hydroxide (80 grams in 120 c.c.) is heated on the water-bath and ethyl diazoacetate (50 grams) added by degrees, with continual shaking; the action soon becomes violent, and further heating is unnecessary. The half-solid contents of the flask are washed by decantation with 95 per cent. alcohol, then with absolute alcohol, and finally with ether. The sodium salt thus obtained is a bright yellow, hygroscopic powder consisting of minute needles; the yield is 55—60 grams. The *free acid* crystallises with 3 mols. H_2O in small, deep orange-red, four-sided, acute-angled, biaxial tables. It is insoluble in cold, easily soluble with partial decomposition in hot water, very easily soluble in cold absolute alcohol, gradually decomposed by hot alcohol, soluble in cold acetone and glacial acetic acid, but insoluble in the other usual solvents. When rapidly heated in a sealed tube, it decomposes at 149°, melts at 152°, and evolves carbonic anhydride at 155°; it decomposes when long heated at 60°, and this prevents a direct determination of its water of crystallisation. Heated on platinum-foil, it explodes like gunpowder, with formation of hydrogen cyanide. Nitric acid turns it red, and it reduces Fehling's solution slowly when boiled with it. The acid may also be obtained crystallised with 2 mols. H_2O in lustrous, golden laminæ.

The *potassium, sodium, silver, copper, manganese, lead, bismuth,* and *barium* salts are described. The *ammonium* salt crystallises in long orange-yellow needles easily soluble in water, and melting at 222°.

Ethyl triazoacetate, $C_3H_3N_6(COOEt)_3$, crystallises in large, ruddy, monosymmetric prisms, $a : b : c = 1{\cdot}2017 : 1 : 1{\cdot}3614$; $\beta = 73° 45'$; readily soluble in hot ether and cold alcohol, sparingly in cold ether and cold water; it melts at 110° without decomposition, sublimes in a sealed tube, and distils with partial decomposition under diminished pressure at about 270°. Its molecular weight has been determined by Raoult's method in a benzene solution.

The *methyl* salt forms small, striated, rectangular, biaxial, brick-red tables; it melts at 167—168° without decomposition, and sublimes, but cannot be distilled. The *isopropyl* salt has been obtained.

Triazoacetamide, $C_3H_3N_6(CONH_2)_3$, is obtained either as a bright yellow crystalline powder, or in golden-yellow, unsymmetrical laminæ, which melt above 300°, are insoluble in water and dilute acids, and cannot be recrystallised.

Triazimidoacetamide, $C_3HN_4(NH)_2(CONH_2)_3$, and its salts, have been described before under the name pseudo-diazoacetamide (Abstr., 1885, 884).

When heated at 100° for many hours, the yellow triazoacetic acid loses water (2 mols.) and carbonic anhydride (3 mols.), leaving a residue of *trimethintriazimide* which is soluble in absolute alcohol, and separates from the solution on the addition of ether in colourless prisms. The formula of this substance, determined by Raoult's method in an aqueous solution, is $C_3N_6H_6$. It melts at 78°, and is not decomposed at 180°; it is extremely hygroscopic, easily soluble in warm absolute alcohol, insoluble in benzene, ether, and chloroform; it is acid to blue litmus, colours Fehling's solution green, and does not evolve ammonia when heated with weak soda. Strong alkalis decompose it with formation of hydrogen cyanide and ammonia. A *silver compound*, $C_3H_6N_6,2AgNO_3$, and a *mercury compound*, $C_3H_6N_6,3HgCl_2$, have been prepared.

By heating potassium triazoacetate with aqueous potash (1 : 1) till it is dissolved, and then adding alcohol, an oil is precipitated; when this is neutralised with sulphuric acid, a white substance, of the formula

$C_3H_4N_6(COOH)_2$, is precipitated; it is equally soluble in dilute acids and alkalis, and is sparingly soluble in hot water, from which it partially crystallises on cooling as minute, lævorotatory tables, pointed at both ends; it melts at 170°. It does not evolve ammonia when heated with alkalis. When heated for some time at its melting point, it loses carbonic anhydride, leaving a residue which crystallises from water in beautiful, unsymmetrical stellate groups, and melts at 145°; its *silver nitrate compound* has the formula $C_3H_6N_6,2AgNO_3$, so that it is isomeric with the residue obtained by heating triazoacetic acid.

An aqueous solution of sodium triazoacetate decomposes after a time, and if then acidified and distilled, a strongly alkaline liquid goes over, which gives a white *silver compound*, of the formula $(CN_2Ag_2)_x$, in small, unsymmetrical crystals; the *mercurochloride* has the formula $C_3H_6N_6,HgCl_2$, so it would appear that there is yet a third isomeride of the formula $C_3H_6N_6$.

Aqueous solutions of triazoacetic acid compounds become coloured a beautiful red on exposure to the air, and its derivatives are all reddened by nitric acid or its vapour. By passing nitrous anhydride through a solution of sodium triazoacetate at 0°, unsymmetrical, carmine-coloured laminæ are precipitated; they are stable in air, and yield a red vapour when heated, which condenses again in red crystals; the formula of this substance is $C_3H_3N_6O_3(COOH)_3$.

A. G. B.

Action of Finely-divided Silver on Ethyl Bromopropionate.

By C. Hell and M. Rothberg (*Ber.*, **22**, 60—66; compare Hell and Mayer, next page).—Ethyl α-bromopropionate is heated at 150—160° for several hours with an equal weight of finely-divided silver, the whole being constantly shaken; after separating the product from the silver bromide, the following compounds can be isolated by repeated fractional distillation. (1.) A considerable portion boiling at 95—110°, which consists chiefly of ethyl propionate mixed with an unsaturated compound, probably ethyl acrylate. (2.) A large portion boiling between 110° and 200°, from which by repeated fractional distillation, a considerable quantity of ethyl α-bromopropionate was isolated. (3.) A considerable fraction boiling at 225—235°, which, on hydrolysis, yielded a mixture of the two isomeric dimethylsuccinic acids, together with a small quantity of pyrocinchonic anhydride. (4.) A considerable fraction boiling at 240—250°; this portion, on hydrolysis, yielded pyrocinchonic anhydride, dimethylsuccinic acid (m. p. 119—120°), and a small quantity of the isomeric acid (m. p. 193°). (5.) A considerable portion boiling above 250°, from which a brown syrupy acid, most probably a polymeric acrylic acid, was obtained in an impure state.

Bromine has no action on the two isomeric dimethylsuccinic acids, but in presence of phosphorus, both acids yield one and the same monobromo-substitution product. This compound crystallises from water in needles, melts at 91°, and is readily soluble in alcohol, ether, and hot water, but only sparingly in cold water. When reduced with hydrochloric acid and zinc, from whichever acid it has been prepared, it is converted into dimethylsuccinic acid (m. p. 120°).

F. S. K.

Derivatives of Phenyl-αβ-Dibromisobutyric Acid. By T. Körner (*Chem. Centr.*, 1888, 1434—1435).—*Phenyl-α-methyl-β-bromacrylic acid*, $C_{10}H_9BrO_2$, melting at 124°, is prepared by heating the alcoholic solution of phenyldibromisobutyric acid with potash at 60°. By heating it with water, carbonic anhydride is eliminated, and *phenyl-β-bromopropylene*, C_9H_9Br, and *phenyl-α-hydroxy-β-bromisobutyric acid*, $C_{10}H_{12}BrO_3$, melting at 148° are formed. Phenylbrompropylene boils at 226°, being partly decomposed thereby with evolution of hydrogen bromide; it has a fruity smell. It is also formed by decomposing phenyldibromisobutyric acid with steam. With bromine, it appears to form a tribromide. *Phenylallylene*, C_9H_8, a disagreeable-smelling, colourless oil, boiling at 185°, is formed when phenylbromopropylene is heated with alcoholic potash at 100°. *Phenylallylene dibromide*, $C_9H_8Br_2$, boils at 250—255°; the *tetrabromide* boils at 75°.

The characteristic property of the hydrocarbons of the acetylene series is the formation of additive compounds with mercury salts, and not necessarily the formation of explosive silver and cuprous compounds.
J. W. L.

Action of Sodium on Ethyl Isobutyrate. By A. Hantzsch (*Annalen*, **249**, 54—65).—Brüggemann denies the accuracy of Wohlbrück's experiments (Abstr., 1887, 1099) on the action of sodium on ethyl isobutyrate. Brüggemann states (Abstr., 1888, 1176) that no acids containing 3 atoms of oxygen are produced, and that the acids formed contain only two oxygen-atoms, and are derivatives of isobutyric acid. The author has repeated these experiments, and finds that the chief product of the reaction is *hydroxycaprylic acid*, $C_8H_{16}O_3$, as stated by Wohlbrück. In the first place, 2 mols. of ethyl isobutyrate undergo condensation in the presence of sodium, forming the compound $CHMe_2\cdot C(OH)(OEt)\cdot CMe_2\cdot COOEt$, which cannot be isolated. This is reduced by the sodium, yielding *ethyl ethoxycaprylate*, $CHMe_2\cdot CH(OEt)\cdot CMe_2\cdot COOEt$, described by Wohlbrück as ethyl dimethylisobutyrylacetate. A portion of the ethoxycaprylate is at the same time saponified, yielding hydroxycaprylic acid, $CHMe_2\cdot CH(OH)\cdot CMe_2\cdot COOH$. The compound obtained by acting on ethyl isovalerate with sodium, and described by Wohlbrück as ethyl isopropylisovalerylacetate, is really *ethyl ethoxycaprate*, $C_4H_9\cdot CH(OEt)\cdot CHPr\cdot COOEt$. It is decomposed by boiling with alcoholic potassium hydroxide, yielding hydroxycapric acid,

$$C_4H_9\cdot CH(OH)\cdot CHPr\cdot COOH.$$

W. C. W.

Action of Finely-divided Silver on Ethyl Bromisovalerate. By C. Hell and W. Mayer (*Ber.*, **22**, 48—60).—When ethyl bromisovalerate is treated with an equal weight of finely-divided silver at the ordinary temperature, much heat is developed; the reaction can be brought to an end by heating the mixture at 150° for about four hours, with constant shaking. The product can be separated by repeated fractional distillation into (1) a small quantity of ethyl bromide; (2) a very large quantity of ethyl valerate; (3) a small quantity of an ethereal salt boiling at 140—150°; and (4) a large portion boiling above 250°.

The fraction boiling at 140—150° yields, on hydrolysis, a viscid acid, probably dimethylacrylic acid, boiling at 180—185°, and having a pungent smell; on treating this acid with bromine in chloroform solution, there is considerable development of heat, and an impure compound, probably dibromovaleric acid, is obtained.

The portion boiling above 250° can be separated into two fractions by distilling under reduced pressure: the one boils under the ordinary pressure at 260—270°, the other at 280—300° with partial decomposition. The lower boiling fraction yields on hydrolysis two isomeric acids which can be separated by distilling with steam, but part of the ethereal salt remains unchanged; when this portion is heated at 120° with concentrated hydrobromic acid, it yields ethyl bromide and a mixture of the same two isomeric acids. The higher boiling fraction, on hydrolysis, gives a syrupy acid, from which only very small quantities of the two isomeric acids can be isolated.

Diisopropylsuccinic acid, COOH·CHPr·CHPr·COOH (m. p. 167—168°), is volatile with steam, and when separated by distillation with steam from the mixture of isomeric acids referred to above, is obtained as a colourless oil, which is probably the anhydride. The pure acid, prepared by decomposing one of the salts, separates from hot water in dendritic crystals, and melts at 167—168° when heated quickly. When heated at 150—160° in large quantities, it is converted into an oily anhydride. It is readily soluble in ether, alcohol, and chloroform, and moderately so in benzene and hot water, but only sparingly in cold water. The *sodium* salt is crystalline, and is readily soluble in water. The *barium* salt, $C_{10}H_{16}O_4Ba + 5H_2O$, *strontium* salt ($+ 3H_2O$), and *calcium* salt ($+ 4H_2O$) are crystalline, and lose the whole of their water at 120°. The *magnesium* salt, *manganese* salt, and *cobalt* salt crystallise with 7 mols. H_2O, the *nickel* salt with 5 mols. H_2O, the *cadmium* salt with 4 mols. H_2O, and the *copper* salt with 1 mol. H_2O. The *zinc*, *lead*, and *silver* salts are anhydrous, and very sparingly soluble in water.

Diisopropylsuccinic acid (m. p. 199—200°) remains when the isomeric acid (see above) is distilled with steam, and separates in granular crystals on evaporating the solution. It is readily soluble in alcohol and chloroform, and moderately so in hot water and benzene, but only sparingly in cold water. It melts at 199—200°, and sublimes in needles when heated at 210°, but does not form an anhydride. When treated with potassium permanganate in neutral aqueous solution, it is converted into an acid, probably acetic acid. The *barium* salt ($+ 2H_2O$), the *strontium* salt ($+ 4H_2O$), and the *calcium* salt ($+ 2H_2O$) are crystalline, and lose their water at 120°. The *magnesium* salt ($+ 5H_2O$), *manganese* salt ($+ 3H_2O$), *nickel* salt ($+ 4H_2O$), *copper* salt ($+ 3H_2O$), *cadmium* salt ($+ 3H_2O$), and the anhydrous and very sparingly soluble *zinc*, *copper*, *lead*, and *silver* salts were also prepared.

The syrupy acid obtained from the fraction boiling at 280—300° is separated from small quantities of the two diisopropylsuccinic acids by distilling with steam, and keeping for a long time until the non-volatile acid separates. By repeatedly extracting with water it is separated into a readily soluble, only slightly coloured acid, and a very sparingly soluble, brownish, resinous acid, both of which are readily soluble in alkalis. The former was obtained in a pure state by means of the readily soluble, crystalline *calcium* salt. Its empirical composition is $C_5H_8O_2$, and it is probably a dipolymeric dimethylacrylic acid. The more sparingly soluble acid is probably a tripolymeric dimethylacrylic acid. Neither acid combines with bromine in chloroform solution, but they both (?) yield considerable quantities of valeric acid, acetic acid, carbonic anhydride, and a small quantity of a crystalline acid, probably diisopropylsuccinic acid (m. p. 167—168°) when treated with potassium permanganate.

These results show that the action of finely divided silver on ethyl bromovalerate is analogous to the action of silver on ethyl bromobutyrate. (Compare Hell and Mülhäuser, Abstr., 1880, 542.) F. S. K.

Oxidation of Angelic and Tiglic Acids by Potassium Permanganate. By I. KONDAKOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 523—524).—The oxidation was carried on by Wagner's method (Abstr, 1888, 665), which consists in adding to a 1 per cent. solution of the potassium salt of the acid under investigation drop by drop, with continual agitation, a solution containing 1 per cent. of permanganate. The quantity of permanganate taken contained 1 atom of oxygen for 1 mol. of the acid. After separating the manganese dioxide by filtration, the liquid was submitted to distillation to remove the volatile neutral products, and the distillate which usually contains aldehyde, was treated with moist silver oxide. The silver salts were converted into sodium salts, and these on fractional distillation with sulphuric acid yielded the free acids; the acids in the different fractions were again converted into silver salts. The analysis of these proved that tiglic acid, on oxidation, yields acetaldehyde, together with some propaldehyde, whereas angelic acid yields propaldehyde as the chief, and acetaldehyde as a subsidiary product. This the author explains by the inefficiency of Kopp's method for the complete separation of angelic acid from tiglic acid. The aqueous residues left on distillation were saturated with carbonic anhydride and evaporated to dryness, and the product extracted with ether in the presence of a little dilute sulphuric acid. The analysis of silver salts prepared from the acid residue proved that tiglic acid yields acetic, angelic, and propionic acids. The investigation of the non-volatile acids has shown that angelic acid yields dihydroxyvaleric and ethyltartronic acids, and that tiglic acid yields dihydroxyvaleric acid together with the first isomeride. B. B.

Olive Oil. By K. HAZURA and A. GRÜSSNER (*Monatsh.*, **9**, 944—946; compare Abstr., 1886, 140; 1887, 359, 798, 913; and 1888, 816, 1269).—Earlier investigations of the authors have made it appear probable that the liquid portion of the fatty acids derived from olive oil consists of a mixture of two or more unsaturated acids. This view is confirmed by its iodine number.

According to Schädler, olive oil consists of a mixture of 72 per cent. of trioleïn with 28 per cent. of palmitin, stearin, and arachin; but its high iodine number points to the conclusion that the portion previously supposed to consist entirely of trioleïn contains an acid having a higher iodine number than oleïc acid. The authors now show that a mixture of hydroxystearic, $C_{18}H_{34}(OH)_2O_2$, and sativic, $C_{18}H_{32}(OH)_4O_2$, acids is formed when the liquid fatty acids of olive oil are oxidised with permanganate. It therefore follows that both oleïc and linoleïc acids are present in olive oil, and in all probability they exist in most non-drying oils. G. T. M.

Oxidation of Unsaturated Fatty Acids by Permanganate. By K. HAZURA and A. GRÜSSNER (*Monatsh.*, **9**, 947—955; compare Abstr., 1886, 140; 1888, 1270).—The authors have oxidised erucic, undecylenic, and stearolic acids with permanganate, in order to ascertain whether these substances yield oxidation products in accordance with the rule laid down by Hazura, "that unsaturated fatty acids, on oxidation with alkaline permanganate, take up as many hydroxyl-groups as they have free valencies, and are thereby converted into hydroxy-derivatives of saturated fatty acids." Under such circumstances they find that erucic acid, $C_{22}H_{42}O_2$, gives *dihydroxybehenic acid*, $C_{22}H_{42}O_2(OH)_2$. This substance is insoluble in water and ether, is only slightly soluble in chloroform, benzene, toluene, and acetic acid, and crystallises from alcohol in rhombic plates melting at 132—133°. The potassium and sodium salts are only slightly soluble in water; the salts of the alkalis and heavy metals are insoluble.

Undecylenic acid, $C_{11}H_{20}O_2$, is converted on oxidation into *dihydroxyundecylic acid*, $C_{11}H_{20}O_2(OH)_2$, crystallising in small, anhydrous needles melting at 85—86°. The acid is monobasic, and dissolves readily in alcohol, hot water, and acetic acid, but is only slightly soluble in ether and cold benzene. The potassium, sodium, barium, calcium, and magnesium salts are all soluble in water; the salts of the heavy metals are, on the other hand, insoluble.

Stearolic acid, $C_{18}H_{32}O_2$, on oxidation is converted chiefly into stearoxylic acid, $C_{18}H_{32}O_4$, which crystallises in yellow, glistening needles melting at 84—86°. At the same time a small quantity of suberic acid, $C_8H_{14}O_4$, crystallising in white needles melting at 139—140°, is formed. G. T. M.

Action of Ethyl Chlorocarbonate on Ethyl Sodacetoacetate and Ethyl Sodomalonate. By L. CLAISSEN (*Ber.*, **21**, 3567).—Vapour-density and molecular weight determinations made with the compounds obtained by Conrad and Guthzeit by the action of ethyl chlorocarbonate on ethyl sodacetoacetate and ethyl sodomalonate establish the correctness of the formulæ originally ascribed to them (*Annalen*, **214**, 31). N. H. M.

Bromazelaïc and Hydroxyazelaïc Acids. By A. BUJARD and C. HELL (*Ber.*, **22**, 68—73; compare Gantter and Hell, Abstr., 1881, 891).—Bromine has very little action on azelaïc acid at 100°, but in presence of a small quantity (0·1 per cent.) of amorphous phosphorus, the action is at an end in three hours at 100°. A mixture of dibrom- and brom-azelaïc acids is thus obtained, the latter being formed in the larger quantity, but the two products cannot be separated.

Hydroxyazelaïc acid, $OH\cdot C_7H_{13}\cdot COOH$, is prepared by boiling the mixture of brom-acids for a long time with excess of soda. The concentrated and acidified solution is shaken with ether to remove azelaïc acid, then neutralised with ammonia, copper sulphate added, and the copper salt decomposed with hydrogen sulphide. It can also be separated from the azelaïc acid by repeatedly evaporating a solution of the two ammonium salts, when ammonium azelate is decomposed, and the free acid can be separated from the more soluble unchanged salt of hydroxyazelaïc acid. Hydroxyazelaïc acid can also be purified by converting it into the zinc salt and decomposing the latter with dilute sulphuric acid. It separates from water or ether in colourless, nodular crystals, melts at 91°, and is very readily soluble in alcohol and water, but more sparingly in ether. A yellowish, viscid anhydride, $C_{18}H_{30}O_9$, is obtained when the acid is heated at 100°, or when the zinc salt is decomposed with concentrated sulphuric acid. It is reconverted into the acid when boiled with a large quantity of water. The *barium* salt, $C_9H_{14}O_5Ba + \frac{1}{2}H_2O$, the *calcium* salt ($+ 1H_2O$), and the *strontium* salt ($+ 1\frac{1}{2}H_2O$) are moderately soluble in water. The *magnesium, zinc*, and *cadmium* salts crystallise with 2 mols. H_2O. The *copper* salt ($+ 1\frac{1}{2}H_2O$), the *lead* salt ($+\frac{1}{2}H_2O$), and the anhydrous *silver* salt were also prepared. F. S. K.

Action of Ethyl Dibromosuccinate, Bromomaleate (or Fumarate), and Tartrate on Potassium Ethoxide. By E. Mulder and C. Wellemann (*Rec. Trav. Chim.*, 7, 334—340).—Analyses are given of the products of the reaction of ethyl dibromosuccinate and bromomaleate (or fumarate) with potassium ethoxide when mixed either in molecular proportion or 1 mol. of the former to 2 mols. of the latter. The product of the action of the dibromosuccinate on the ethoxide (2 mols.) gives on extracting with ether a substance that forms a compound with silver. Ethyl tartrate and potassium ethoxide form different compounds according as the reaction takes place in the cold or with heating. H. C.

Diazosuccinic, Diazosuccinamic, and Diazopropionic Acids. By T. Curtius and F. Koch (*J. pr. Chem.* [2], 38, 472—490).—This paper is mainly a continuation of a summary of the authors' previous work on the subject (compare Abstr., 1885, 885, and 1887, 33).

By the action of zinc and glacial acetic acid, diazosuccinic acid is split up into ammonia and aspartic acid. Copper aspartate crystallises with 3 mols. H_2O; Ritthausen obtained it with $4\frac{1}{2}$ mols. H_2O.

Ethyl amidopropionate hydrochloride forms groups of crystals which melt at 64—68°. When it is treated with nitrous acid, a yellow oil is obtained, which behaves like an ethyl salt of a diazo-fatty acid, and probably contains ethyl diazopropionate. *Ethyl dihydroxypropionate*, $O[CMe(OH)\cdot COOEt]_2$, distils from this oil between 80° and 86° (120 mm. pressure) as a colourless, refractive, neutral liquid, of a peculiarly penetrating odour; it gives a freely soluble *barium salt*. The rest (one-third) of the oil distils between 120° and 150°, giving an oil which solidifies, forming colourless, lustrous prisms of *ethyl azoxypropionate*, $ON_2(CHMe\cdot COOEt)_2$. This substance is neutral, melts at 95°, and is soluble in ether and alcohol; its *barium salt* is pulverulent and sparingly soluble. A. G. B.

Action of Potassium Cyanide on α-Brominated or α-Chlorinated Fatty Ethereal Salts. By N. ZELINSKY and A. BITSCHICHIN (*Ber.*, **21**, 3398—3401).—Ethyl cyanosuccinate is formed, together with ethyl α-cyanoacetate, when ethyl α-bromacetate is treated with potassium cyanide in alcoholic solution (compare Zelinsky, this vol., p. 122, and Haller, Abstr., 1888, 937). It is a heavy liquid, boils at 280—290° with only slight decomposition, and is insoluble in water. On hydrolysis with hydrochloric acid, it is converted into succinic acid.

Ethyl diethylcyanosuccinate, COOEt·C(CN)Et·CHEt·COOEt, is obtained, together with ethyl α-cyanobutyrate, by treating ethyl α-bromobutyrate in like manner, or by the action of ethyl sodocyanobutyrate on ethyl α-bromobutyrate. It is a heavy liquid, boils at 280—286°, and when hydrolysed with hydrochloric acid yields the two isomeric diethylsuccinic acids, melting at 191° and 126—127° respectively.

These experiments seem to show that the formation of such condensation products as those described above by the action of potassium cyanide on the ethereal salt of an α-brominated or α-chlorinated fatty acid is a general reaction. F. S. K.

Symmetrical Diethylsuccinic Acids. By C. HELL (*Ber.*, **22**, 67).—The author points out that he has already described the properties of the two isomeric diethylsuccinic acids (compare Hell and Mülhäuser, Abstr., 1880, 542—543). F. S. K.

Isomalic Acid. By W. OSTWALD (*Ber.*, **21**, 3534—3537).—Determinations of the molecular conductivity (Abstr., 1888, 331) of a preparation of isomalic acid made by Kämmerer (*Annalen*, **139**, 257) showed that this acid is identical with citric acid.

N. H. M.

Action of Ethyl Chlorocarbonate on the Sodium-derivatives of Acetylacetone, Ethyl Acetoacetate, and Ethyl Malonate. By L. CLAISEN and W. ZEDEL (*Ber.*, **21**, 3397—3398).—*Ethyl acetylacetonedicarboxylate*, $C(COMe)_2(COOEt)_2$, is obtained when sodacetylacetone is treated with ethyl chlorocarbonate. When ethyl sodacetoacetate is treated in like manner, the compound $COMe·C(COOEt)_3$ is formed (compare Ehrlich, *Ber.*, **7**, 892; Conrad and Guthzeit, Abstr., 1883, 45; and Michael, Abstr., 1888, 1054). The compound described as ethyl methenyltricarboxylate (Conrad and Guthzeit, *loc. cit.*) seems to be ethyl methanetetracarboxylate, $C(COOEt)_4$. F. S. K.

Glycuronic Acid. By H. THIERFELDER (*Zeit. physiol. Chem.*, **13**, 275—284; compare Abstr., 1887, 717).—An attempt to prepare a benzoyl-derivative of glycuronic acid by the method adopted by Baumann (Abstr., 1887, 228) in the preparation of tetrabenzoyldextrose, gave only a small precipitate; a better result was obtained by shaking together a mixture of substances present in the proportion of 1 mol.

of glycuronic acid, 9 mols. of benzoic chloride, and 12 mols. of sodium hydroxide (in a 10 per cent. solution); the resulting precipitate was viscous; it was dried over sulphuric acid, and freed from adherent benzoic acid by light petroleum, and from sodium benzoate and chloride by water. The substance prepared in this way dissolves readily in alcohol, especially hot alcohol. It melts at 107°; it reduces Fehling's solution. Elementary analysis gave results which correspond with the formula $C_6H_8O_7Bz_2$.

Glycuronic anhydride reacts very vigorously with aniline; better results are obtained by using potassium glycuronate dissolved in 85—90 per cent. alcohol. The crystalline compound obtained has the formula $NPh\colon C_6H_9O_6K$, it thus corresponds exactly with Sorokin's anilide of dextrose (Abstr., 1886, 526, 683; 1888, 807). It is easily soluble in water, sparingly soluble in alcohol and in ether, melts at 177°, becoming dark coloured; its solutions reduce Fehling's solution, are lævorotatory, and in the air become dark coloured, losing much of their action on polarised light.

A compound with toluylenediamine, $C_7H_6(N\colon C_6H_9O_6K)_2$, was also prepared; this corresponds to the similar compound with dextrose, prepared by Hinsberg (Abstr., 1888, 476).

The action of potassium hydroxide solutions of various strengths at different temperatures was then investigated. Oxalic acid was found in all cases. Catechol was also present, especially when strong alkali was used, and in this case a certain amount of protocatechuic acid was also formed.

The effect of putrefaction was investigated by Hoppe-Seyler's method; mud and chalk were added to the substance, and the resulting gases were analysed from time to time. The following formulæ represent the different stages in the process, as denoted by the gases formed :—(1.) $(C_6H_9O_7)_2Ca + CaCO_3 = (C_2H_3O_2)_2Ca + (C_3H_5O_3)_2Ca + 3CO_2 + H_2O$; (2.) $(C_3H_5O_3)_2Ca + 2H_2O = (C_2H_3O_2)_2Ca + 2CO_2 + 4H_2$; (3.) $(C_2H_3O_2)_2Ca + H_2O = CO_2 + CaCO_3 + 2CH_4$.

W. D. H.

Change in the Rotatory Power of Tartaric Acid in Mixed Solutions. By R. Přibram (*Ber.*, 22, 6—11).—The author has previously shown (Abstr., 1888, 1229) that the rotatory power of solutions of tartaric acid is altered considerably by various optically inactive substances, and that in many cases the rotation may be completely prevented, or even changed in direction.

When tartaric acid (5 grams) is dissolved in ethyl alcohol (20 c.c.) and the solution mixed with an equal volume of benzene, toluene, xylene, or cymene, the angle of rotation ($l = 2$ dm.) is $-0·411$, $-0·619$, $-0·652$, and $-0·791$ respectively, whereas when alcohol alone (40 c.c.) is present the angle of rotation is $+0·379$.

Chlorinated and brominated derivatives of aromatic hydrocarbons have a similar and a more marked effect, but the influence of nitro-compounds is not so great, as is shown by the following table :—

2 grams of tartaric acid contained in	In 100 c.c. of solution.		Observed angle of rotation α^{20}_{D}.
	Inactive substance.	Tartaric acid.	
	c.c.	grams.	
40 c.c. ethyl alcohol	0	5	+0·379
20 c.c. ethyl alcohol + 20 c.c. benzene .	50	5	−0·411
20 c.c. ethyl alcohol + 20 c.c. nitrobenzene	50	5	+0·317
20 c.c. ethyl alcohol + 20 c.c. toluene..	50	5	−0·619
20 c.c. ethyl alcohol + 20 c.c. nitrotoluene	50	5	−0·069
20 c.c. ethyl alcohol + 20 c.c. chlorobenzene	50	5	−0·809
20 c.c. ethyl alcohol + 20 c.c. ethyl bromide	50	5	−0·362
20 c.c. ethyl alcohol + 20 c.c. nitroethane	50	5	+0·309

Substances containing the amido-group, such as glycocine, alanine, carbamide, and aniline, increase the dextrorotatory power. In the case of carbamide, the specific rotatory power is expressed approximately by the formula $[\alpha]_D = 2·582 + 0·0515x + 0·0002313x^2$, where x = the percentage of carbamide in a solution containing 9·389 per cent. of tartaric acid.

The specific rotatory power of a solution containing 10 per cent. of tartaric acid and 4 per cent. of pyridine is $[\alpha]_D = 24·85°$, that of a solution containing 50 per cent. of pyridine and 10 per cent. of tartaric acid is $[\alpha]_D = 50·28°$, whilst that of a 10 per cent. solution of tartaric acid alone is 13·12° under the same conditions.

In a second series of experiments with solutions containing 4·8662 per cent. of tartaric acid ($[\alpha]_D = 14·405°$), it was found that the specific rotatory power is increased to 45·888, 48·950, and 49·484 by adding 25, 50, and 55 per cent. of pyridine respectively; but that on adding 60, 75, and 100 per cent. of pyridine the specific rotatory power falls to 48·364, 41·778, and 18·957 respectively (compare Thomson, Abstr., 1886, 925, and *J. pr. Chem.* [2], **35**, 145).

The results hitherto obtained show that all substances which form salts with tartaric acid increase the specific rotatory power of solutions of this acid, but in all other cases the rotatory power is decreased, and in some cases actually reversed. The fact that the decrease in the rotatory power of tartaric acid produced by members of a homologous series is, within certain limits, dependent on the molecular weight of these substances, seems to show that this phenomenon is the result of some mass-action of the molecules (compare Landolt, *Optisches Drehungsvermögen*, 1879, 59, and van't Hoff, *Études de Dynamique Chimique*, 34—42). In those cases where the change in rotatory power reaches a maximum and then decreases, it may be assumed that up to the point of maximum rotation a salt is produced, and that the subsequent decrease is caused by some mass-action of the free inactive molecules of the salt thus produced.

F. S. K.

Polarisation of Tartrate Solutions. By J. H. Long (*Amer. J. Sci.*, **36**, 351—358).—All these observations were made in a new model Laurent instrument at 20°, and with a 200 mm. tube. A solution containing 15 grams of tartaric acid in 100 c.c. of water showed a specific rotation $[\alpha]_D = 13·03$; this was diminished by free mineral acids, and also by certain neutral salts: thus with 15 grams of tartaric acid and 8 grams of sodium chloride, $[\alpha]_D = 6·16$. Rochelle salt has a rotation of 22·1; this is decreased by sodium, lithium, and thallium salts, the decrease being greater as the amount of sodium salt increases, whereas potassium and ammonium salts increase the rotation in a similar manner; calculated on the molecular proportions, the following numbers indicate the specific rotation when 1 mol. of tartrate is mixed with 1, 2, or 3 mols. of inactive salt :—

Salt.	1 mol.	2 mols.	3 mols.
$NaCl$	21·86	21·41	20·99
$NaBr$	21·79	21·42	—
$NaNO_3$	21·68	21·41	21·16
Na_2SO_4	21·32	20·49	—
$Na_2HPO_4,12H_2O$	21·40	—	—
$Na_2S_2O_3,5H_2O$	21 07	—	—
NaH_2PO_2,H_2O	21·67	20·92	—
$NaC_2H_3O_2,3H_2O$	21·72	21·16	—
KCl	22·73	22·88	23·14
KBr	22·78	23·00	—
KI	22·63	23·09	—
KNO_3	22·60	23·07	—
$KSCy$	22·52	22·66	22·82
$KC_2H_3O_2$	22·60	22·87	23 25
K_2SO_4	22·79	—	—
NH_4Cl	22·54	22·67	22·81
NH_4Br	22·54	22·70	—

The molecular rotation of the three salts, $K_2C_4H_4O_6$, $KNaC_4H_4O_6$, $Na_2C_4H_4O_6$, is respectively 64·42, 62·34, 59·85; the formation of a salt with higher or lower rotation, as the case may be, is suggested as partly explaining the above phenomenon, the cause of which, however, is still obscure.

D. A. L.

Decomposition of Amides with Alcohols. By L. Meyer (*Ber.*, **22**, 24—27).—The formation of amides and alcohols by the action of ammonia on ethereal salts is a reversible reaction, but the inverse change takes place only very partially when equivalent quantities of ammonia and ethereal salt are employed. If equilibrium is expressed thus—

p Amide + *p*′ ammonia + *q* ethereal salt + *q*′ alcohol, the reaction quotients are expressed by the formula $p'q = K^2pq'$, where K is a moderately small number. When equilibrium is established, the quantities of alcohol and amide present are, therefore, relatively large; those of ethereal salt and ammonia relatively small. The higher the temperature, the larger the quantity of ethereal salt produced, the constant K increasing as the temperature rises; in preparing amides, the temperature should therefore be kept as low as possible. K also increases as the molecular weight of the alcohol or acid radicle increases, the average value of K at 210° in reactions between ammonia and ethereal salts, formed from various acid and alcohol radicles containing an increasing number of carbon-atoms, is given in tabular form. This constant is very small in the case of secondary and tertiary alcohols.

Guldberg and Waage's law only holds good in reactions of this kind as long as the ammonia and ethereal salt are present in the proportion in which they are formed by the action of the alcohol on the amide; if either is present in excess of this quantity, the constant is changed in value.

In the case of acetamide and ethyl alcohol, $K = 0·094$; in presence of excess of ammonia it falls to 0·084, but rises to 0·134 in presence of excess of ethyl acetate. Excess of ammonia increases the formation of amide to a greater extent, and excess of ethereal salt decreases the formation of ethereal salt to a less extent than is in accordance with Guldberg and Waage's law in its usual simplest form.

In attempting to determine this relation experimentally, discordant results were obtained, when the tubes employed were slowly cooled, because, during the cooling, re-formation of amide took place. It was also found that during the reaction a considerable quantity of amine salt was produced; this salt, however, immediately decomposed, partly into water and a substituted amide, and partly into amine and ammonium salt, as shown by the following equations:— $CH_3·CONH_2 + MeOH = CH_3·COOMe + NH_3$; $CH_3·COOMe + NH_3 = CH_3·COO·NH_3Me$; $CH_3·COO·NH_3Me = CH_3·CONHMe + H_2O$; $CH_3·COO·NH_3Me + NH_3 = CH_3·COO·NH_4 + NH_2Me$. If an amine salt is present, it has no influence on the course of the reaction; acetamide is decomposed by ethyl alcohol to the same extent, whether ethylamine acetate is present or not, the amine salt being almost completely converted into ethyl acetamide.

When a few hundredths per cent. of acid are present, the formation of ethereal salt is hastened very considerably: 5 mols. of ethyl alcohol only decomposed 8·3 per cent. of pure butyramide in 24 hours; whereas in presence of 0·044 per cent. of butyric acid, 42 per cent. was decomposed in the same time, and in presence of 4·4 per cent. of acid, 44 per cent. was decomposed.

Pure acetamide is odourless, has a neutral reaction, and melts at 81—82° (see Mason, Trans., 1882, **108**). Pure propionamide melts at 79—80°, butyramide at 115°, and isobutyramide at 129°.

F. S. K.

Synthesis of the Asparagines. By A. Piutti (*Chem. Centr.*, 1888, 1459—1460).—*Ethyl β-aspartate*, $COOH·CH(NH_2)·CH_2·COOEt$, is prepared by reducing 5 grams of the oxime of ethyl oxalacetate in

50 c.c. of aqueous alcohol with acetic acid and 30 grams of sodium-amalgam (5 per cent.), the solution being retained acid by occasional addition of acetic acid; any great development of heat must also be avoided. After filtering, cupric acetate is added, and the copper salt allowed to crystallise out. The latter is anhydrous, and the determination of the copper agreed with the formula $(C_6H_{10}NO_4)_2Cu$. Precipitation of the copper in the cold with hydrogen sulphide and concentration, and ultimate crystallisation over sulphuric acid, gave the ethyl salt in leaf-like, anhydrous crystals melting at 200—201°; a small quantity of inactive aspartic acid was found in the mother-liquor.

Ethyl α-aspartate, $COOH{\cdot}CH_2{\cdot}CH(NH_2){\cdot}COOEt$, is prepared by reducing 80 grams of the oxime of ethyl oxalacetate in absolute alcohol with 9 grams of sodium, in a vacuum over sulphuric acid during two to three days, whereby one ethyl-group is eliminated. The dark-yellow, gelatinous mass is dissolved in water, alcohol added until slight precipitation ensues, and then acidified with acetic acid and reduced with sodium-amalgam until ferric chloride no longer produces a violet coloration, and until cupric acetate produces a heavy precipitate. Generally 6—7 parts of the amalgam to 1 part of the oxime are sufficient. Cupric acetate is added to the filtrate, when a green or blue, crystalline precipitate soon separates; this is nearly insoluble. Precipitation with hydrogen sulphide, expulsion of the excess of the latter in a vacuum over lime, filtration and concentration at a low temperature, first in a current of air and finally over sulphuric acid in a vacuum, results in the separation of the ethyl α-salt in large crystals, in addition to a little crystalline aspartic acid. It is purified by fractional crystallisation from water and alcohol. The ethyl salt is anhydrous, melts at 165° with decomposition, is very soluble in water, but only sparingly in alcohol, insoluble in ether. It is saponified by boiling potash or hydrogen chloride, with separation of inactive aspartic acid, as in the case of the ethyl β-salt.

According to L. Brugnatelli, the crystals of the ethyl α-salt are monoclinic; $a : b : c = 1{\cdot}8822 : 1 : 1{\cdot}1883$; $\beta = 82° 15'$. The plate-like crystals showed complete cleavage in the direction (100). The plane of the optical axis is at right angles to (010). The double refraction is strong and positive. The *copper salt* of the ethyl α-salt, $(C_6H_{10}NO_4)_2Cu + 2H_2O$, crystallises in blue, flattened needle clusters which yield water and alcohol at 100°. The *hydrochloride* of the ethyl α-salt, $C_6H_{11}NO_4,HCl$, is a white, crystalline mass readily soluble in water, little soluble in alcohol. The aqueous solution of the ethyl α-salt is optically inactive.

Inactive asparagine, $COOH{\cdot}CH_2{\cdot}CH(NH_2){\cdot}CONH_2$, is prepared by heating the ethyl α-salt with alcoholic ammonia for five to six hours. The solution is concentrated at first at a low temperature, then in a vacuum, the residue dissolved in a little water, precipitated with alcohol, and recrystallised from water. Thus obtained, it forms a mass of lustrous plates containing 1 mol. H_2O, which become opalescent but do not melt at 118—120°, yellow-coloured at 200°, and are completely decomposed at 215°. α-Asparagine is readily soluble in hot water, somewhat soluble in cold water, nearly insoluble in alcohol and ether. It is acid, and liberates acetic acid from its salts. Magnesia does not decompose it, but with 30 per cent. potash, ammonia is evolved. In a vacuum, or at 100°, it loses its water of crystallisation. Addition of cupric acetate to the aqueous solution precipitates after a time the salt $(C_4H_7N_2O_3)_2Cu + 2H_2O$, in small, light blue, transparent masses of prisms. The *hydrochloride*, $C_4H_8N_2O_3,HCl$, is a crystalline, deliquescent mass. By boiling with hydrogen chloride (2 mols.) and subsequent treatment with ammonia (1 mol.), the (inactive) α-asparagine, like the two active asparagines, is changed to inactive aspartic acid.

According to L. Brugnatelli, α-asparagine crystallises in the triclinic system. $a : b : c = 1\cdot5959 : 1 : 0\cdot5668$; $\alpha = 91° 19$, $\beta = 113° 12'$, $\gamma = 83° 48'$. J. W. L.

Constitution of the Monethyl Aspartates and the Asparagines. By A. Piutti (*Chem. Centr.*, 1888, 1460).—In order to determine the constitution of the monethyl aspartates and the asparagines, the author prepared the corresponding ethyl oximidosuccinates, and compared them with the ethyl α-oximidosuccinate,

$$COOH\cdot CH_2\cdot C(NOH)\cdot COOEt,$$

of Ebert. One of these ethyl salts is prepared by treating the oxime of ethyl oxalacetate with sodium ethoxide in alcohol, evaporating the mixture in a vacuum, and decomposing the residue with the calculated quantity of sulphuric acid. The salt is reduced with sodium-amalgam in alcohol in presence of acetic acid, and the copper salt of monethyl aspartate precipitated with cupric acetate. The salt has the formula $(C_6H_{10}NO_4)_2Cu + 2H_2O$, is crystalline, insoluble in water, and from it the ethyl salt, melting at 165°, is obtained. The *ethyl oximidosuccinate* derived from this differs from that obtained by Ebert, the melting point of the former being 54·7°, that of the latter 110—111°. It crystallises in needles, is somewhat soluble in water, readily so in alcohol, ether, and chloroform, little soluble in benzene and light petroleum, and does not give ethyl α-nitrosopropionate when its solution is heated, as is the case with that of Ebert's salt. With ferric chloride, an intense violet coloration is produced.

In the solution of the ammonium salt, mercuric salts produce white precipitates, which become forthwith reduced. The barium salt is white, and crystallises from acetic acid. If melted in a vacuum or over sulphuric acid, the *anhydride* $C_6H_7NO_4$ is formed.

The *silver* salt, $C_6H_8AgNO_5$, forms needles and leaves; it is sparingly soluble in water, not affected by the light, and readily decomposed by heat. It also loses 1 mol. H_2O when heated or when placed in a vacuum over sulphuric acid. With methyl iodide, the oxime of ethyl oxalacetate is not regenerated, the *anhydride*, $C_8H_{12}NO_4$, being formed. This boils at about 160° under 40 mm. pressure. With ammonia, the *amide*, $C_6H_8N_2O_3$, melting at 166—167° is formed, whereas the oxime of ethyl oxalacetate with ammonia forms the amide, $C_4H_7N_3O_3$, melting at 184°.

By reducing ethyl α-oximidosuccinate with 5 per cent. sodium-amalgam, inactive aspartic acid is produced in the aqueous solution, and monethyl aspartate melting at 165° in the acetic acid solution. The latter has therefore the formula $COOH{\cdot}CH_2{\cdot}CH(NH_2){\cdot}COOEt$. Since the ethyl oximidosuccinate (m. p. 54·7°) also yields monethyl aspartate (m. p. 165°), it probably has the constitution

$$OH{\cdot}N\left\langle\begin{array}{l}CH{\cdot}COOH\\ \,|\\ CH{\cdot}COOEt\end{array}\right. .$$

The *inactive* asparagine obtained from the ethyl aspartate (m. p. 165°) has therefore the constitution $COOH{\cdot}CH_2{\cdot}CH(NH_2){\cdot}CONH_2$. The ethyl aspartate, melting point 200°, has accordingly the formula $COOH{\cdot}CH(NH_2){\cdot}CH_2{\cdot}COOEt$, and the *active* asparagine the formula $COOH{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CONH_2$. This result confirms that obtained by Guareschi (this Journal, 1876, i, 457) for the lævorotatory common asparagine, and shows that the dextrorotatory asparagine is its physical isomeride. J. W. L.

Derivatives of Maleïnimide. By G. Ciamician and P. Silber (*Ber.*, 22, 33—35).—The salt $C_4HN_2O_5K$ separates in light-yellow crystals, when a dilute alcoholic solution of dichloromaleïnimide (5 grams) is warmed with potassium nitrite (15 grams) for four hours. It is almost insoluble in cold water, explodes slightly when heated, and is converted into oxalic acid when treated with stannous chloride and hydrochloric acid. When a warm, aqueous solution is mixed with dilute sulphuric acid, the salt separates unchanged, but if the mixture is boiled for a long time, the solution becomes colourless, and oxalic acid is obtained. The constitution of this salt is probably

$$NH\left\langle\begin{array}{l}CO{\cdot}C{\cdot}NO_2\\ \quad\ \ \|\\ CO{\cdot}C{\cdot}OK\end{array}\right. .$$

The compound  $NHPh{\cdot}C\left\langle\begin{array}{l}CCl{\cdot}CO\\ \quad\quad\ |\\ \ CO{\cdot}NH\end{array}\right.$ is obtained when an alcoholic solution of the imide (3 grams) is boiled with aniline for 15 minutes. It crystallises from alcohol in yellow needles melting at 196°.

Dichloromaleïnimide also combines with phenylhydrazine in alcoholic solution, yielding an orange-red, crystalline compound. F. S. K.

Constitution of Carbopyrotritartaric Acid. By L. Knorr (*Ber.*, 22, 146—152).—According to Fittig, carbopyrotritartaric acid has the unsymmetrical formula  $CO\left\langle\begin{array}{l}-CH{:}CMe-\\ CH(COOH)\end{array}\right\rangle CH{\cdot}COOH$, whilst the author ascribes to it the constitution  $O\left\langle\begin{array}{l}CMe{:}C{\cdot}COOH\\ \quad\quad\ \ |\\ CMe{:}C{\cdot}COOH\end{array}\right.$. The correctness of this symmetrical formula is shown by the fact that the acid yields only one ethyl hydrogen salt and only one pyrotritartaric acid. (Compare next Abstract.) N. H. M.

Carbopyrotritartaric Acid. By L. Knorr and W. Cavallo (*Ber.*, 22, 153—158).—Diethyl carbopyrotritartrate (Abstr., 1885, 248) is a colourless, strongly refractive oil, boiling at 275·5° (under 735 mm. pressure). Alcoholic potash hydrolyses it readily to carbopyrotritartaric acid, whilst aqueous potash converts it into Harrow's monethyl salt. *Silver ethyl carbopyrotritartrate*, $C_{10}H_{11}AgO_3$, forms a white, voluminous precipitate; when distilled, ethyl pyrotritartrate is formed. *Dimethyl carbopyrotritartrate*. $C_{10}H_{12}O_5$, prepared by heating the di-silver salt with methyl iodide at 100°, melts at 63—64°, boils at 258° under 756 mm. pressure, dissolves readily in the usual organic solvents, very sparingly in water. Cold concentrated hydrochloric acid converts it into the *methyl hydrogen salt*, $C_9H_{10}O_5$, which melts at 129°. The *silver methyl salt*, $C_9H_9AgO_5$, was prepared. When this is distilled, *methyl pyrotritartrate*, $C_8H_{10}O_3$, is formed; it boils at 192° under 759 mm. pressure.

Methyl ethyl carbopyrotritartrate, $C_{11}H_{14}O_5$, obtained by the action of methyl iodide on the silver ethyl salt, or by the action of ethyl iodide on the silver methyl salt, boils at 268° under 756 mm. pressure; it shows a blue fluorescence. On hydrolysis with fuming hydrochloric acid, methyl hydrogen and ethyl hydrogen carbopyrotritartrates are formed. N. H. M.

Derivatives of Ethyl Diacetosuccinate. By L. KNORR (*Ber.*, **22**, 158—168).—*Ethyl isocarbopyrotritartrate*, $C_{10}H_{12}O_5$, prepared by heating pure ethyl diacetosuccinate at 170—180°, melts at 110°, and distils at 280° under 15 mm. pressure. Ethyl pyrotritartrate and diethyl carbopyrotritartrate are also formed. It crystallises from water in slender needles, very sparingly soluble in water, readily in ether, chloroform, hot alcohol, and in alkali. It reduces gold and silver solutions in the cold, and gives a blue coloration with ferric chloride. It reacts with phenylhydrazine at the ordinary temperature, yielding bis-phenylmethylpyrazolone. When heated on a water-bath with hydroxylamine, bis-phenylmethylisoxazolone, $C_8H_8N_2O_4$, is formed. This is identical with the compound previously prepared by the action of hydroxylamine on ethyl diacetosuccinate (compare *Annalen*, **236**, 298; also Münchmayer, Abstr., 1886, 877; and Meyer, *Ber.*, **21**, 1361).

Isocarbopyrotritartaric acid, $C_8H_8O_5$, is obtained by boiling the ethyl salt with 20 per cent. soda solution (8 parts) for 5—10 minutes, cooling with ice and pouring into dilute (1 : 4) sulphuric acid. It melts at 200—209° (according to the rate at which it is heated), with evolution of carbonic anhydride, and formation of two compounds melting respectively at 175° and 60°. The *barium salt*, $C_{16}H_{14}O_5Ba + 2H_2O$, separates in slender aggregates of crystals. When the acid is heated with water at 110—120°, it is converted into acetonylacetone (Paal, Abstr., 1885, 505); the decomposition takes place at 100°.

N. H. M.

Hydrolysis of Ethyl Diacetosuccinate: Acetonylacetone and Diacetosuccinic Acid. By L. KNORR (*Ber.*, **22**, 168—172).—Acetonylacetone is readily prepared by keeping ethyl diacetosuccinate with a slight excess of 30 per cent. aqueous soda for some days at the ordinary temperature. The solution is saturated with ignited potassium carbonate, when the acetonylacetone separates as an oil, which is extracted with ether and distilled. It boils at 194° (under

754 mm. pressure). Sp. gr. = 0·9955 and 0·9945, compared with water at 11·6° and 19·1°. When the solution in acetic acid is heated to boiling with phenylhydrazine, phenylamidodimethylpyrroline is formed. This melts at 90—92°, and boils at 270° (not at 170°; Abstr., 1885, 995).

Diacetosuccinic acid is obtained as follows: the ethyl salt is kept with 25 per cent. aqueous soda (5 parts) for at least eight days at the ordinary temperature; it is then acidified and extracted with ether. The oily product is dried in a vacuum, the mass of crystals thus obtained washed with ether, and then crystallised from ether. It decomposes at about 160°, is soluble in water and alcohol, sparingly soluble in ether. It gives no coloration with ferric chloride, and has no reducing properties. Boiling water has no action on it. When heated with hydrochloric acid on a water-bath, it is converted into carbopyrotritartaric acid. The *barium salt*, $C_8H_8BaO_6$, was prepared.

N. H. M.

Substituted Pyromucic Acids. By H. B. Hill and A. W. Palmer (*Amer. Chem. J.*, **10**, 409—425; compare this vol., p. 37).—The β-sulphonic acids are prepared by sulphonating δ-bromopyromucic acid.

β-Sulpho-δ-bromopyromucic Acid.—The sulphonation of δ-bromopyromucic acid proceeds regularly, and the product is purified by conversion into the acid barium salt, $Ba(C_5H_2BrSO_6)_2 + 4H_2O$, which forms large crystals, readily soluble in hot water, whilst the neutral salt, $BaC_5HBrSO_6 + 5H_2O$, is only sparingly soluble (2·68 per cent. at 20°). The free acid is crystalline, but deliquescent. The following salts are also described:—$CaC_5HBrSO_6 + 2H_2O$; $PbC_5HBrSO_6 + 1\frac{1}{2}H_2O$; $Ag_2C_5HBrSO_6 + 2H_2O$, and $K_2C_5HBrSO_6$. By treating the barium salt with bromine in the requisite quantity, the barium salt of *αα-dibromofurfuran-β-sulphonic acid*, $Ba(C_4HBr_2SO_4)_2H_2O$, is readily obtained; both it and the potassium salt, $KC_4HBr_2SO_4$, are crystalline and readily soluble; by using more bromine, or by again treating these first products, the salts of *sulphofumaric acid* are obtained; of these the barium, lead, and silver salts are very sparingly soluble in water, the potassium and calcium salts are very soluble, and neither the salts nor the free acid could be obtained in the crystalline form. Only the barium and silver salts were analysed, $Ba_3(C_4HSO_7)_2 + xH_2O$ and $Ag_3C_4HSO_7 + xH_2O$. Nitric acid also converts β-sulpho-δ-bromopyromucic acid into sulphofumaric acid, but sometimes this suffers decomposition, yielding oxalic acid. Fusion with potash gives nothing but oxalic acid. Zinc-dust and ammonia convert β-sulpho-δ-bromopyromucic acid or its barium salt into *β-sulphopyromucic acid*, which is purified by means of its acid barium salt, $Ba(C_5H_3SO_6)_2 + 3H_2O$; the salts $BaC_5H_2SO_6 + 3H_2O$, $CaC_5H_2SO_6 + 2H_2O$, and $K_2C_5H_2SO_6 + 2\frac{1}{2}H_2O$ are also described; they are all crystalline.

Attempts to prepare a γ-sulphopyromucic acid by acting with fuming sulphuric acid on β-δ-dibromopyromucic acid were of no avail, as only monobromomaleic acid is formed; and similarly tribromopyromucic acid yields only a dibromomaleic acid.

H. B.

Physical Properties of Benzene and Thiophen. By G. CIAMICIAN (*Ber.*, **22**, 27—30).—Horstmann (Abstr., 1888, 1069) has shown that the contradictory results obtained when attempts are made to deduce the constitution of benzene from a study of its physical properties, can be explained in a satisfactory manner if the formula recently advanced by Baeyer is accepted. He compared the heat of combustion of benzene with that of hexane, and found that the difference ($4H_2$) is four times as great as the difference between the heat of combustion of methane and methylene (CH_2), and is equal to 211·7 Cals. The author points out that the difference in the heat of combustion of ethyl sulphide and thiophen is equal to $3H_2$, namely, 158·8 Cals. According to R. Schiff, the molecular volume of benzene is 95·94, that of the C_4H_4-group is therefore 95·94 × $\frac{2}{3}$ = 63·96. Now since the molecular volume of thiophen is 84·93, the atomic volume of sulphur is 84·93—63·96 = 20·97, and if this value is taken instead of 22·6, as determined by H. Kopp (*Annalen*, **96**, 303), the calculated molecular volume of ethyl mercaptan, amyl mercaptan, ethyl sulphide, and methyl sulphide, are more in accordance with the observed results. Taking the value for the molecular refractive energy of benzene determined by Brühl, $p\frac{\mu_a - 1}{d} = 44·03$, and $p\frac{\mu^2_a - 1}{(\mu^2_a + 2)d} = 25·93$, and taking that of thiophen determined by Nasini, $p\frac{\mu_a - 1}{d} = 41·40$, and $p\frac{\mu^2_a - 1}{(\mu^2_a + 2)d} = 24·13$, it follows that the molecular refractive energy of the C_4H_4-group is $p\frac{\mu_a - 1}{d} = 29·39$, and $p\frac{\mu^2_a - 1}{(\mu^2_a + 2)d} = 17·28$. The atomic refractive energy of sulphur is therefore 12·04 and 6·85. The values found by Nasini being 14·10 and 7·87 in compounds containing singly-bound sulphur, and 15·61 and 9·02 in carbon bisulphide and compounds containing doubly-bound sulphur.

These considerations seem to show that the constitution of the C_4H_4-group in the thiophen molecule is similar to that of the same group in benzene.

F. S. K.

Nitration. By L. MEYER (*Ber.*, **22**, 18—23. Compare also p. 341). —The quantity of nitrobenzene formed in a given time by the action of a given volume of nitric acid on benzene is greater the less the quantity of benzene present; for example, 100 mols. of nitric acid and 100 mols. of benzene yield 17 mols. of nitrobenzene in 15 minutes at 3°; but when 300 mols. of benzene are employed, the quantity of nitrobenzene produced is 10·02, and when 700 mols. of benzene are used, only 3·6 mols. of nitrobenzene are produced in the same time under exactly similar conditions. The results are similar when small quantities of benzene mixed with a constant quantity of nitrobenzene are treated with a constant quantity of nitric acid. A mixture of 100 mols. of nitric acid and 5 mols. of benzene diluted with 100 mols. of nitrobenzene yielded 4·4 mols. of nitrobenzene in 15 minutes at 3°; as the quantity of benzene was gradually increased from 5 to 100 mols., the quantity of nitrobenzene formed in the same time and under the same conditions gradually decreased from 4·4 to 2·2 mols.

When a mixture of 100 mols. of benzene and 100 mols. of nitrobenzene is treated with quantities of nitric acid varying from 50 to 450 mols., the quantity of nitrobenzene produced in 15 minutes at 3° is proportional to the square of the quantity of the acid employed. The quantity of acid decomposed is almost proportional to the quantity added, the increase being about 2 55 per cent. on the average for every additional 50 mols. of acid. The quantity of nitrobenzene produced in 15 minutes at 3° is expressed very closely by the formula $N = 5 \cdot 1(A/B)^2 - 2 \cdot 9A/B$, where A is the number of molecules of acid, and B the number of molecules of benzene in the mixture.

Nitrobenzene retards the reaction between nitric acid and benzene far more than benzene does, and even to a greater extent than an equivalent quantity of water, but less than an equal volume of water. As soon as the volume of water produced becomes equal to that of the anhydrous acid present, the reaction ceases, so that at least 2 mols. of acid are required to nitrate 1 mol. of benzene unless sulphuric acid is also added. If the proper quantity of anhydrous acid is employed in nitrating benzene, equilibrium is established very soon even in the cold, but if the acid is not quite anhydrous, or if excess of benzene or nitrobenzene is present, hours or even days are required to complete the reaction, and in any case the nitration, which is most rapid at first, gradually decreases. For example, with a mixture of equal molecules of nitric acid, benzene, and nitrobenzene at the average temperature of 18°, the reaction was not finished until after 71 hours' time; 50 per cent. of the benzene had by this time been changed, but even then there was a slight subsequent reaction. A table is given showing the quantity of acid decomposed after various lengths of time, when quantities of benzene varying from 25 to 150 mols. are added to a mixture of 100 mols. of nitric acid and 100 mols. of nitrobenzene. The table shows that in the experiments with 25 mols. of benzene the conversion into nitrobenzene is complete in half an hour, and that then the formation of dinitrobenzene commenced. In the other experiments, the reaction proceeded at first the more quickly the smaller the quantity of benzene present, this difference gradually becoming less and less the nearer the process reached the point at which half the acid is decomposed.

F. S. K.

Orthodiethylbenzene. By A. Voswinkel (*Ber.*, **21**, 3499—3501).—*Orthodiethylbenzene*, $C_6H_4Et_2$, is prepared by the action of sodium on a well-cooled mixture of orthodichlorobenzene and ethyl bromide; in 12 hours the reaction is finished. The product is distilled and purified by conversion into the sulphonamide, &c. It is a colourless liquid, of a slightly aromatic odour, boils at 184—184·5°, and becomes viscid at −20°; sp. gr. = 0·8662 at 18° (water at 4° = 1). Aqueous alkaline permanganate solution oxidises it to orthophthalic acid. *Barium diethylbenzenesulphonate*, $(C_{10}H_{13} \cdot SO_3)_2Ba + H_2O$, crystallises in concentrically grouped prisms rather readily soluble in water; the *potassium salt* is very readily soluble in water. The *sulphonamide*, $C_{10}H_{13}\cdot SO_2NH_2$, crystallises from dilute alcohol in colourless, rhombic plates melting at 119°. *Tetrabromorthodiethylbenzene*, $C_6Et_2Br_4$, crystallises from alcohol in colourless prisms melting at 64·5°. N. H. M.

Creolin. By T. WEYL (*Ber.*, **22**, 138—139).—Two preparations known as creolin were examined, with the following result:—Artmann's creolin is a dark-brown oil of a sharp odour, which forms an emulsion with water; when cooled, crystals of naphthalene separate. It contains 84·9 per cent. of hydrocarbons, 3·4 per cent. of phenols, 1·5 per cent. of acids, and 0·8 per cent. of sodium. Pearson's creolin is easily distinguished from the above in being readily soluble in ether. It contains hydrocarbons, 56·9 per cent.; phenols, 22·6 per cent.; acids, 0·4 per cent.; and sodium, 2·4 per cent. These two preparations were used medicinally, notwithstanding that their composition or freedom from poisonous constituents was not known. N. H. M.

Metacresols. By A. CLAUS and J. HIRSCH (*J. pr. Chem.* [2], **39**, 59—64).—2 : 4 : 6-*Tribromometacresol* is formed when bromine acts on a chloroform solution of metacresol in presence of iron; it forms colourless crystals melting at 82° (uncorr.). Its *potassium* and *sodium* salts are described. The *ethyl ether* forms colourless aggregates of needles melting at 36° (uncorr.), and the *acetate* melts at 68° (uncorr.). When it is oxidised by chromic acid in strong acetic acid solution, several bromotoluquinones are formed, but in weaker acetic acid (50 per cent.) 2 : 6-*dibromotoluquinone* is obtained in lustrous, yellow crystals melting at 115° (uncorr.), soluble in ordinary solvents and distilling with steam. When reduced, it yields 2 : 6-*dibromotoluquinol*, which crystallises in small, colourless needles or large, monosymmetrical tables melting at 117° (uncorr.), and becoming brown on exposure to light.

Nitrodibromometacresol, [Br : Br = 2 : 6], obtained by acting on a cold glacial acetic acid solution of tribromometacresol with nitric acid (sp. gr. 1·4), crystallises in yellow, lustrous needles, melting with decomposition at 143° (uncorr.), insoluble in water, easily soluble in alcohol and chloroform. The *potassium* and *sodium* salts are described.

Bromometacresyl acetate is obtained by brominating metacresyl acetate as colourless, lustrous needles melting at 83° (uncorr.); it yields bromometacresol on hydrolysis.

The nitrocresol (m. p. 56°, Abstr., 1883, 662) yields a *nitrodibromocresol* which crystallises in yellow needles melting at 93° (uncorr.), whereas the nitrocresol of melting point 127° (uncorr.) yields the nitrodibromometacresol described above, so this latter nitrocresol is *paranitrometacresol*. A. G. B.

Derivatives of Hydroxyquinol. By W. SCHWEITZER (*Chem. Centr.*, 1888, 1434).—Methoxyquinone combines with aniline to form *methoxyquinone anilide*, $OMe\cdot C_6H(NHPh)_2O_2$; this dissolves in concentrated sulphuric acid to a dark-blue solution, sublimes in copper-coloured needles, and melts above the boiling temperature of sulphuric acid.

Methoxyquinone anisidide, $OMe\cdot C_6H(NH\cdot C_6H_4\cdot OMe)_2O_2$, forms purple-red needles.

Methoxyquinone orthotoluidide, $OMe\cdot C_6H(NH\cdot C_6H_4Me)_2O_2$, of a brown colour, melts at 239°; the *paratoluidide* shows the red colour of the anisidide, and the *ortho-xylidide* forms brown needles similar to the orthotoluide, and melts at 228°; the *diphenylamide*, $OMe\cdot C_6H(NPh_2)_2O_2$, forms dark-blue flakes, and melts at 120°.

Tribromomethoxyquinone, $OMe\cdot C_6Br_3O_2$, prepared by the action of bromine on methoxyquinone, melts at 169° and forms red needles. *Dinitromethoxyquinone*, $OMe\cdot C_6H(NO_2)_2O_2$, prepared by the action of nitric acid on the quinone, forms light-yellow needles melting at 213°. *Methoxyquinol*, $OMe\cdot C_6H_3(OH)_2$, melting at 194°, is prepared by reducing the quinone with sulphurous acid, and forms light-grey prisms. The presence of a methyl-group was determined by the application of Zeisel's reaction.

Trimethoxybenzene, $C_6H_3(OMe)_3$ [1 : 2 : 4], is an oil boiling at 247°. *Dinitrotrimethoxybenzene*, melting at 131°, is formed from the last-named compound, and crystallises in brownish-yellow needles. It is identical with the compound obtained from asarone by Butlerow and Rizza (Abstr., 1888, 458). J. W. L.

Products of Decomposition of Chlor-, Brom-, and Nitr-anilic Acids. By S. Levy and K. Jedlicka (*Annalen*, **249**, 66—98).—The action of bromine on chloranilic and bromanilic acids has been previously described by the authors (Abstr., 1887, 1106). When nitranilic acid is treated with chlorine or bromine, oxalic acid and chloropicrin or bromopicrin are formed. The action of chlorine on chloranilic acid has already been described (Abstr., 1888, 443).

W. C. W.

Pentamidotoluene. By A. W. Palmer (*Ber.*, **21**, 3501—3502).—*Trinitrodibromotoluene*, $C_6MeBr_2(NO_2)_3$, obtained by boiling symmetrical dibromotoluene (m. p. 39°) with a mixture of sulphuric and nitric (sp. gr. = 1·52) acids (equal vols. 20 parts), crystallises from alcohol in long, pale-yellow prisms melting at 229—230°.

Trinitrodiamidotoluene, $C_6Me(NO_2)_3(NH_2)_2$, is prepared by heating the above compound with alcoholic ammonia in a water-bath for eight hours; the product is washed with cold alcohol and crystallised from boiling alcohol. It forms small, yellow prisms melting at 222°.

Pentamidotoluene, $C_6Me(NH_2)_5$, is formed when trinitrodiamidotoluene is reduced with tin and hydrochloric acid; the tin salt is precipitated by saturating the liquid with hydrogen chloride, and is then decomposed with hydrogen sulphide. The filtrate from the tin sulphide is precipitated by passing hydrogen chloride through it, the hydrochloride washed with hydrochloric acid and ether, and dried first over soda-lime and afterwards at 100°. The *hydrochloride*, $C_6Me(NH_2)_5,3HCl$, forms white, microscopic prisms, very readily soluble in water, sparingly in alcohol; the crystals became quickly dark when exposed to air; the *sulphate* is readily soluble in water;

the *platinochloride*, $[C_6Me(NH_2)_5]_2,3H_2PtCl_6$, forms black crystals. The *picrate* forms a yellow, crystalline precipitate. N. H. M.

Metaxylylamidomethane. By W. HINRICHSEN (*Ber.*, **22**, 121—124; compare this vol., p. 131).—Dimethylbenzaldehyde (metaxylobenzaldehyde) is best prepared by oxidising the alcohol in the cold. It boils at 215—216° (not 232°), and when kept for some time in alcohol cooled to —40° solidifies to a crystalline mass, which melts at —9° to —8°. When heated with dilute nitric acid, xylylic acid is formed.

Metaxylylbenzamidomethane, $C_9H_{11}\cdot NHBz$, is obtained by treating xylylamidomethane (2 grams) with benzoic chloride (2 grams), heating the product for a short time on a water-bath, neutralising, and extracting twice with hot water. The undissolved substance is crystallised from alcohol, from which it separates in matted needles. It melts at 98°, dissolves readily in alcohol and benzene, &c., very sparingly in water

Dimethylbenzylcarbamide, $C_6H_2Me_2\cdot CH_2\cdot NH\cdot CONH_2$, is formed by the action of potassium cyanate on a concentrated aqueous solution of xylylamidomethane hydrochloride; the mixture is afterwards heated on a water-bath to finish the reaction. It crystallises from alcohol in slender needles, melts at 184·5°, and is rather sparingly soluble in water. The *thiocarbamide*, $CS(NH\cdot C_9H_{11})_2$, is prepared by adding carbon bisulphide (4·5 grams) to xylylamidomethane (10 grams), dissolved in alcohol, and heating the product for about 10 hours on a water-bath until no more carbon bisulphide is given off. It crystallises from hot alcohol in lustrous needles melting at 176—177°.

Dimethylbenzyl isothiocyanate, $CS{:}N\cdot C_9H_{11}$, was prepared by boiling the carbamide with syrupy phosphoric acid (3 parts) in a reflux apparatus. The yield was bad, and the product was not analysed.

Dimethylbenzyl acetate, $C_9H_{11}\cdot OAc$, obtained by treating metaxylyl carbinol (2 grams) with acetic chloride (4 grams), forms a clear liquid of an aromatic odour, and boils at 230—234° with slight decomposition. The *benzoate*, $C_9H_{11}\cdot OBz$, is a yellow oil boiling at 332—333°.

N. H. M.

Dibenzamidodihydroxytetrene. By L. RÜGHEIMER (*Ber.*, **22**, 114—118).—When dibenzamidodihydroxytetrene (this vol., p. 249) is boiled with water and lead carbonate, the *lead salt*, $C_{18}H_{12}N_2O_4Pb$, is formed; it is a sparingly soluble, crystalline substance. The *calcium salt*, $(C_{18}H_{13}N_2O_4)_2Ca$, crystallises in microscopic prisms, sparingly soluble in water. The normal *calcium salt*, obtained by treating the very concentrated ammoniacal solution of dibenzamidohydroxytetrene with calcium chloride, is extremely soluble in water. When a solution of dibenzamidodihydroxytetrene in methyl alcohol (10 parts) is saturated with hydrogen chloride, the compound $C_{11}H_{10}N_2O_3$ is formed. This crystallises from methyl alcohol in lustrous plates, melts at 200° with partial decomposition, and is moderately soluble in cold methyl alcohol. The compound has probably the constitution

, or or

.

Two Isomeric Azoxytoluenes Derived from Paranitrotoluene. By J. V. Janovsky and K. Reimann (*Ber.*, 22, 40—45).—When the crude product of the action of zinc-dust and soda on pure paranitrotoluene is dissolved in a large quantity of hot, glacial acetic acid, parazotoluene (m. p. 144°) alone separates on cooling; if the mother-liquor is evaporated, a mixture of several substances is obtained, from which, by recrystallisation from alcohol, a red substance (m. p. 109—110°) very similar to azotoluene is first obtained, then an orange-yellow, crystalline substance melting at 75°, then the azoxytoluene (m. p. 70°) obtained by Melms (*Ber.*, 3, 549); and finally, on adding water, the crystalline hydrazotoluene (m. p. 126°) already prepared by Werigo, is precipitated. The compound melting at 75°, and that melting at 70°, both have the composition $C_{14}H_{14}N_2O$, and determinations of their molecular weight by Raoult's method show that they are isomeric. They are named by the authors β-azoxytoluene and α-azoxytoluene respectively.

β-Azoxytoluene can also be obtained by oxidising parazotoluene with a small quantity of fuming nitric acid in glacial acetic acid solution. It crystallises in orange-yellow needles or prisms.

α-Azoxytoluene crystallises in pale yellow needles or plates, and is more readily soluble than the β-compound.

Azoxytoluenesulphonic acid is obtained when α-azoxytoluene is gradually added to a mixture of sulphuric acid and sulphuric anhydride, and the mixture heated at 80—90°. It is a brownish-red, amorphous mass, with a metallic lustre. The *potassium* salt and the *sodium* salt crystallise in golden plates. The *barium* salt, *lead* salt, and *silver* salt are sparingly soluble.

β-Azoxytoluene yields a disulphonic acid under the same conditions; the *potassium* salt of this acid crystallises in needles, the other salts are very readily soluble, and are not easily obtained in crystals.

α- and β-azoxytoluene appear to yield the same nitro-compound (m. p. 194—196°) when treated with fuming nitric acid, but acid of sp. gr. 1·41—1·45 reacts differently with these two substances.

When treated with bromine, the two azoxytoluenes yield several products, two of which seem to be identical. F. S. K.

Derivatives of Phenylhydrazine. By L. Marckwald (*Chem. Centr.*, 1888, 1410).—A mixture of ethylene bromide and phenylhydrazine in molecular proportion, when heated with an equal volume of alcohol in a reflux apparatus, yields, in addition to benzene, aniline hydrobromide and ammonium bromide, a base, $C_{16}H_{20}N_4$, melting at 178°; as this, when reduced by zinc-dust and acetic acid, gives a basic mixture containing aniline, the author infers that the constitution of the base is $(C_2H_4)_2(N_2HPh)_2$. Trimethylene bromide and phenylhydrazine, when submitted to similar treatment, give a substance of the formula $C_9H_{12}N_2$, melting at 52—53°. By heating it with trimethylene bromide in an oil-bath, a compound, $(PhN_2)_2(C_3H_6)_3$, melting at 224—226°, is formed.

Benzenyldiphenylazidine, $C_{19}H_{16}N_4$, prepared from benzotrichloride and phenylhydrazine, melts at 178—180°; it dissolves in alcoholic hydrogen chloride, and on evaporating the solution the hydrochloride is obtained as a colourless oil. When heated with carbon bisulphide at 100°, a compound melting at 136° is formed; by heating in hydrogen sulphide at 160—166° ammonia is liberated and a compound, $C_{38}H_{33}NS$, is obtained, melting at 62°. From the analysis of the platinochloride, it would seem to be bibasic. Plumbic oxide desulphurises it, and the product melts at 96°.

Phenylhydrazine and sulphocarbanilide, when boiled with plumbic oxide until completely desulphurised, yield *anildiphenylguanidine*, melting at 138—139°. This base dissolves in alcohol and becomes coloured superficially red, owing to oxidation. A bluish-black dye is found in the alcoholic mother-liquor, which is also formed from phenylhydrazine, diphenylsemicarbazide, and plumbic oxide, and has the formula PhNC·N·NPh·NH·NHPh. J. W. L.

Condensation-products of Hydrazine with Aldehydes. By T. Curtius and R. Jay (*J. pr. Chem.*, **39**, 43—58).—*Benzalazine*, $N_2(CHPh)_2$, prepared by the action of benzaldehyde on crude hydrazine sulphate (see p. 340), crystallises from hot alcohol in long, lustrous, bright yellow, anisotropic prisms which melt at 93°, are insoluble in water and soluble in other solvents. It is decomposed by heat into nitrogen and stilbene, a secondary product of the formula $N_2(CHPh)_3$, melting at 78°, being also formed. The molecular formula of benzalazine has been established by Raoult's method. By reducing an alcoholic solution of benzalazine with sodium, benzylamine is formed; but if sodium amalgam is used, dibenzylhydrazine is formed.

Dibenzylhydrazine hydrochloride, $N_2H_2(CH_2Ph)_2,HCl$, crystallises from hot alcohol in small, lustrous, biaxial tables, melting at 140°, and very soluble in water.

Orthohydroxybenzalazine, $N_2(CH{\cdot}C_6H_4{\cdot}OH)_2$, is prepared by the action of salicylaldehyde on hydrazine salts; it crystallises in tables, insoluble in water and cold alcohol, and melts at 205°.

Orthonitrobenzalazine, $N_2(CH{\cdot}C_6H_4{\cdot}NO_2)_2$, prepared from orthonitrobenzaldehyde and hydrazine salts, crystallises in aggregates of bright-yellow needles melting at 181°.

Cinnamylidenazine, $[C_6H_5(CH)_3]_2N_2$, crystallises in long, yellow clinobasic tables melting at 162°. A condensation product of glyoxal and hydrazine has also been obtained.

Methylpyrazolone,  $CH_2<\begin{matrix}CMe{:}N\\ |\\ CO{\cdot}NH\end{matrix}$, is obtained when ethyl acetoacetate acts on hydrazine hydrate; it crystallises from water in vitreous prisms, and from alcohol in needles. It melts at 215°, sublimes unchanged in laminæ, tastes sweet, and dissolves in both acids and alkalis.

Symmetrical and asymmetrical azinsuccinic acids and their salts have been described before (Abstr., 1885, 885, 886). A. G. B.

Additive Compounds of Cyanic Acid. By W. Traube (*Chem. Centr.*, 1888, 1435).—*Benzyl allophanate*, $NH_2{\cdot}CO{\cdot}NH{\cdot}COO{\cdot}C_7H_7$, prepared by passing cyanic acid into an ethereal solution of benzyl alcohol, melts at 183°. With benzyl alcohol, it forms *benzylurethane*, $NH_2{\cdot}COO{\cdot}C_7H_7$, melting at 83° and boiling at 235°; this forms substituted ethereal salts of allophanic acid with substituted salts of isocyanic acid. *Benzyl monophenylallophanate*, $NHPh{\cdot}CO{\cdot}NH{\cdot}COO{\cdot}C_7H_7$, melts at 158°. *Resorcinyl allophanate*, $NH_2{\cdot}CO{\cdot}NH{\cdot}COO{\cdot}C_6H_4{\cdot}OH$, formed by the action of resorcinol on cyanic acid, melts at 120° with partial decomposition. A similar but more feeble reaction takes place with quinol. *Hydroxyphenylcarbamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}OH$, is prepared from cyanic acid and orthoamidophenol. *Ethyl allophanyl-α-lactate*, $NH_2{\cdot}CO{\cdot}NH{\cdot}COO{\cdot}CHMe{\cdot}COOEt$, melting at 170°, is prepared from cyanic acid and ethyl α-lactate, from which the free *allophanyl-α-lactic acid*, melting at 190°, is obtained by hydrolysis with hydrogen chloride. The silver and lead salts were prepared, also the amyl salt. *Ethyl allophanylglycollate* melts at 144°, and is not identical with the compound obtained by Saytzeff from chloracetic acid. The free acid melts at 192°. *Diethyl allophanyltartrate*, $C_{10}H_{16}O_8N_2$, melts at 188°; the free acid is a syrup, and is bibasic. J. W. L.

Oxidation of Benzene-derivatives with Potassium Permanganate. By W. A. NOYES (*Amer. Chem. J.*, **10**, 472—487; compare Abstr., 1886, 142; also Niementowski, Abstr., 1888, 873; and Niementowski and Rozanski, *ibid.*, 1088).—*β-Nitroparatoluic acid*,

$$NO_2{\cdot}C_6H_3Me{\cdot}COOH,$$

is formed when nitro-xylene (4 to 7 c.c.) is boiled for 3—4 hours with potassium ferricyanide (100 grams), potash (40 grams), and water (400 c.c.). The yield is not good, and the acid is best prepared as follows: nitroparatoluidine, obtained by Gattermann's method (*Ber.*, **18**, 1482), slightly modified, is converted into the cyanide, as described by Sandmeyer (*Ber.*, **18**, 1492), using a somewhat large amount of potassium cyanide to prevent the separation of cuprous cyanide at the end of the reaction. The cyanide crystallises in slender needles, melts at 100°, and is moderately soluble in alcohol, readily in ether. The cyanide is heated with strong hydrochloric acid (15 parts) at 150—160°, and the acid which separates is purified by dissolving in dilute ammonia, precipitating with hydrochloric acid, and crystallising from hot water. It forms slender needles, melts at 164—165° (corr.), and dissolves readily in hot water, alcohol, and ether. The *copper salt* (with 1 mol. H_2O) forms bright green, microscopic crystals, almost insoluble in water. The *barium salt* (with 5 mols. H_2O) separates in hemispherical groups of crystals readily soluble in water; the *calcium salt* (with 2 mols. H_2O) separates as a network of needles, much less soluble than the barium salt.

β-Amidoparatoluic acid, $NH_2{\cdot}C_6H_3Me{\cdot}COOH$, prepared by reducing the nitro-acid with tin and hydrochloric acid, crystallises in fine plates, usually brownish, melts at 177—178° (corr.) with decomposition, dissolves sparingly in water, readily in alcohol. The aqueous solution shows a bluish-violet fluorescence, which disappears on adding strong acid, and reappears on adding ammonia. The *barium salt* (with 4 mols. H_2O) crystallises in brown leaflets, very sparingly soluble in water; the *calcium salt* (with 2 mols. H_2O) separates in slightly brown scales; the *copper salt* is a light green, amorphous substance, almost insoluble in water. When the acid is dissolved in dilute sulphuric acid and treated with potassium nitrite, hydroxyparatoluic acid, [Me : OH : COOH = 4 : 2 : 1], is formed.

α-Nitroparatoluic acid was prepared from nitroparatoluidine in a manner similar to the β-acid. The *copper salt*, $(NO_2{\cdot}C_6H_3Me{\cdot}COO)_2Cu + 4H_2O$, crystallises in bright blue needles; *copper salts* of the formulæ $(C_7H_6NO_2{\cdot}COO)_4Cu_3(OH)_2 + H_2O$ and $(C_7H_6NO_2{\cdot}COO)_5Cu_3{\cdot}OH + H_2O$, were also obtained.

In the preparation of nitroparatoluic acid by oxidising nitroparaxylene with potassium ferricyanide, two more substances were obtained. The one melted at 266—268°, and was evidently nitroterephthalic acid (m. p. = 270°), the other separated in well-formed plates, having the same composition as nitroterephthalic acid, with the addition of 2 mols. H_2O. Various attempts were made to obtain these plates in other ways, but with negative results. It is therefore probable that the water (which the substance loses on heating) is not water of crystallisation but of constitution, and that the substance has the formula $NO_2{\cdot}C_6H_3[C(OH)_3]_2$.

β-Nitroisophthalic acid, [COOH : COOH : NO_2 = 1 : 3 : 4], prepared by oxidising nitrometaxylene, melts at 257—259°; it seems to be identical with Beyer's acid, obtained by nitrating isophthalic acid (*J. pr. Chem.* [2], **22**, 352). The *barium salt* (with 1½ mol. H_2O) crystallises in slightly yellow needles. N. H. M.

γ- and δ-Isatropic Acids. By C. Liebermann and, in part, W. Drory and O. Bergami (*Ber.*, **22**, 124—130; compare Abstr., 1888, 1211).—When γ-isatropic acid is distilled, it is converted into cinnamic acid and a small quantity of a substance insoluble in alkali, probably dicinnamyl. Calcium cinnamate crystallises with 3 mols. H_2O, and does not give up 1 mol. H_2O at the ordinary temperature (compare Kopp, *Compt. rend.*, **53**, 634); the anhydrous salt dissolves in 430 parts of water at 19° (compare Kraut, *Annalen*, **147**, 112).

δ-Isatropic acid also yields cinnamic acid when distilled; but a larger amount of the insoluble product seems to be formed.

γ-Isatropic anhydride, $(C_9H_7O)_2O$, is prepared by heating the acid (3 parts) with acetic anhydride (10 parts) and sodium acetate (4 parts) on a water-bath. On adding light petroleum to the benzene solution, it crystallises in white needles melting at 191°.

ε-Isatropic acid, $C_9H_8O_2$, is formed when the anhydride is dissolved in alkali and precipitated with hydrochloric acid. It crystallises from very dilute alcohol in needles melting at 228° and closely resembles the γ-acid, being readily soluble in ether and very sparingly soluble in hot water. The *barium salt* is very readily soluble. The acid is converted into cinnamic acid when distilled. The acid is also obtained by heating the anhydride of the γ-acid with hydrochloric acid at 160°. The *methyl salt* crystallises in lustrous needles melting at 126°, and is rather soluble in cold methyl alcohol and glacial acetic acid. The acid yields an anhydride identical with that obtained from the γ-acid.

δ-Isatropic anhydride, $(C_9H_7O)_2O$, is purified by dissolving the dry substance in benzene, carefully precipitating the resinous impurity with light petroleum, and letting the filtrate evaporate spontaneously. It forms rhombic crystals, melts at 116°, and is readily soluble in the usual solvents except water. When dissolved in alkali and precipitated with acid, the δ-acid is again formed.

When γ-isatropic acid is heated with sulphuric acid (8 to 10 parts) for three hours at 80°, two isomeric sulphonic acids are formed; on diluting with water (5 parts) and evaporating, the one (*a*) crystallises in slender needles, whilst the other (*b*) remains dissolved. The acids are readily separated by means of the barium salts. *Barium sulpho-γ-isatropate* (*a*),  $C_8H_6<\substack{CO_2\\SO_3}>Ba + 2H_2O$, forms a crystalline powder, insoluble in alcohol, sparingly soluble in hot water, very readily in cold water. When the sulphonic acid is heated at 220° with fuming hydrochloric acid, it is converted, with partial decomposition, into an isomeride which seems to be identical with the acid (*b*). *Barium sulpho-γ-isatropate* (*b*) with 2 mols. H_2O is readily soluble in cold and in hot water.

Barium sulpho-δ-isatropate, $C_9H_6SO_5Ba + 2H_2O$, was also prepared.

N. H. M.

Paranitrophenylbutinecarboxylic Acid. By A. EINHORN and C. GEHRENBECK (*Ber.*, **22**, 45—47).—*Paranitrophenylbutinecarboxylic acid*, $NO_2{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH{:}CH{\cdot}COOH$, obtained from paranitrocinnamaldehyde by Perkin's reaction, crystallises from dilute alcohol in yellowish needles melting at 271°. It combines with bromine with development of heat, forming the *tetrabromide*, $NO_2{\cdot}C_6H_4{\cdot}[CHBr]_4{\cdot}COOH$, which crystallises from alcohol in plates melting at 254° with decomposition.

Paranitrophenylbutinedicarboxylic acid,

$$NO_2{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH{:}C(COOH)_2,$$

is formed by the condensation of paranitrocinnamaldehyde with malonic acid in glacial acetic acid solution. It crystallises in yellow needles melting at 208°.

Paranitrophenyldibromethylbromacrylic acid,

$$NO_2{\cdot}C_6H_4{\cdot}CHBr{\cdot}CHBr{\cdot}CBr{:}CH{\cdot}COOH,$$

is formed, with evolution of hydrogen bromide and carbonic anhydride, when the preceding compound is treated with excess bromine; it is also obtained, in the form of the *sodium* salt, when th tetrabromide described above is dissolved in sodium carbonate. crystallises from alcohol in plates and melts at 205—206°. Wh the sodium salt is warmed with alkaline carbonates, it loses 1 mol. H and is converted into a compound, probably *paranitrophenyldibrom butinecarboxylic* acid, $NO_2{\cdot}C_6H_4{\cdot}C_2HBr{\cdot}CBr{:}CH{\cdot}COOH$, which crystallises from glacial acetic acid in light yellow plates melting 242—244°.

Paran[illegible]yldihydrodibromobutinecarboxylic acid,

$$NO_2{\cdot}C_6H_4{\cdot}C_2BrH_3{\cdot}CHBr{\cdot}CH_2{\cdot}COOH,$$

is produced, with evolution of carbonic anhydride, when paranitrophenylbutinedicarboxylic acid is treated with hydrobromic acid; melts at 146—147°.

The lactone of *paranitrophenylbromethyllactic acid,*

$$NO_2\cdot C_6H_4\cdot C_2H_3Br<\begin{matrix}CH\cdot CH_2\\ -O\cdot CO-\end{matrix}>,$$

is obtained when the preceding compound is neutralised with sodium carbonate and the solution kept for some time. It crystallises in colourless plates melting at 146°. When dissolved in a mixture of alcohol and ethyl acetate and treated with excess of sodium carbonate in the cold, it is converted into the lactone of *paranitrophenylvinylhydroxypropionic acid*, $NO_2\cdot C_6H_4\cdot CH{:}CH<\begin{matrix}CH\cdot CH_2\\ -O\cdot CO-\end{matrix}>$, melting at 110—111° This lactone can also be obtained by dissolving paranitrophenyldihydrodibromobutinecarboxylic acid in excess of sodium carbonate.

F. S. K.

Hydrazinesulphonic Acids and Triazo-compounds. By H. LIMPRICHT (*Ber.*, **21**, 3409—3423).—*Metahydrazinebenzenesulphonic* acid is prepared by gradually adding metadiazobenzenesulphonic acid to a well-cooled hydrochloric acid solution of stannous chloride, precipitating the tin, and concentrating the filtered solution. It crystallises in colourless plates or needles with 2 mols. H_2O, loses its water at 110°, and is not decomposed when heated at 200°. It is readily soluble in hot, sparingly in cold water, and almost insoluble in alcohol and ether; it is decomposed when warmed with ferric chloride, and it reduces Fehling's solution and solutions of silver under the same conditions. The compound $SO_3Na\cdot C_6H_4\cdot N_2H\cdot CHPh + 2H_2O$ is formed when the sodium salt is warmed with benzaldehyde in alcoholic solution. It crystallises in plates, loses its water at 110°, and is readily soluble in hot water, but sparingly in alcohol and ether. It is not decomposed at 100°, but by the action of acids it is reconverted into benzaldehyde and the acid.

Metatriazobenzenesulphonic acid, $N_3\cdot C_6H_4\cdot SO_3H$, is produced when nitrous acid is passed for a long time into alcohol containing the hydrazine-compound in suspension. It can also be prepared by mixing equivalent quantities of metadiazobenzenesulphonic acid and metahydrazinebezenesulphonic acid in presence of a small quantity of water. It crystallises in colourless, deliquescent needles, is decomposed when warmed with alkalis or when heated with hydrochloric acid, and yields metamidobenzenesulphonic when reduced with zinc and acetic acid. The *barium* salt, $(C_6H_4N_3SO_3)_2Ba$, crystallises in slender, colourless needles and explodes when heated at 130°.

Metahydrazinebenzenedisulphonic acid, $N_2H_3\cdot C_6H_3\cdot (SO_3H)_2$, is obtained in small quantities when metahydrazinebenzenesulphonic acid is treated with chlorosulphonic acid; it is best prepared by treating metamidobenzenesulphonic acid with chlorosulphonic acid and reducing the barium salt of the diazodisulphonic acid, which is obtained on diazotising the product, with well-cooled stannous chloride and hydrochloric acid. It crystallises in slender, colourless, deliquescent needles, is readily soluble in alcohol and is decomposed when gently heated. It gives the hydrazine reaction with ferric chloride and Fehling's solution. The *barium* salt, $C_6H_6N_2S_2O_6Ba$, separates in reddish, nodular crystals when alcohol is added to the concentrated aqueous solution. The hydrogen barium sulphonate,

$$(C_6H_6N_2S_2O_6)_2BaH_2,$$

crystallises in thick needles and is rather sparingly soluble in water.

Parahydrazinebenzenedisulphonic acid, prepared by treating paramidobenzenedisulphonic acid as described above, crystallises in plates, decomposes at 120°, and is readily soluble in water and alcohol. The *barium* salt, $N_2H_3\cdot C_6H_3(SO_3)_2Ba$, is a yellow, crystalline, unstable compound; the *hydrogen barium sulphonate* crystallises from water in colourless, rhombic plates.

Potassium triazonitrobenzenesulphonate, $N_3\cdot C_6H_3(NO_2)\cdot SO_3K$, prepared by gradually adding hydrazinenitrobenzenesulphonic acid to a well-cooled, concentrated solution of potassium nitrite, crystallises in light brown plates, is very unstable, explodes when heated to 130°, and is readily soluble in hot water. It dissolves in excess of potash with a red coloration, but when boiled with potash or when treated with stannous chloride or ammonium sulphide in the cold, it is decomposed with evolution of nitrogen. When reduced with zinc-dust and acetic acid, it is converted into a very unstable substance, which is decomposed by cold ferric chloride and reduces Fehling's solution. It is partially decomposed, with evolution of nitrogen, when boiled for a long time with hydrochloric acid; and when heated for a long time with moderately concentrated sulphuric acid it is converted into nitranilinesulphonic acid.

Diazotriazobenzenesulphonic acid,  $N_3\cdot C_6H_3\left\langle\begin{array}{c}-N\\ SO_3\end{array}\right\rangle N$, is obtained when hydrazineamidobenzenesulphonic acid is suspended in alcohol and treated with nitrous acid. It is an orange-red, crystalline, very explosive substance, and quickly turns blue on exposure to the air. It is decomposed with evolution of nitrogen when boiled with water, but it does not reduce Fehling's solution. When treated with stannous chloride in the cold, it is converted into a very unstable and readily soluble, crystalline hydrazine-derivative.

Paratriazorthotoluenesulphonic acid, [Me : SO_3H : N_3 = 1 : 2 : 4], is prepared by gradually adding the finely divided hydrazine acid to a very dilute solution of the corresponding diazo-derivative and keeping the mixture for 24 hours. It crystallises in colourless, deliquescent needles. The *barium* salt crystallises with 3 mols. H_2O in colourless needles. The corresponding *ortho*-acid is prepared in like manner, but the mixture of the diazo- and hydrazine-compounds must be kept for eight days; it resembles the preceding compound.

Diazodibromobenzenesulphonic acid separates in yellow crystals when a well-cooled solution of sodium dibromamidobenzenesulphonate is treated with sodium nitrite and hydrochloric acid. The yield is almost theoretical. It is very sparingly soluble in cold water, is decomposed by boiling water, and explodes violently when heated.

Hydrazinedibromobenzenesulphonic acid is formed when the diazo-compound is dissolved in a well-cooled hydrochloric acid solution of stannous chloride. It is sparingly soluble in warm water, and gives the hydrazine reaction with ferric chloride, Fehling's solution, and silver nitrate.

Triazodibromobenzenesulphonic acid, $N_3\cdot C_6H_2Br_2\cdot SO_3H$, is obtained together with metamidobenzenesulphonic acid, dibromamidobenzenesulphonic acid, and triazobenzenesulphonic acid, when the dibromhydrazine acid is treated with metadiazobenzenesulphonic acid or when diazodibromobenzenesulphonic acid is treated with metahydrazinebenzenesulphonic acid. It crystallises in small needles. The *barium* salt, $(N_3\cdot C_6H_2Br_2\cdot SO_3)_2Ba$, crystallises in pale red plates, is sparingly soluble in cold water, and explodes when heated

Hydrazobenzenedisulphonic acid is best prepared by warming metanitrobenzenesulphonic acid with zinc-dust and soda until the yellow colour, due to the formation of the azo-compound, has disappeared. The solution is quickly filtered, saturated with hydrogen chloride, and, after keeping for 24 hours, the precipitate is collected, dissolved in soda, and reprecipitated from the filtered solution by hydrochloric acid. The diazo-compound,

$$OH\cdot C_6H_3<\begin{smallmatrix}NH\\ SO_3\end{smallmatrix}>N\cdot N<\begin{smallmatrix}NH\\ SO_3\end{smallmatrix}>C_6H_3\cdot OH,$$

is most easily prepared by mixing a concentrated solution of sodium hydrazobenzenedisulphonate with the calculated quantity of sodium nitrite, and gradually adding hydrochloric acid to a well-cooled solution until the brown colour disappears. It yields a yellow, crystalline compound when heated with alcohol under pressure, and the smell of aldehyde is distinctly perceptible. (Compare Balentine, Abstr., 1880, 809.) The corresponding hydrazine-derivative is readily obtained by gradually adding the diazo-compound to a well-cooled hydrochloric acid solution of stannous chloride; the product is dissolved in hot soda, the filtered solution precipitated with hydrochloric acid, and the hydrazine boiled with water to remove sodium chloride. It is a yellow, crystalline powder, insoluble in most of the usual solvents, and explodes when heated. When mixed with cold hydrobromic acid, it yields the hydrobromide of the diazo-compound, which is converted into the diazo-derivative when treated with water. The *barium* salt, $NH_2\cdot N[NH\cdot C_6H_3(OH)\cdot SO_3]_2Ba,2H_2O$, crystallises in yellowish needles and is readily soluble in water.

Equivalent quantities of hydrazinebenzenedisulphonic acid and the diazo-compound were mixed together in presence of a large quantity of water; evolution of gas commenced and the solution became deep red. As, after several days, some of the hydrazine-compound was still undecomposed, more diazo-acid was added, whereupon *triazobenzenedisulphonic* acid separated after a short time. This acid is also formed, together with hydrazobenzenedisulphonic acid, metamidobenzenesulphonic acid, and triazobenzenesulphonic acid, when metahydrazinebenzenesulphonic acid is treated with the calculated quantity of diazohydrazophenoldisulphonic acid in ice-cold aqueous solution.

Barium triazobenzenedisulphonate,

$$\left.\begin{matrix}N\cdot N\cdot NH\cdot C_6H_3(OH)\cdot SO_3\\ \|\ \ \|\\ N\cdot N\cdot NH\cdot C_6H_3(OH)\cdot SO_3\end{matrix}\right>Ba + 3H_2O,$$

crystallises in yellowish plates, explodes when heated, and decomposes slowly at the ordinary temperature. F. S. K.

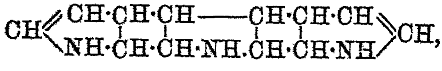
Aromatic Lead Compounds. By A. POLIS (*Ber.*, **21**, 3424—3428; compare Abstr., 1887, 572).—Lead tetratolyl is converted into chlorotoluene and lead chloride when heated at 200° with hydrochloric acid, and is decomposed when treated with cold, concentrated nitric acid.

Lead ditolyl chloride, $Pb(C_7H_7)_2Cl_2$, prepared by passing a stream of dry chlorine over a carbon bisulphide solution of lead tetratolyl, is a colourless powder, sparingly soluble in chloroform, carbon bisulphide, and benzene, and insoluble in ether and alcohol. It is decomposed when heated, and is converted into the corresponding nitrate when treated with alcoholic silver nitrate. The *bromide*, $Pb(C_7H_7)_2Br_2$, is prepared by gradually mixing lead tetratolyl and bromine in carbon bisulphide solution; it resembles the chloride in all respects. The *iodide*, $Pb(C_7H_7)_2I_2$, prepared in like manner, is a yellow powder, and is more readily soluble in chloroform and carbon bisulphide than the chloride or bromide.

The *nitrate*, $Pb(C_7H_7)_2(NO_3)_2 + 3H_2O$, is obtained by gradually adding finely divided lead tetratolyl to boiling nitric acid of sp. gr. 1·4, and finally concentrating the solution. It crystallises in very small, colourless needles, is sparingly soluble in alcohol and dilute nitric acid, and explodes when heated. The *salt* $OH{\cdot}Pb(C_7H_7)_2{\cdot}NO_3$ is formed when the nitrate is heated with water, or when a dilute nitric acid solution of this salt is treated with ammonia; it is a white, amorphous powder, and explodes slightly when heated.

The *acetate*, $Pb(C_7H_7)_2(C_2H_3O_2)_2 + 2H_2O$, prepared by dissolving lead tetratolyl in boiling acetic acid, crystallises in needles, melts at 183·5°, and is moderately soluble in alcohol and dilute acetic acid. The *formate*, $Pb(C_7H_7)_2(CHO_2)_2$, crystallises in colourless needles, decomposes at 233°, and resembles the acetate in its behaviour towards solvents. The *chromate*, $Pb(C_7H_7)_2CrO_4$, is precipitated when a solution of the acetate is mixed with potassium bichromate; it is a yellow powder, and is insoluble in the ordinary solvents. The *sulphide*, $Pb(C_7H_7)_2S$, prepared by treating a solution of the acetate with hydrogen sulphide, is a yellow, crystalline compound which begins to decompose at 90° and melts at 98°. It is very readily soluble in benzene, carbon bisulphide, and chloroform, but sparingly in alcohol and ether, and decomposes on exposure to light. F. S. K.

Conversion of Pyrroline-derivatives into Indole-derivatives. By M. DENNSTEDT (*Ber.*, **21**, 3429—3440).—The compound obtained by passing dry hydrogen chloride into an ethereal solution of pyrroline (compare Dennstedt and Zimmermann, Abstr., 1888, 849) is *tripyrroline*, the constitution of which is probably



and the compound obtained in like manner from isopropylpyrroline
]

(*loc. cit.*) is diisopropyldipyrroline, the constitution of which is probably

$$\mathrm{CH}\begin{matrix}\diagup\mathrm{C(C_3H_7)\cdot CH\cdot CH\cdot C(C_3H_7)}\diagdown\\ \diagdown\mathrm{NH}\text{——}\mathrm{CH\cdot CH}\text{——}\mathrm{NH}\diagup\end{matrix}\mathrm{CH.}$$

3 . 3′ *Diisopropylindole*, $C_{14}H_{19}N$, is obtained by mixing an aqueous solution of diisopropyldipyrroline hydrochloride with dilute sulphuric acid, and, after keeping the mixture for some time at the ordinary temperature, distilling the product with steam. A dark oil collects in the receiver at the commencement of the process, but the longer the distilling is continued the purer is the product obtained, so that finally the oily distillate solidifies. As the base is only very slightly volatile with steam but readily volatile with alcohol vapour, alcohol is added after some time and the distillation continued. The yield of the crude product is about 50 per cent. of the theoretical quantity. The crystals, after separation from oily impurities by filtration, are dissolved in a small quantity of alcohol and boiled with animal charcoal; water is then carefully added to the filtered solution until a turbidity is produced, crystallisation being promoted by rubbing. This process is repeated until a colourless product is obtained, and the indole is then finally recrystallised from dilute alcohol.

Diisopropylindole can also be prepared by dissolving isopropylpyrroline in dilute sulphuric acid, keeping the mixture for 24 hours, and purifying the product in the manner described above. It crystallises in colourless needles, melts at 65°, and boils at 295—300° with slight decomposition. It gives the pinewood reaction, is very readily soluble in alcohol, acetone, ether, glacial acetic acid, chloroform, &c., and dissolves in concentrated hydrochloric acid, but is reprecipitated unchanged on adding water. The *picrate* separates in red needles when an alcoholic solution of equivalent quantities of diisopropylindole and picric acid is gradually evaporated; it melts at 115°, dissolves in alcohol with a yellow coloration, and is insoluble in cold water, but dissolves on boiling and is decomposed. When diisopropylindole is melted with 20 to 30 times its weight of anhydrous potash, a small quantity of a colourless, crystalline acid is obtained; if this acid is gradually heated, carbonic anhydride is evolved and indole is probably formed. When the base is treated with the calculated quantities of sodium nitrite in glacial acetic acid solution, the mixture darkens in colour, and, on carefully adding water or acetic acid, a yellow, crystalline precipitate separates; this precipitate does not show the nitroso-reaction.

Benzylidinediisopropylindole, $C_{35}H_{42}N_2$, is formed when diisopropylindole (2 parts) is heated with benzaldehyde (1 part) and a small quantity of zinc chloride. It is a yellowish, crystalline compound, melts at 162—165° with decomposition, and is readily soluble in most of the ordinary solvents, but is precipitated from its alcoholic solution on adding water.

Diisopropylindole and metanitrobenzaldehyde yield, under the same conditions, a condensation product melting at 185°, and the condensation product with phthalic anhydride is a dark-red, crystalline substance, which is decomposed when boiled with water.

An *acetyl*-derivative, $C_{11}H_{21}NO$, is obtained when the indole is heated at 180—190° with acetic anhydride and sodium acetate; it crystallises in yellowish needles melting at 185—186°, is insoluble in water, and is hydrolysed when boiled for a long time with hydrochloric acid, but is not decomposed by boiling potash. Silver nitrate, in presence of ammonia, produces a white, crystalline precipitate in an alcoholic solution of the acetyl-derivative.

Diisopropylmethyldihydroquinoline is formed when diisopropylindole (1 part) is heated at 120° for 15 hours with methyl alcohol (1 part) and methyl iodide ($2\frac{1}{2}$ parts). The mixture is distilled with steam until no more oil passes, then made alkaline and the distillation continued. The yellowish oil which collects in the receiver is dissolved in hydrochloric acid, the solution is shaken with ether, and, after acidifying, the base is extracted with ether, dried, and distilled. It is a yellowish oil, boils at 298—300° with partial decomposition, and gradually turns rose-coloured on exposure to the air. The *hydrochloride* is a colourless, vitreous mass. The *platinochloride*, $(C_{16}H_{23}N)_2,H_2PtCl_6$, is a light-yellow substance, melts at 177° with decomposition, and is insoluble in water. The *mercurochloride* is a white, amorphous, and the *picrate* is a yellow, crystalline compound.

When dimethyldipyrroline hydrochloride, prepared by passing hydrogen chloride into an ethereal solution of α-methylpyrroline boiling at 147—148°, is treated with dilute sulphuric acid as described above, a yellowish oil, boiling at about 275°, is obtained. This base is soluble in concentrated hydrochloric acid, but is reprecipitated on adding water. The *picrate*, $C_{10}H_{11}N,C_6H_3N_3O_7$, separates in dark-red crystals when a benzene solution of the base is mixed with a benzene solution of picric acid and evaporated; it softens at 150° and melts at 155—156° with decomposition. The base obtained in like manner from β-methylpyrroline, boiling at 142—143°, has a strong scatole-like smell, and boils at about 270°; it dissolves in concentrated hydrochloric acid, but is reprecipitated on adding water. The *picrate*, $C_{10}H_{11}N,C_6H_3N_3O_7$, crystallises in red needles and melts at 149°. F. S. K.

Derivatives of Paradiphenol. By H. Schütz (*Ber.*, **21**, 3530—3534).—Metadinitroparadiphenol (Kunze, this vol., p. 262) melts at 280° (not 272°), is insoluble in alcohol, sparingly soluble in glacial acetic acid. The *diacetyl-compound* forms straw-coloured needles melting at 215°; the *dibenzoyl-derivative* crystallises in colourless plates melting at 206°. Both compounds dissolve readily in hot glacial acetic acid.

Metadiamidoparadiphenol sulphate, $C_{12}H_6(NH_2)_2(OH)_2,H_2SO_4$, separates in needles; the *picrate* crystallises in groups of needles. The *diacetyl*-derivative forms white needles melting at 210°. When the base is heated with acetic chloride at 150°, diethenyldiamidodiphenyl, melting at 195°, is formed.

Tetranitrodiphenol melts at 225° (not 220°). The *sodium salt*, $C_{12}H_4(NO_2)_4(ONa)_2$, crystallises in red, lustrous needles, soluble in hot water; on cooling, the *salt*, $C_{10}H_4(NO_2)_4(ONa)\cdot OH$, separates in brownish-red needles. The *diacetyl-compound*, $C_{12}H_4(NO_2)_4(OAc)_2$, forms yellow, sparingly soluble needles, melting at 236°.

Tetramidodiphenol crystallises in plates of a silvery lustre and is very unstable. The *sulphate* and *picrate* crystallise in white needles and reddish-yellow needles respectively. The *hexacetyl-derivative*, $C_{12}H_4(NHAc)_4(OAc)_2$, is a white, crystalline powder; when heated with aqueous soda, the *tetracetyl-compound*, $C_{12}H_4(NHAc)_4(OH)_2$, is obtained. This forms lustrous needles melting at 280°. Acetic chloride acts on tetramidodiphenol with formation of the compound $C_{16}H_{14}N_4O_2$, which, on prolonged boiling with hydrochloric acid, yields tetramidodiphenol hydrochloride. N. H. M.

Isomerism of the Benzildioximes. By K. Auwers and V. Meyer (*Ber.*, **21**, 3510—3529).—*α-Benzildioxime dimethyl ether*, $C_{16}H_{16}N_2O_2$, is obtained, together with a non-ethereal isomeride, by treating the α-dioxime (10 grams) with methyl iodide (50 grams) and diluting with methyl alcohol; the whole is gently boiled for some hours in a reflux apparatus, during which time a solution of sodium (7·5 grams) in methyl alcohol is gradually added (compare Japp and Klingemann, *Annalen*, **247**, 201). The method employed for the separation of the products is described in detail. The dimethyl ether crystallises in well-formed, lustrous, triclinic prisms, melts at 109—110°, dissolves very readily in benzene, chloroform, &c., more sparingly in alcohol and ether, and is insoluble in cold water. It unites with hydrogen chloride, yielding the compound $C_{16}H_{16}N_2O_2{\cdot}HCl$, which forms short, lustrous prisms melting at 157—158° with evolution of gas; it is decomposed by cold water.

The *isomeride*, $C_{16}H_{16}N_2O_2$, crystallises from alcohol in small, lustrous prisms, melts at 165—166°, dissolves readily in benzene, chloroform, and carbon bisulphide, sparingly in alcohol, ether, and glacial acetic acid, and is insoluble in cold water.

Besides the two compounds just described, a base, $C_{16}H_{14}N_2$, and benzil are formed in the reaction; both these substances are also formed in a similar manner from β-benzildioxime.

β-Benzildioximedimethyl ether, $C_{16}H_{16}N_2O_2$, prepared in a manner similar to the α-compound, crystallises in rosettes of slender, white needles, melts at 88—89°, dissolves very readily in benzene, chloroform, and carbon bisulphide, readily in alcohol and ether, and is insoluble in cold water. The *hydrochloride*, $C_{16}H_{16}N_2O_2,HCl$, resembles the corresponding α-derivative very strongly, but melts at about 130°.

The non-ethereal *isomeride* of the β-dioxime forms flat, lustrous needles, melts at 72—73°, and is very readily soluble in ether, benzene, and chloroform, readily soluble in glacial acetic acid, less in alcohol.

The *base*, $C_{16}H_{14}N_2$, which is formed from both dioximes, crystallises from dilute alcohol in long, slender needles of a silky lustre, melts at 158—159°, is insoluble in water, readily soluble in alcohol, benzene, and carbon bisulphide, very readily in chloroform. The *nitrate* forms sparingly soluble, flat needles; the *platinochloride*, $(C_{16}H_{14}N_2)_2,H_2PtCl_6$, crystallises in lustrous, gold-coloured plates. The base is isomeric with Japp and Wynne's methyldiphenylglyoxaline (Trans., 1886, 462) and with Mason's diphenyldihydropyrazine (Abstr., 1887, 493).

All four isomerides ($C_{16}H_{16}N_2O_2$) yield dibenzyl when reduced with phosphorus and hydriodic acid.

When the α-dioxime dimethyl ether is heated with alcohol at

170—180° it is more or less decomposed, whilst the non-ethereal isomeride remains unchanged even at 240—250°.

When the α- and β-dioxime ethers are heated with strong hydrochloric acid for 10 hours at 100°, they are decomposed into benzil and methylhydroxylamine; the latter is further decomposed. Under similar conditions, the non-ethereal compound, $C_{16}H_{16}N_2O_2$, from the α-dioxime is converted almost quantitatively into that of the β-dioxime, whilst this compound is not acted on at all by hydrochloric acid at 100; at 170° it is converted into benzoic acid and ammonia. No benzil is formed in either case.

Both α- and β-benzildioxime, when reduced with zinc-dust and aqueous soda, yield tetraphenylaldine, benzil, a non-nitrogenous substance melting at 54°, probably dibenzyl, and several other compounds which were not examined.

Attempts were made to obtain an isomeride of dimethylglyoxine, but without success, a result which supports the authors' views as to the isomerism of the benzildioximes. N. H. M.

β-Naphthol Sulphide. By S. ONUFROWICZ (*Ber.*, **21**, 3559—3563).—β-Naphthol sulphide, $S(C_{10}H_6\cdot OH)_2$, is prepared by heating β-naphthol (250 grams) and sulphur (55 grams) at 170—180° for some hours. The product is boiled with alcohol in a reflux apparatus, filtered hot, and the brown prisms which separate recrystallised from alcohol. It is colourless, melts at 215°, is insoluble in water, ether, and benzene, soluble in alcohol. The *diacetate*, $S(C_{10}H_6\cdot OAc)_2$, forms slender, white needles, melts at 154°, and is sparingly soluble in ether and cold alcohol, readily in hot benzene. The *dibenzoate*, $S(C_{10}H_6\cdot OBz)_2$, crystallises in long, white plates, melts at 208°, dissolves readily in hot benzene, sparingly in ether and alcohol. When β-naphthol sulphide is heated with copper at 230—240°, β-dinaphthol, melting at 212°, is formed. N. H. M.

Evidence of Quantivalence of Oxygen derived from the Study of the Azo-naphthol Compounds. By R. MELDOLA (*Phil. Mag.* [5], **26**, 403—413).—After reviewing the different formulæ proposed for the azo-β-naphthol and naphthylamine compounds, the author suggests a closed ring,  $C_{10}H_6\left<\begin{matrix}NH_2\\|\\N\end{matrix}\right>N\cdot X$ (X = an aromatic radicle), for the azo-β-naphthylamines, the ring being formed by the interaction of the azo- and amido-groups. Such a formula would explain the difficulty with which they form salts and diazo-compounds, the acid having first to break the nitrogen-ring. From this formula, the azimides are easily derived by the removal of hydrogen. From the analogy between the β-naphthylamine and β-naphthol-derivatives, a similar formula,  $C_{10}H_6\left<\begin{matrix}N\\|\\O\\H\end{matrix}\right>N\cdot X$, is obtained for the latter. The only objection to this view is that it requires that oxygen should be tetravalent. This, however, is in accordance with later researches, and with the position of oxygen in the periodic system. It is also required by Friedel's compound OMe_2HCl.

The benzene-azo-β-naphthol, formed by the action of diazobenzene salts on β-naphthol, can be represented by the formula

$$C_{10}H_6\left\langle\begin{matrix}N-\\ |\\ OH\end{matrix}\right\rangle NPh\ [N = \alpha;\ O = \beta],$$

whilst the nitrogen- and oxygen-atoms hold a reversed position in the compound produced by the action of phenylhydrazine on β-naphthaquinone: hence the insolubility in alkali is due to the fact that the H is non-hydroxylic, but is attached to an oxygen-atom forming part of a closed chain. The above constitution may be applied to all amidoazo- and oxyazo-compounds of the ortho-series. H. K. T.

Action of Sunlight on Organic Compounds. By H. Klinger (*Annalen*, **249**, 137—146).—The action of light on ethereal solutions of benzil and phenanthraquinone has been previously investigated by the author (Abstr., 1886, 885). When a mixture of phenanthraquinone and acetaldehyde, isovaleraldehyde, or benzaldehyde is exposed to sunlight in sealed tubes, combination takes place resulting in the formation of acetylphenanthraquinol, isovalerylphenanthraquinol, or monobenzoylphenanthraquinol respectively. Phenanthraquinone appears to behave in a similar way with furfuraldehyde, salicaldehyde, and grape-sugar. It is remarkable that exposure to blue light is much more favourable to these changes than the action of red rays.

Anthraquinone, naphthaquinone, benzil, and benzoquinone appear to yield ethers of quinhydrone when they are exposed to the light in contact with aldehydes. W. C. W.

Action of Halogens on Rufigallol. By C. S. S. Webster and L. G. Hunt (*Chem. News*, **59**, 40—41).—When chlorine acts on rufigallol in acetic acid solution, *dichlorhexahydroxyanthraquinone* is obtained in nodules of brilliant-red, microscopic prisms. A bromine-derivative, obtained in a similar manner at 80°, crystallises from absolute alcohol in light-red, microscopic needles. D. A. L.

Chrysene Hydrides. By C. Liebermann and L. Spiegel (*Ber.*, **22**, 135—137).—*Chrysene perhydride*, $C_{18}H_{30}$, is obtained together with the hydride, $C_{18}H_{28}$, when chrysene (1 part), phosphorus (1 part), and hydriodic acid (sp. gr. = 1·7, 5 parts) are heated for 16 hours at 250—260°. The product is diluted with water, filtered, washed, and dissolved in dilute alcohol. The perhydride separates in slender, white needles; it melts at 115°, boils at 353° (corr.), and dissolves very readily in hot alcohol; it dissolves in bromine unchanged, and is not affected by cold nitric acid (sp. gr. = 1·48). Chromic acid oxidises it when boiled, but without yielding chrysoquinone. When treated with sulphuric acid, only a small amount of sulphonic acid is formed. When distilled over zinc-dust, chrysene is formed in considerable amount. It does not give a compound with picric acid.

Chrysene heckaidecahydride, $C_{18}H_{28}$, which remains as an oil on evaporating the mother-liquor from the above compound, is purified by freezing and spreading on cooled porous plates, which absorb the liquid hydrocarbon. The solid hydrocarbon is then removed mechanically, whilst the liquid is extracted from the plates by means of ether. The substance is dried, and at the same time freed from traces of iodine and hydrogen iodide by digesting it with sodium at 200° for a long time. It is a colourless, slightly fluorescent, viscid oil, without odour, boiling at about 360°. In its chemical properties it resembles the perhydride.

N. H. M.

Chemical Composition of the Russian White Resin from Pinus silvestris. (Part I.) By V. SHKATELOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 477—485).—Owing to the discrepancies in the results obtained with the resin of *Pinus maritima*, *P. larix*, and *P. abies*, and the uncertain composition of pimaric, sylvic, pinic, and abietic acids, the author has investigated the crystalline acid from the Russian resin obtained from *Pinus silvestris*, growing in the Archangel and Wologda Governments. In order to remove the uncrystallisable substances, the resin, ground fine, was extracted with alcohol of 50—60 per cent. (Maly, *J. pr. Chem.*, **86**, 111), and the residue, which was much whiter than before, was now treated with boiling spirit; the filtered alcoholic solution, after remaining some time, becomes almost entirely converted into a crystalline mass. The crystals were washed with alcohol of 85 per cent. and again recrystallised. After thrice repeating this process, 30 per cent. of a perfectly white product was obtained; whereas on repeating the same process with a resin that had been exposed to the action of air for one year, only 20 per cent. was obtained. In order to prevent this from becoming yellow and oxidising in the air, the operations have to be carried on as quickly as possible; finally a compound, melting at 143°, was obtained. The acid, $C_{40}H_{58}O_5$, is insoluble in water, but easily soluble in alcohol, ether, acetic acid, and liquid hydrocarbons. After fusion, it solidifies to an amorphous, transparent mass, and when heated above 360°, a colourless, uncrystallisable distillate passes over. The rotatory power of the alcoholic solution was found, $[\alpha]_j = -73{\cdot}59°$. It decomposes alkaline carbonates with liberation of carbonic anhydride, and the original acid is reprecipitated from the solution on adding a mineral acid. By the action of hydrogen chloride on the alcoholic solution, the acid is converted into an isomeric acid of the same composition—but of different properties, as it melts at 159—160°, and the rotatory power is $[\alpha]_j = -92{\cdot}58°$. From the sodium salt of the original acid, other salts of the following composition were obtained: $C_{20}H_{29}AgO_3$; $(C_{20}H_{29}O_3)_2Ba + 2H_2O$; $(C_{20}H_{29}O_3)_2Ca$, and $(C_{20}H_{29}O_3)_2Cu$. The acid $C_{40}N_{58}O_5$ appears to be a partial anhydride of an acid which gives the above salts, and whose formation may be represented as follows:—$C_{40}H_{58}O_5 + H_2O = 2C_{20}H_{30}O_3$. The ethyl salt, $C_{20}H_{29}O_3Et$, was obtained as a heavy oil by acting on the silver salt with ethyl iodide. On distillation, it decomposes with elimination of water and the formation of another ethyl salt, according to the equation $C_{20}H_{29}O_3Et = C_{20}H_{27}O_2Et + H_2O$. This new compound is a heavy, yellow oil which yields a resin with potassium hydroxide. Finally the author shows that the resinification of the acid when exposed to the air consists in an oxidation accompanied by loss of water. The acid described above agrees in properties with Maly's abietic acid, but differs from it in composition. B. B.

Apiole. By G. Ciamician and P. Silber (*Ber.*, **22**, 119—121; compare Abstr., 1888, 1100).—Apiolic acid (2 grams), potash (6 grams), and absolute alcohol (10 grams) were heated at 180° for four to six hours, the product evaporated on a water-bath, dissolved in water, acidified, and extracted with ether. On distilling the brown syrup left after evaporating the ether, a liquid was obtained which had an odour of phenol, and soon solidified. By repeating the operation several times, the substance was obtained pure. The new compound, $C_6H_2(OH)_2(OMe)_2$, melts at 105—106°, boils at 298°, and is soluble in ether, alcohol, benzene, hot water, and in potash. The *potassium-derivative* forms slender, dark-brown, bronze-like needles. The compound gives with ferric chloride a violet-black colour which changes to brownish-black. The *acetyl-derivative* melts at 143°.

When isoapiole is heated with alcoholic potash, it yields the same phenol ether.

Apiolaldehyde is best obtained by oxidising isoapiole with alkaline permanganate solution, extracting with ether and treating the ethereal solution with sodium hydrogen sulphite. *Apionacrylic acid*, prepared by Perkin's method from apiolaldehyde, crystallises in needles melting at 196°. N. H. M.

Crystalline Compound from glabrous Strophantus. By Arnaud (*Compt. rend.*, **107**, 1162—1164; compare Abstr., 1888, 848 and 1310).—The seeds of the glabrous *Strophantus* of Gabon, which constitute Inée or Onaye, the arrow-poison of the Pahouins, was treated in practically the same way as *S. kombé* (*loc. cit.*). They yield 4·7 per cent. of transparent, rectangular lamellæ which become thick and opaque if they form slowly. The crystals become pasty when heated, and melt at about 185°; they contain 17—18 per cent. of water, which is all expelled above 120° but is not given off in air dried by sulphuric acid. They dissolve in 150 parts of water at 8°, and a 6·5 per cent. solution at 50° has a rotatory power $[\alpha]_D = -33° 8'$. When heated with dilute acids, this substance yields a sugar and a peculiar resin.

The properties of this compound agree with those of ouabaine from Acokantheria, and it is identical in composition, the substance dried at 100° having the formula $C_{30}H_{46}O_{12} + H_2O$. The original crystals contain 7 mols. H_2O, six of which are expelled below 100°, but the seventh is not driven off below 120°. C. H. B.

Ergosterin. By C. Tanret (*Compt. rend.*, **108**, 98—100).—Ergot of rye contains a crystallisable substance which has always been regarded as cholesterin. If the ergot is treated with several times its weight of alcohol, the alcoholic extract distilled, and the residue treated with ether, the ethereal solution on distillation leaves an oily residue containing crystals. These are drained and recrystallised, first from alcohol containing alkali and afterwards from pure alcohol. The yield is about 0·2 gram per kilo.

The crystals have the composition $C_{26}H_{40}O_2 + H_2O$, and lose their water when heated at 110° or if fused in a vacuum. They separate from alcohol in nacreous plates and from ether in slender needles, dissolve in alcohol and ether, and are especially soluble in chloroform. They melt at 154°, boil at 185° under a pressure of 20 mm., and are lævogyrate; $[\alpha]_D = -114°$ in a chloroform solution; sp. gr. of the fused substance 1·040.

This compound, *ergosterin*, oxidises when exposed to the air, with development of a colour and odour, the change taking place rapidly at 100°. It is not attacked by boiling concentrated solutions of the alkalis. It has an alcoholic function and yields an *acetate*, $C_{26}H_{39}O{\cdot}OAc$, which crystallises in anhydrous, nacreous plates, insoluble in water and almost insoluble in cold alcohol, but readily soluble in hot alcohol and ether, and melting at 169° with decomposition; rotatory power $[\alpha]_D = -80°$. The *formate* has similar properties and melts at 154°, rotatory power $[\alpha]_D = -93° 4'$; the *butyrate* is very soluble in ether, from which it is precipitated by alcohol, melts with decomposition at 95°, and has a rotatory power $[\alpha]_D = -57°$.

With nitric acid, hydrochloric acid and ferric chloride, ergosterin gives reactions very similar to those of cholesterin, but if the latter is treated with sulphuric acid, it turns brown and does not dissolve completely, and if the product is agitated with chloroform the latter acquires an orange-yellow colour which becomes red and then violet when exposed to the air. Ergosterin, on the other hand, is completely dissolved by sulphuric acid without discoloration, and chloroform remains almost colourless when agitated with the solution.

C. H. B.

Embelic Acid. By C. J. H. WARDEN (*Pharm. J. Trans.* [3], **19**, 305).—From *Embelia ribes*, the author has isolated *embelic acid*, $C_9H_{14}O_2$, which he has obtained from its alcoholic solution in the form of crystals, insoluble in water, and melting at 140° to a deep-red liquid; they begin to decompose at 155°, with indications of partial sublimation. The alkali, lead, and silver salts were prepared. The ammonium salt was found effective as an anthelmintic for tænia; it has the advantage of being tasteless.

R. R.

Derivatives of Metadimethylpyrroline. By G. MAGNANINI (*Ber.*, **22**, 35—40).—The compound which is obtained by boiling tetramethylpyrocoll (dimethylpyrocoll) with alcoholic potash until the whole is dissolved (compare Magnanini, this vol., p. 57) is *tetramethylpyrroylpyrrolinecarboxylic acid*, $C_{14}H_{16}N_2O_3$. It is a monobasic acid, but the salts, especially the ammonium salt, are very unstable and are readily decomposed with formation of tetramethylpyrocoll when warmed in aqueous solution. The *barium* salt, $(C_{14}H_{15}N_2O_3)_2Ba$, crystallises in rhombic plates. The *methyl* salt, $C_{15}H_{18}N_2O_3$, melts at 163—163·5°, is readily soluble in chloroform and moderately soluble in ethyl acetate and benzene, but only sparingly in light petroleum, and insoluble in water. It is very unstable, and when heated above its melting point, when boiled with dilute alcohol, or when warmed with sodium carbonate solution, is converted into tetramethylpyrocoll. The acid is decomposed, with evolution of carbonic anhydride, when heated at 145°, and is converted into a crystalline compound, probably tetramethylpyrroylpyrroline, which is insoluble in alkalis. The molecular weight determined by Raoult's method is 287 as a mean of two experiments in benzene solution, but determinations in glacial acetic solution gave results varying from 174 to 239 as the concentration was increased from 0·5382 to 2·0860. Its constitution is

$$\mathrm{CMe}<\begin{matrix}\mathrm{CH{:}CMe-}\\ \mathrm{C(COOH)}\end{matrix}>\mathrm{N\cdot CO\cdot C}<\begin{matrix}\mathrm{CMe\cdot CH}\\ \mathrm{NH\cdot CMe}\end{matrix}.$$

Dimethylpyrrolinecarboxylic acid, $C_7H_9NO_2$, is obtained when tetramethylpyrroylpyrrolinecarboxylic acid (1 part) is boiled with potassium hydrate (4 parts) and water (20 parts) until the formation of dimethylpyrroline commences. The product is precipitated with acetic acid, dried, dissolved in benzene, decolorised with animal charcoal, and precipitated from the concentrated solution with light petroleum. It melts at 137°, and is sparingly soluble in cold water, but dissolves in warm water with partial decomposition into carbonic anhydride and dimethylpyrroline. It is converted into tetramethylpyrocoll when boiled with acetic anhydride and then heated alone. A neutral solution of the ammonium salt gives precipitates with lead acetate, copper acetate, and ferric chloride. The constitution of this acid is probably  $\mathrm{NH}<\begin{matrix}\mathrm{C(COOH)}\\ \mathrm{CMe:CH}\end{matrix}>\mathrm{CMe}$, and that of the isomeric compound obtained by Knorr (Abstr., 1887, 275),

$$\mathrm{CMe}<\begin{matrix}\mathrm{NH-CH}\\ \mathrm{C(COOH)}\end{matrix}>\mathrm{CMe}.$$

F. S. K.

Pyrazole and Pyrazoline. By L. Knorr and H. Laubmann (*Ber.*, **22**, 172—181).—*Trinitrodiphenylmethylpyrazole*,

$$\mathrm{NO_2\cdot C_6H_4\cdot N}<\begin{matrix}\mathrm{CMe{=}C(NO_2)}\\ \mathrm{N{:}C(C_6H_4\cdot NO_2)}\end{matrix}>,$$

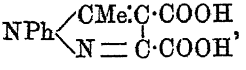
is obtained by heating 1.3-diphenyl-5-methylpyrazole (from ethyl benzoylacetate) with nitric acid (10 parts) and sulphuric acid (15 parts) on a water-bath until no more red fumes are given off. It melts at 176—178°, is insoluble in water and light petroleum, very sparingly soluble in ether and alcohol, readily in chloroform, benzene, and glacial acetic acid.

Diphenylpyrazoledicarboxylic acid,  $\mathrm{NPh}<\begin{matrix}\mathrm{C(COOH)}\\ \mathrm{N{=}CPh}\end{matrix}>\mathrm{C\cdot COOH}$, is formed by boiling potassium diphenylmethylpyrazolecarboxylate with 10 per cent. aqueous permanganate in a reflux apparatus for a long time; it is then freed from the excess of permanganate and from the manganese peroxide, and precipitated with dilute sulphuric acid. It crystallises from acetic acid in lustrous needles, having the composition $3C_{17}H_{12}N_2O_4 + H_2O$, melts at 217—218°, dissolves readily in alcohol and hot glacial acetic acid, sparingly in ether, chloroform, and water. The *hydrogen ammonium salt*, $C_{17}H_{15}N_3O_4$, crystallises in needles which melt at 270° with decomposition. The *barium salt*,

$C_{17}H_{10}N_2BaO_4 + H_2O$, crystallises in slender needles; the *calcium salt*, with 2 mols. H_2O, separates in microscopic needles.

1.3-*Diphenylpyrazole*,  $NPh<\begin{matrix}CH{:}CH\\N{:}CPh\end{matrix}>$, obtained by distilling the dicarboxylic acid, is obtained as a thick, colourless, strongly refractive oil which becomes crystalline when kept a few days. It melts at 56° and boils at 337° under 736 mm. pressure. It is a feeble base. When reduced with sodium and alcohol, 1.3-*diphenylpyrazoline*, $C_{15}H_{14}N_2$, melting at 135—136°, is formed (compare Beyer and Claisen, Abstr., 1887, 743, and Claisen and Fischer, Abstr., 1888, 690).

1-*Phenyl*-5-*methylpyrazole*-3.4-*dicarboxylic acid*,



$$NPh\langle\begin{matrix}CMe{:}C{\cdot}COOH\\N = C{\cdot}COOH\end{matrix},$$

is prepared by the prolonged boiling of phenyldimethylpyrazolecarboxylic acid (Abstr., 1887, 678) with potassium permanganate ($1\frac{1}{2}$ part) in dilute alkaline solution. It crystallises from hot water in small needles, decomposes at 198°, dissolves readily in alcohol and glacial acetic acid, sparingly in ether.

1-*Phenyl*-5-*methylpyrazole*,  $NPh<\begin{matrix}-CMe\\N{:}CH\end{matrix}>CH$, obtained by distilling the dicarboxylic acid, boils at 262° under 754 mm. pressure, and remains liquid at −20°. The *platinochloride*, $(C_{10}H_{10}N_2)_2,H_2PtCl_6 + 2H_2O$, crystallises in long needles, melts at 147°, and decomposes at above 150°.

1-*Phenylpyrazole*-3.4.5-*tricarboxylic acid*,

$$NPh<\begin{matrix}-C(COOH)\\N{:}C(COOH)\end{matrix}>C{\cdot}COOH,$$

is obtained by boiling phenylmethylpyrazoledicarboxylic acid with potassium permanganate ($1\frac{1}{2}$ part) in alkaline solution. It separate from the concentrated ethereal solution in white needles with 1 mo H_2O, melts at 184°, is readily soluble in water, sparingly in chlor form and ether. The *barium salt*, $C_{12}H_6N_2O_6Ba + \frac{1}{2}H_2O$, forn colourless plates. When the acid is distilled, 1-*phenylpyrazole* (?) *ca boxylic acid*, $C_{10}H_8N_2O_2$, is formed. This crystallises in long needle melts at 219—220°, and sublimes in long needles. It dissolves readil in alcohol, rather sparingly in ether and water. When the monocarboxylic acid is heated for a long time in a reflux apparatus, 1-phenylpyrazole,  $NPh\langle\begin{matrix}CH{:}CH\\N = CH\end{matrix},$ is obtained. This distils at 246- under 757 mm. pressure; the *platinochloride*, $(C_9H_8N_2)_2,H_2Pt$ $2H_2O$, crystallises from hydrochloric acid in needles which d pose at 175°. The compound is therefore identical with tha tained by Balbiano from phenylhydrazine and epichlorhydrin.

N. H. M.

α-Alkylcinchonic Acids and α-Alkylquinolines. By O. Döbner (*Annalen*, **249**, 98—109).—The preparation of the α-alkylcinchonic acids has already been described by the author (Abstr., 1888, 299, and 1887, 504). *Orthohydroxy-α-phenylcinchonic acid*, $C_9NH_5(C_6H_4{\cdot}OH){\cdot}COOH$ [= 2′ : 4′], prepared from aniline, salicaldehyde, and pyruvic acid, crystallises in needles of a brownish-yellow colour. It is freely soluble in alcohol, benzene, acetic acid, and chloroform. The *platinochloride*, $(C_{16}H_{11}NO_3)_2,H_2PtCl_6$, forms golden needles. The acid melts at 238°, and decomposes at a higher temperature, yielding *orthohydroxy-α-phenylquinoline*, $C_{15}H_{11}NO$. The base forms pale-yellow needles. It melts at 115°, and boils above 360°; it is soluble in acids and in alkalis. The *picrate* melts at 184°, and the platinochloride crystallises in needles. In ethereal solution, pyruvic acid, aniline, and cumaldehyde unite together, forming an indifferent compound of the composition $C_{25}H_{24}N_2O$, which melts at 216°, but in alcoholic solution they yield *paraisopropyl-α-phenylcinchonic acid*, $C_{19}H_{17}NO_2$. The acid is deposited from solution in acetic acid or alcohol in yellow plates, and melts at 201°. It is decomposed by heating with soda-lime, yielding *paraisopropyl-α-phenylquinoline*, $C_9NH_6{\cdot}C_6H_4Pr^\beta$. The base crystallises in needles, melts at 60°, and forms a crystalline hydrochloride, dichromate, picrate, and platinochloride. The latter contains 2 mols. H_2O.

α-Phenylquinic acid, $OMe{\cdot}C_9NH_4Ph{\cdot}COOH$ [= 3 : 2′ : 4′], prepared from paranisidine, pyruvic acid, and benzaldehyde, melts at 237°, and dissolves freely in alcohol, forming a fluorescent liquid. The *platinochloride*, $(C_{17}H_{13}NO_3)_2,H_2PtCl_6$, forms orange-red crystals. The acid is decomposed by heat, yielding *α-phenylparamethoxyquinoline*, $C_{16}H_{13}NO$. The base crystallises in plates, and melts at 133°. The hydrochloride, platinochloride, chromate, and picrate are crystalline.

α-Phenylorthomethoxycinchonic acid, [OMe : Ph : COOH = 1 : 2′ : 4′], prepared from orthanisidine, forms needle-shaped crystals of a lemon colour. It melts at 216°, and dissolves in alcohol, forming a feebly fluorescent solution. The *lead salt*, $(C_{17}H_{12}NO_3)_2Pb + H_2O$, is sparingly soluble. The *platinochloride* is crystalline. *α-Phenylorthomethoxyquinoline* is an oily liquid. The *platinochloride*, $(C_{16}H_{13}NO)_2,H_2PtCl_6 + 2H_2O$, and the *chromate* form orange-coloured needles.

W. C. W.

α-Phenylnaphthacinchonic Acids. By O. Döbner and P. Kuntze (*Annalen*, **249**, 109—136).—Pyruvic acid and benzaldehyde act on α- or β-naphthylamine in warm alcoholic or cold ethereal solutions, yielding naphthacinchonic acids.

α-Phenyl-α-naphthacinchonic acid,  $C_{10}H_6<\begin{matrix}N = CPh\\C(COOH)\end{matrix}>CH$, crystallises in yellow needles, and dissolves in acetone, alkalis, chloroform, and also in boiling alcohol and acetic acid. The alcoholic solution exhibits a blue fluorescence. The *sodium salt*, $C_{20}H_{12}NO_2Na + \frac{1}{2}H_2O$, is sparingly soluble in cold water. The potassium and ammonium salts are much more soluble. The zinc, copper, lead, silver, and calcium salts, $(C_{20}H_{12}NO_2)_2Ca$, are insoluble in water. The *ethyl salt* forms long, yellow needles, soluble in alcohol; it melts at 103°. The free acid melts at 300° with decomposition, yielding carbonic anhydride and *α-phenyl-α-naphthaquinoline*; a better yield of the base is obtained by heating the acid or its salts with soda-lime. The base is deposited from a mixture of alcohol and ether in pale-yellow needles melting at 68°. The solution in amyl alcohol is dichroic. The *platinochloride*, $(C_{19}H_{13}N)_2,H_2PtCl_6 + 2H_2O$, is amorphous. The picrate melts at 167°.

Diphenylpyridinetricarboxylic, α-phenylpyridinephenyleneketonecarboxylic, and benzoic acids are the products of the oxidation of α-phenyl-α-naphthacincinchonic acid with a dilute solution of potassium permanganate.

αα'-Diphenylpyridinetricarboxylic acid, $\mathrm{C_5NHPh(COOH)_2{\cdot}C_6H_4{\cdot}COOH}$ [= 2 : 4 : 5 : 6, and 1 : 2], is easily separated from the other product of oxidation by its greater solubility in hot water and in dilute acetic acid. The salts of silver, $\mathrm{C_{20}H_{10}NO_6Ag_3}$, lead, iron, mercury, and copper are insoluble. The acid melts at 250° with decomposition. When heated with soda-lime, it yields 2 : 6-diphenylpyridine, $\mathrm{Ph_2C_5H_3N}$. This base melts at 71—73°, and dissolves freely in alcohol and ether. It yields a crystalline picrate, platinochloride, and chromate.

α-Phenylpyridinephenyleneketonecarboxylic acid,

$$\mathrm{COOH{\cdot}C_5NHPh}\left<\begin{array}{l}\mathrm{C_6H_4}\\ \;| \\ \mathrm{CO}\end{array}\right.,$$

is sparingly soluble in dilute acetic acid and in cold water, but dissolves freely in alcohol and acetone. It crystallises in needles of an orange-red colour, and melts at 226°. Its salts are sparingly soluble. On distillation with soda-lime, α-phenylpyridinephenyleneketone, $\mathrm{CO}\left<\begin{array}{l}\mathrm{C_6H_4}\text{——}\\ \mathrm{C_5NH_2Ph}\end{array}\right>$, melting at 68° is produced.

α-Phenyl-α-naphthaquinoline is converted into tetrahydro-α-phenyl-α-naphthaquinoline, $\mathrm{C_{10}H_6}\left<\begin{array}{l}\mathrm{NH{\cdot}CHPh}\\ \qquad\;\; | \\ \mathrm{CH_2{\cdot}CH_2}\end{array}\right.$, by reduction with tin and hydrochloric acid, or better by the action of sodium on the solution of the naphthaquinoline in amyl alcohol. The hydro-base is a thick syrup boiling above 400°.

α-Phenyl-β-naphthacinchonic acid, $\left.\begin{array}{l}\mathrm{N{\cdot}C_{10}H_6}\diagdown\\ \| \\ \mathrm{CPh{\cdot}CH}\diagup\!\!\diagup\end{array}\right.\mathrm{C{\cdot}COOH}$, is deposited from a mixture of alcohol and hydrochloric acid, or of amyl alcohol and acetic acid, in needles. The acid is also soluble in alkalis, but none of the solutions are fluorescent. The *potassium* salt, $\mathrm{C_{20}H_{12}NO_2K + 5H_2O}$, forms silky needles sparingly soluble in cold water. The *sodium salt* closely resembles the potassium salt. The calcium salt forms needles containing 6 mols. $\mathrm{H_2O}$. On distillation with soda-lime, the acid yields *α-phenyl-β-napthaquinoline*, $\mathrm{C_{10}H_6}\left<\begin{array}{l}\mathrm{N{=}CPh}\\ \qquad | \\ \mathrm{CH{:}CH}\end{array}\right.$. The quinoline forms silky needles or nacreous plates, melts at 188°, and is soluble in alcohol, ether, and benzene. Its salts are partly decomposed by pure water. The *platinochloride*, $\mathrm{(C_{19}H_{13}N)_2,H_2PtCl_6 + H_2O}$, picrate, and dichromate are crystalline. The picrate melts at 250°. The *ethiodide* crystallises in orange-coloured plates, melts at 232°, and is soluble in alcohol. It is reprecipitated from its alcoholic solution by ether. α-Phenyl-β-naphthaquinoline appears to yield a diphenylpyridinedicarboxylic acid on oxidation with potassium permanganate.

W. C. W.

Quinoline-derivatives of Isatinic Acid. By W. PFITZINGER (*J. pr. Chem.* [2], 38, 582—584; compare Abstr., 1886, 370).—The author has obtained α-phenylcinchonic acid by the action of acetophenone on isatinic acid in solution in caustic potash. It is insoluble in water, and crystallises from hot alcohol in slender needles melting at 208—209°. It forms yellow, crystalline salts both with acids and with bases; when distilled with lime, it splits up into carbonic anhydride and α-phenylquinoline; this crystallises from weak alcohol in long needles melting at 84°. This acid has been previously obtained by Döbner (Abstr., 1887, 504) by the interaction of aniline, paraldehyde and pyruvic acid.

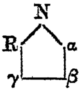
αβ-Diphenylcinchonic acid,

$$C_9NH_4Ph_2{\cdot}COOH\ [Ph_2 : COOH = 2' : 3' : 4']_2,$$

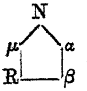
is obtained by the action of deoxybenzoïn on isatinic acid in alkaline solution; it is soluble in hot alcohol, and crystallises in needles which melt at 191°.

Acetone reacts with methylisatin, forming *para-α-dimethylcinchonic acid*, $C_9NH_4Me_2{\cdot}COOH$; this crystallises from water in shining leaflets melting at 261—262°. A. G. B.

Azoles. By A. Hantzsch (*Annalen*, **249**, 1—6).—A purely theoretical paper. The positions of the displaceable hydrogen-atoms in the isazoles are distinguished by the letters α, β, γ, thus:—



, in the azoles by α, β, μ, thus:



(R = O, S, Se, &c.).

The thiazoles are subdivided into three groups: the true thiazoles, containing the trivalent nucleus $(C_3SN)'''$; the thiazolines or dihydrothiazoles, derivatives of the pentavalent radicle, $(C_3SN)^{v}$; and the heptavalent thiazolidines or tetrahydrothiazoles. The author proposes to substitute the more correct term *thiazylamine* for the name *thiazoline*, which he formerly (Abstr., 1888, 573) suggested for the amidothiazoles. W. C. W.

Conversion of Ketone Thiocyanates into Oxythiazoles, and Reduction of the Latter to Thiazoles. By L. Arapides (*Annalen*, **249**, 7—27).—*Acetophenone thiocyanate*, $COPh{\cdot}CH_2{\cdot}SCN$, is conveniently prepared by mixing alcoholic solutions of barium thiocyanate and bromacetophenone. Barium bromide is deposited, and on evaporating the alcoholic filtrate, acetophenone thiocyanate is left in thick, rhombic prisms. It melts at 74°, and exhibits the characteristic properties of a ketone. It dissolves in strong boiling hydrochloric acid, and the clear solution contains the hydrochloride of carbaminethioacetophenone, $COPh{\cdot}CH_2{\cdot}S{\cdot}CO{\cdot}NH_2,HCl$. On the addition of water, the hydrochloride is deposited in silky needles. This salt melts between 175° and 180°, and is soluble in alcohol; it is unstable. The free base cannot be isolated, being transformed into the original acetophenone thiocyanate at the moment of liberation. The platinochloride, $(C_9H_9O_2SN)_2,H_2PtCl_6$, is a pale-yellow, microcrystalline powder, insoluble in alcohol. It decomposes at about 200°.

A warm alcoholic solution of carbaminethiacetophene hydrochloride is rapidly converted into *α-phenyl-μ-hydroxythiazole*,

 $N\!<\!\genfrac{}{}{0pt}{}{CPh{\cdot}CH}{C(OH){\cdot}S}\!>$, by the addition of a few drops of hydrochloric acid. The hydroxythiazole is generally prepared by boiling acetophenone thiocyanate with hydrochloric acid until crystals are deposited from the originally clear solution. Phenylhydroxythiazole melts at 204°; it is dissolved by alkalis and reprecipitated by acids. This compound has been already described by Dyckerhoff (this Journal, 1877, ii, 327) as a polymeride of acetophenone thiocyanate.

The hydroxyl in phenylhydroxythiazole can be displaced by chlorine by the action of phosphorus pentachloride. *Phenylchlorothiazole* crystallises in prisms and melts at 98°. The compound is decomposed by warm water with the formation of the hydroxythiazole.

Acetone thiocyanate, $COMe{\cdot}CH_2{\cdot}SCN$, is obtained as an oily liquid by the action of pure monochloracetone on anhydrous barium thiocyanate dissolved in absolute alcohol. It unites with hydroxylamine, forming a stable *acetoxime*, $OH{\cdot}N{:}CMe{\cdot}CH_2{\cdot}SCN$, which melts at 135° and dissolves in alcohol. In the presence of hydrochloric acid, acetone thiocyanate is transformed into methylhydroxythiazole; an intermediate product could not be isolated.

The preparation and properties of *α-methylthiazole* have been described by Hantzsch and Arapides (Abstr., 1888, 573). *Phenylthiazole* is also prepared by distilling phenylhydroxythiazole with zinc-dust. It boils at about 271.° W. C. W.

Isothiocyanoacetic Acid. By L. Arapides (*Annalen*, **249**, 27—31).—*ν-Methyl-ψ-dioxythiazole*,  $NMe\!<\!\genfrac{}{}{0pt}{}{CO{\cdot}CH_2}{CO\,-\,S}\!>$, is prepared by digesting dioxythiazole (1 mol.), and sodium methoxide (1 mol.), with excess of methyl iodide and methyl alcohol. It is a deliquescent substance freely soluble in alcohol and water, and is decomposed by boiling with alkalis, yielding carbonic anhydride, thioglycollic acid and methylamine. The formation of methylamine shows that the methyl-group is directly attached to the N-atom. The analogous ν-phenyldioxythiazole has been described by Lange (Abstr., 1880, 44) as diphenylthiocarbamide. Phosphorus pentachloride acts on dioxythiazole, yielding a chloride, $C_3H_3Cl_2NOS$. This compound melts at 161° and decomposes at 170°. The author regards isothiocyanoacetic acid as diketo-thiazolidine. W. C. W.

Amidothiazoles and their Isomerides. By V. Traumann (*Annalen*, **249**, 31—53).—The preparation of mesamidothioazole, or *thiazylamine*, by the action of thiocarbamide on dichlorether, has been described by the author (Abstr., 1888, 573). Thiazylamine crystallises from alcohol in yellow plates, and melts at 90°. It is a monacid base, and forms a crystalline hydrochloride, $C_3SNH_2{\cdot}NH_2,HCl + H_2O$, and platinochloride. The acetyl-derivative melts at 203°, and crystallises in silky needles. *Methylthiazylamine*, prepared from thiocarbamide and monochloracetone, is identical with the compound obtained by Tscherniac and Norton (Abstr., 1883, 568) from ammonium thiocyanate and monochloracetone, and identified by Hantzsch and Weber (Abstr., 1888, 257).

Phenylthiazylamine is deposited from an ethereal solution in yellow prisms, freely soluble in alcohol and ether. It melts at 147°. The hydrochloride and platinochloride are crystalline. The acetic derivative melts at 208°. The existence of diazo-derivatives of thiazylamine, such as thiazolazoresorcinol, has already been mentioned (Abstr., 1888, 573).

The derivatives of thiazylamine are divided into two classes, namely, alkylthiazylamines, obtained by the action of α-chloroketones on monoalkylthiocarbamides,  $N<\substack{CH{=}CH\\ C(NHR)\cdot S}>$, and isoalkylthioazylamines, or *imidoalkylthiazolines*, $NR<\substack{CH{=}CH\\ C(NH)\cdot S}>$, prepared by the action of alkyl chlorides or iodides on mesoamidothiazoles.

α-Methyl-μ-methylamidothiazole, prepared by acting on monochloracetone with methylthiocarbamide, is not identical with, but an isomeride of, α-methylimidomethylthiazoline, described by Hantzsch and Weber (Abstr., 1888, 257). The free base is hygroscopic and melts at 42°. The hydriodide is anhydrous and melts at 136°. The platinochloride crystallises in orange plates and decomposes at 167°. The acetyl-derivative is anhydrous and melts at 110°. The base is decomposed by hydrochloric acid at 220°, yielding methylamine, but the imidomethylthiazoline yields ammonia under similar treatment.

α-Phenyl-μ-methylamidothiazole, prepared from methylthiocarbamide and phenacylbromide, is deposited from ether in large yellow plates, soluble in alcohol. It melts at 138°, and is not decomposed by hydrochloric acid below 138°. The isomeride, *α-phenylmethyl-μ-imidothiazoline*,  $NMe<\substack{CPh{=}CH\\ C(NH)\cdot S}>$, is prepared by the action of methyl iodide on phenylthiazylamine at 110°. It has only been obtained in the form of a syrup, but the hydrochloride is crystalline.

α-Methylthiazylaniline, obtained from phenylthiocarbamide and monochloracetone, crystallises in white needles and melts at 115°. On decomposition with hydrochloric acid, aniline is liberated. *Thiazylaniline*, prepared from dichlorether and phenylthiocarbamide, is deposited from alcohol in white needles. It is freely soluble in alcohol and ether and melts at 126°.

The condensation products of the symmetrical dialkylthiocarbamides with chloracetone, &c., are identical with the so-called dialkylamidothiazoles. The compounds described by Hantzsch and Weber as dialkylamidothiazoles are really *dialkylimidothiazolines*.

Dimethylimidomethylthiazoline, prepared by the action of monochloracetone on dimethylthiocarbamide, is identical with dimethylmethylthiazylamine (Abstr., 1888, 256).

Diphenylimidomethylthiazoline, prepared from monochloracetone and diphenylthiocarbamide, forms yellow prisms soluble in ether. It melts at 138·5°. Attempts to prepare dialkylamidothiazoles, the isomerides of the dialkylimidothiazolines, were unsuccessful.

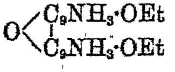
W. C. W.

Isoquinoline. By A. Claus and A. Edinger (*J. pr. Chem.* [2], 38, 491—496).—When an aqueous solution of isoquinoline methiodide (Abstr., 1887, 505) is treated with silver oxide, a strongly alkaline liquid is obtained, containing the corresponding hydroxide, together with another product, from which it may be separated by shaking with ether, which dissolves the bye-product. A crystalline carbonate of this base is formed when carbonic anhydride is passed through its aqueous solution, and from this the platinochloride, $(C_9NH_7Me)_2PtCl_6$, may be obtained in small, lustrous, yellow crystals.

With concentrated aqueous potash, isoquinoline methiodide yields a yellowish-brown oil, insoluble in water, but soluble in other solvents. This base differs from the above in that, (1) its platinochloride, $(C_9NH_6Me)_2,H_2PtCl_6$, does not crystallise; (2) its salts are precipitated by weak ammonia, and (3) it does not form a carbonate.

Papaverine methiodide, $C_{20}H_{21}NO_3,MeI$, crystallises in small, yellow laminæ, which after drying melt at 193—195° (uncorr.). When heated with silver oxide, it gives a base which is soluble in water, forms a carbonate from which other papaverine methyl salts may be formed, and yields a crystalline platinochloride. With potash, a sparingly soluble base is produced, which forms no carbonate, and whose platinochloride does not crystallise. A. G. B.

A Base derived from Diquinoline. By A. COLSON (*Compt. rend.*, **107**, 1003—1005).—A mixture of 7 grams of tetrethoxybenzidine from diethylquinol (Nietzki), 4 grams of orthonitrophenol, and 30 c.c. of sulphuric acid containing one-third of its volume of Nordhausen acid, was gradually heated to 120—125° in a large flask, mixed with 22—25 c.c. of glycerol, and heated to 140—145°. An energetic reaction takes place, and the temperature rises to 190°. After cooling, the product is treated with water, neutralised with sodium carbonate, and extracted with ether. The product crystallises from ether in long, flattened, highly birefractive, white needles, with a slightly bitter taste. It dissolves in six times its weight of dilute hydrochloric acid, and in 10 times its weight of alcohol of 92°, but is only slightly soluble in water, in the vapour of which it volatilises. With concentrated ferric chloride solution, it gives a green coloration; with platinic chloride, it yields a platinochloride, $C_{22}H_{16}N_2O_3,H_2PtCl_6 + 2H_2O$, crystallising in pale yellow crystals, soluble without decomposition in 15 times their weight of boiling water; with auric chloride, it yields a nacreous, deep-yellow aurochloride, insoluble in boiling water. The mode of formation of the base indicates that it is a diethoxydiquinoline base, probably derived from oxydiphenylene,



$$O\left\langle\begin{array}{l}C_9NH_3{\cdot}OEt\\ \,|\\ C_9NH_3{\cdot}OEt\end{array}\right. [OEt : O : C_9N = 1 : 4 : 3].$$

C. H. B.

Alkaloïd from Tea. By B. H. PAUL and A. J. COWNLEY (*Pharm. J. Trans.* [3], **19**, 24).—In the alcoholic extract from 200 grams of Himalayan tea, the authors found no theobromine. After extracting the whole of the theine from the acidified solution by frequent agitation with chloroform, the solution was made alkaline with potash, and again shaken with chloroform. On evaporating this solution, a small quantity of a yellow, amorphous alkaloïd was obtained, which was insoluble in hot water, but soluble in ether, and was therefore neither theïne nor theobromine. The operations are to be repeated with a larger quantity of the tea. The base which Kossel has obtained from tea, to which he has given the name of theophylline, and ascertained to be an isomeride of theobromine, may be identical with this alkaloïd. R. R.

Morphine. By L. Knorr (*Ber.*, **22**, 181—185).—Methylmorphimethine methiodide was treated with silver oxide, and the solution of the ammonium hydroxide evaporated down in a flask connected with a Volhard's receiver containing hydrochloric acid. A thick syrup remained, which when heated at 160° evolved a basic gas in considerable quantity. When the decomposition was complete, the base was completely driven into the acid by a stream of air. The residue in the flask was purified and found to be v. Gerichten and Schrötter's phenanthrene-derivative (Abstr., 1882, 1112). The acid solution contained trimethylamine hydrochloride.

When methylmorphimethine is heated with acetic anhydride at 160—200°, the following compounds are formed:—(1.) Fischer and v. Gerichten's acetylmethyldihydroxyphenanthrene (Abstr., 1886, 563). (2.) An oily *base*, which yields a *methiodide* melting at 295°. (3.) An oily substance, which is not decomposed by water; it can be separated from its aqueous solution by means of potassium carbonate, and distils at 160—186°. (4.) Dimethylamine.

These results show that, of the three carbon atoms in morphine, of which the mode of combination was still unexplained, one is attached to the nitrogen-atom as methyl. Morphine, therefore, cannot contain a pyridine-ring (compare Grimaux, Abstr., 1882, 218; and Hesse, Abstr., 1884, 613). N. H. M.

Water of Crystallisation in Morphine. By O. Hesse (*Pharm. J. Trans.* [3], **19**, 148).—The amount of water found by Dott and by Dietrich in air-dried morphine led them to represent it by the formula $8(C_{17}H_{19}NO_3) + 9(H_2O)$. The author points out that crystalline morphine frequently encloses small quantities of the solvent, which may have vitiated these results. On repeating the determinations with all precautions, values were obtained agreeing very closely with the formula $C_{17}H_{19}NO_3 + H_2O$. R. R.

Narcotine. (Parts III and IV.) By W. Roser (*Annalen*, **249**, 156—168; 168—172).—Methyl iodide acts on cotarnine, yielding a mixture of the hydriodide and of cotarnmethine methiodide. *Cotarnine hydriodide*, $C_{12}H_{13}NO_3,HI$, forms glistening needles, sparingly soluble in cold water and in cold alcohol. Cotarnine melts at 132—133° with decomposition. *Cotarnmethine methiodide*, $C_{11}H_{11}O_4NMe_3I$, forms yellow needle-shaped crystals sparingly soluble in cold water. The *chloride*, $C_{14}H_{20}NO_4Cl + 3H_2O$, and the *platinochloride*, $(C_{14}H_{20}NO_4)_2,PtCl_6$, are also crystalline. The chloride and iodide are decomposed by alkalis, yielding trimethylamine, water, and *cotarnone*, $C_{11}H_{10}O_4$. The conversion of cotarnine into cotarnone leads the author to the following conclusions:—The true formula of cotarnine is $C_{12}H_{15}NO_4$, not $C_{12}H_{13}NO_3 + H_2O$. Cotarnine is a secondary base. The salts of cotarnine contain the pyridine-ring, but the free base does not.

Cotarnone dissolves freely in alcohol, ether, and acetic acid, and melts at 78°; it is an indifferent substance, with ketone-like properties. *Cotarnonoxime*, $C_{10}H_{11}O_3\!:\!NOH$, melts with decomposition about 130—132°. *Cotarnic acid*, $C_8H_6O_3(COOH)_2$, prepared by the oxidation of cotarnone with potassium permanganate, crystallises in plates and melts at 178° with decomposition, yielding the anhydride which melts at 161—162°. The salts of barium, $C_{10}H_6O_7Ba$, potassium, $C_{10}H_7O_7K + 2\frac{1}{2}H_2O$, and silver, $C_{10}H_6O_7Ag_2$, are crystalline.

The action of methyl iodide on hydrastinine is analogous to its action on cotarnine; a volatile base and an indifferent substance being formed; the latter is a viscid oil which yields an oxime melting at 129°.

The constitution of cotarnine and its derivatives as deduced from the results of these experiments and previous researches, can be represented by the following formulæ:—

Cotarnine, a secondary base and an aldehyde—

$$CHO\cdot C_8H_6O_3\cdot CH_2\cdot CH_2\cdot NHMe.$$

Cotarnmethine methiodide, $CHO\cdot C_8H_6O_3\cdot CH_2\cdot CH_2\cdot NMe_3I$.

Cotarnone, $CHO\cdot C_8H_6O_3\cdot CH\!:\!CH_2$.

Cotarnonoxime, $OH\cdot N\!:\!CH\cdot C_8H_6O_3\cdot CH\!:\!CH_2$.

Cotarnic acid, $C_8H_6O_3(COOH)_2$.

Cotarnine iodide, 
$$C_8H_6O_3\left\langle\begin{array}{l}CH\!:\!NMeI\\ CH_2\cdot CH_2\end{array}\right..$$

Hydrocotarnine, 
$$C_8H_6O_3\left\langle\begin{array}{l}CH_2\cdot NMe\\ CH_2\cdot CH_2\end{array}\right..$$

Hydrastinine, $CHO\cdot C_7H_4O_2\cdot CH_2\cdot CH_2\cdot NHMe$.

Hydrohydrastinine, 
$$C_7H_4O_2\left\langle\begin{array}{l}CH_2\cdot NMe\\ CH_2\cdot CH_2\end{array}\right..$$

Oxyhydrastinine, 
$$C_7H_4O_2\left\langle\begin{array}{l}CO\cdot NMe\\ CH_2\cdot CH_2\end{array}\right..$$

W. C. W.

Additive Compound of Papaverine with Phenacyl Bromide. By E. v. SEUTTER (*Monatsh.*, 9, 1035—1044).—When a finely-powdered mixture of papaverine (10 grams) and phenacyl bromide (6 grams) is heated for three hours at 70—80°, the colourless mass melts to form a reddish-yellow oil which solidifies to a yellow crystalline mass; this, on recrystallisation from much hot water, furnishes fan-shaped groups of pyramids of the formula $C_{20}H_{21}NO_4,COPh\cdot CH_2Br + 2\frac{1}{2}H_2O$. This compound loses $1\frac{1}{2}$ mols. of water on exposure to the air, and is rendered anhydrous when heated at 110°. It is insoluble in cold water and in cold alcohol, dissolves readily in chloroform and carbon bisulphide, blackens at 190°, and decomposes rapidly at 194°. It dissolves in concentrated sulphuric acid, forming a beautiful carmine-red solution.

Papaverine phenacyl nitrate, $C_{20}H_{21}NO_4,COPh{\cdot}CH_2{\cdot}NO_3 + 2H_2O$, is insoluble in cold water, slightly soluble in hot water and alcohol, and decomposes at 173°. The *picrate* crystallises from hot alcohol in silky needles, softening at 180°, and melting at 182° with previous blackening. It is almost insoluble in cold water and cold alcohol. The *dichromate* crystallises in short needles, the *chloride* in long needles, and the *platinochloride* is only slightly soluble in boiling water.

When a solution of papaverine phenacyl bromide is decomposed with a dilute solution of sodium hydroxide, an orange-red precipitate forms which appears to have the formula $C_{20}H_{21}NO_4,COPh{\cdot}CH_2{\cdot}OH$; this, on warming to 80° or on recrystallising from hot alcohol, loses water and is converted into *papaverine phenacyl oxide*, $(C_{20}H_{21}NO_4,COPh{\cdot}CH_2)_2O$, which crystallises in needles, is insoluble in water and ether, but dissolves in alcohol, benzene, chloroform, and carbon bisulphide; it softens at 180°, and melts at 186—187°. The alcoholic solution has a splendid violet-blue fluorescence. This base can also be obtained by boiling papaverine phenacyl bromide for a long time with much water. G. T. M.

Cocaïnes. By C. LIEBERMANN (*Ber.*, **22**, 130—133).—*ε-Isatropylcocaïne*, $C_{19}H_{23}NO_4$, is obtained by heating ecgonine (2 parts), water (1 part), and γ-isatropic anhydride (2 parts) on a water-bath for three hours. The product is extracted with water, dried, dissolved in a little methyl alcohol, and the solution saturated with hydrogen chloride, and kept over night. It is then filtered, and the solution evaporated in a partial vacuum over lime and sulphuric acid. The residue is treated with water, extracted with ether, and the solution precipitated by means of sodium carbonate. The compound thus prepared has all the properties of the natural isatropylcocaïne. The two compounds are, however, not identical. When the substance, prepared as above, is decomposed it does not yield γ-isatropic acid (m. p. 274°), but ε-isatropic acid (m. p. 228°).

Anisylecgonine, $C_8H_7O_2{\cdot}C_9H_{14}NO_3$, obtained from ecgonine, anisic anhydride, and water, crystallises from alcohol in colourless needles melting at 194°.

Anisylcocaïne, is a viscous substance insoluble in water. The *aurochloride*, $C_8H_7O_2{\cdot}C_9H_{14}MeNO_3,HAuCl_4$, is yellow; it is insoluble in water and dilute alcohol.

Cinnamylcocaïne forms small, colourless, monoclinic prisms; $a : b : c = 0{\cdot}8616 : 1 : 0{\cdot}8479$; $\beta = 84° 20'$. N. H. M.

Cinnamic Acid in the Product of Decomposition of Crude Cocaïne. By H. FRANKFELD (*Ber.*, **22**, 133—134).—The crude material was extracted with water, treated with cold, dilute alkali, and the residue boiled with alkali; it contained cinnamic, γ- and δ-isatropic acids, and a trace of benzoic acid. N. H. M.

A Metameric Cocaïne and its Homologues. By A. EINHORN (*Ber.*, 21, 3441—3443).—*Methyl cocaylbenzoylhydroxyacetate*, $C_5H_7NMe\cdot C(OH)(COPh)\cdot COOMe$, prepared by passing hydrogen chloride into an alcoholic solution of the acid (compare this vol., p. 169), is a colourless oil. The *hydrochloride*, *hydrobromide*, and the sparingly soluble *hydriodide*, $C_{16}H_{19}NO_4,HI$, crystallise in needles. The *ethyl* salt is a colourless oil; the *hydrochloride* and the *hydrobromide* crystallise in needles; the sparingly soluble *hydriodide* crystallises in prisms. The *propyl* salt crystallises in slender needles, melts at 56—58°, and is very readily soluble in most of the ordinary solvents, but insoluble in water. The *hydrochloride*, $C_{18}H_{23}NO_4,HCl$, *hydrobromide*, and *hydriodide* crystallise in needles. F. S. K.

Alkaloïds of Areca-nut. By E. JAHNS (*Ber.*, 21, 3404—3409).—The bases contained in areca- or betel-nut can be isolated by either of the following methods:—

(1.) The crushed seeds (1 kilo.) are extracted three times with cold water containing 2 grams of concentrated sulphuric acid, the filtered solution concentrated to about 1 litre, and the cold and filtered solution precipitated with potassium bismuth iodide and sulphuric acid. The red, crystalline precipitate, which is soluble in excess of the reagent, is separated after some days, washed, and decomposed by boiling with barium carbonate and water. The filtered and concentrated solution is mixed with barium oxide, and the oily alkaloïd, which the author names arecoline, extracted with ether. The residual mixture is neutralised with sulphuric acid, and the filtered solution is treated consecutively with silver sulphate, barium oxalate, and carbonic anhydride. The solution of the bases is evaporated to dryness, and the residue extracted with cold absolute alcohol or chloroform; an alkaloïd, which the author names arecaïne, remains, and a third alkaloïd, together with colouring matters, &c., are dissolved, and are obtained as an amorphous mass when the solution is evaporated.

(2.) The crushed seeds are treated with cold milk of lime, the filtered extract is neutralised with sulphuric acid, evaporated to a syrupy consistency and then diluted with a small quantity of water; after concentrating the filtered solution and adding alkali, the arecoline is extracted with ether and the other bases are isolated as described above. The yield of arecoline is 0·07—0·1 per cent., that of arecaïne is about 0·1 per cent.; the third base is obtained in very small quantities.

Arecoline, $C_8H_{13}NO_2$, is obtained in the pure state by shaking the ethereal extract (see above) with dilute acid, concentrating the neutralised solution, and, after adding alkali, extracting the alkaloïd with ether. The base is neutralised with hydrobromic acid, the salt is repeatedly recrystallised from absolute alcohol, and the alkaloïd is then obtained by decomposing the pure hydrobromide with alkali. It is a colourless, oily liquid, with a strongly alkaline reaction, and is miscible with water, alcohol, ether, and chloroform in all proportions. It seems to boil at about 220°. The salts are readily soluble and, although some are deliquescent, they are mostly crystalline. Potassium bismuth iodide gives a garnet-red, and phosphomolybdic acid a white precipitate in solutions of the salts. Potassium mercuric iodide, solutions of iodine, picric acid, and auric chloride produce oily precipitates, which, as a rule, crystallise after some time, but platinic chloride, mercuric chloride, and tannic acid give no precipitation.

The *hydrobromide*, $C_8H_{13}NO_2,HBr$, crystallises in prisms, melts at 167—168°, and is readily soluble in water. The *hydrochloride* crystallises in slender, deliquescent needles, and is readily soluble in alcohol or in a mixture of alcohol and ether; it seems to form several double salts with cadmium chloride. The *sulphate*, *acetate*, and *nitrate* resemble the hydrochloride. The *aurochloride*, $C_8H_{13}NO_2,HAuCl_4$, is a yellow oil, and is sparingly soluble in cold water. The *platinochloride*, $(C_8H_{13}NO_2)_2,H_2PtCl_6$, separates in flocks when ether is added to an alcoholic solution of the hydrochloride and platinic chloride, and, after washing with alcoholic ether, it separates from water in orange-red, rhombic crystals, melting at 176° with decomposition.

Arecoline is a powerful poison, and is doubtless the active physiological constituent of areca-nut.

Arecaïne, $C_7H_{11}NO_2 + H_2O$, is purified by repeatedly recrystallising from 60 per cent. alcohol. It is colourless, and is readily soluble in water and dilute alcohol, but almost insoluble in absolute alcohol, ether, chloroform, and benzene. It loses its water at 100° and melts at 213° with decomposition. It has no apparent physiological action. Potassium bismuth iodide, when added to a dilute sulphuric acid solution, produces a red, amorphous precipitate, which soon becomes crystalline; potassium mercuric iodide gives a yellow, crystalline precipitate under the same conditions. Potassium iodide gives a dark, crystalline precipitate in dilute acid solutions, but phosphomolybdic acid and tannin only produce a slight turbidity, whilst picric acid causes no precipitation. The *hydrochloride*, $C_7H_{11}NO_2,HCl$, the *aurochloride*, $C_7H_{11}NO_2,HAuCl_4$, melting at 186—187°, and the *platinochloride*, $(C_7H_{11}NO_2)_2,H_2PtCl_6$, melting at 213—214° with decomposition, are crystalline.

The third alkaloïd referred to above is an amorphous, strongly alkaline base; it is readily soluble in water, alcohol, and chloroform, but only sparingly in ether. The *platinochloride* crystallises in prisms or plates. F. S. K.

Ptomaïnes. By O. DE CONINCK (*Compt. rend.*, **108**, 58—59).—When the alkaloïd obtained from the cuttle-fish (Abstr., 1888, 730, 1118) is oxidised with dilute potassium permanganate solution, it yields a gummy acid, which in concentrated solutions gives a bulky, pale-blue precipitate with cupric acetate. This acid is almost insoluble in cold water, but dissolves readily in warm water and in alcohol. It melts at 220—228°, and when distilled with calcium oxide, it yields pyridine. The properties of the acid very closely resemble those of nicotinic acid. These results confirm the author's view that this base is a ptomaïne of the pyridine series. C. H. B.

Ptomaïnes and their Genesis, in relation to Panum's Sepsin. By J. M. WYBORN (*Chem. News*, **59**, 2).—As it seems probable that in many cases where ptomaïnes have been attributed to putrefaction, they may really have been produced by the action of acids on lecithin and albuminoïds, the author has made experiments avoiding the use of acids.

Finely minced beef was macerated with twice its weight of water and exposed to the heat and light of the sun for 16 days, free access of air being prevented. The strained liquor was precipitated with an equal bulk of absolute alcohol, the precipitate boiled with the same quantity of alcohol, washed with boiling alcohol, and dried in warm air. It was then treated with water, filtered, and evaporated to dryness. The residue from the evaporation, amounting to 0·067 per cent. of the beef used, consisted of:—1. A heavy brownish-red matter freely soluble in water; 2. A very light, pale-greenish substance, sparingly soluble; and 3. Brilliant, white, crystalline plates. With a mixture of equal volumes of glycerol and water, it yielded an amber-coloured solution and a brown precipitate; the solution was at first nearly neutral, but after exposure to the air became acid, and acquired the odour of stale pepsin. After keeping a month, 5 or 6 minims, containing $\frac{1}{16}$ grain of residue, injected under the skin, proved fatal to mice in about an hour. Reactions with various reagents indicate the presence of peptones and cadaveric alkaloïds, and "unless the alcohol were alone sufficient to produce them (the latter) in the putrid solution, their pre-existence may be reasonably inferred." D. A. L.

Acids of Pig's Bile. By S. JOLIN (*Zeit. physiol. Chem.*, **13**, 205—247).—A further contribution relating to the acids of pig's bile (see Abstr., 1888, 1213). Various metallic compounds (with sodium, potassium, lead, magnesium, copper, &c.) of the α- and β-hyoglycocholic acids were prepared and analysed. The following conclusions were arrived at: the α-acid is precipitated by dilute acids more easily than the β-acid. The salts of the alkalis are less soluble in water in the case of the α-acid, and are more easily precipitated by saturated salt solutions. The barium, calcium, and magnesium salts of the α-acid do not dissolve in excess of the bile salt, like those of the β-acid, but form a flocculent or granular, not a sticky precipitate. The salts of the α-acid with the heavy metals do not fuse on heating the solution like those of the β-acid. The sodium salt of the α-acid dissolved in water is optically inactive, that of the β-acid, dextrorotatory. The alkaline salts of the α-acid are bitter to the taste, whilst those of the β-acid are first sweet then bitter.

Further experiments were performed to ascertain correctly the proportion of various neutral salts necessary to cause precipitation of the sodium salts of the two acids. The salts investigated were sodium chloride, sulphate, nitrate, and potassium nitrate. The hyocholic acids prepared from the two acids were very much alike, but not identical, the differences consisting chiefly in the amount of neutral salt (sodium chloride, sulphate, potassium nitrate) necessary to cause precipitation of the sodium hyocholate; the salt of the α-hyocholic acid being precipitated more easily than that of the β-acid. The barium and silver salts were also prepared, analysed, and their reactions described.

W. D. H.

Elastin and Elastoses. By R. H. CHITTENDEN and A. S. HART (*Zeit. Biol.*, **25**, 368—389).—Horbaczewski (Abstr., 1887, 270) observed that elastin is digested by gastric juice. The final product is a peptone, and the intermediate substances he named hemielastin. In the present research, elastin was prepared from the ligamenta nuchæ of the ox, soluble substances being removed by prolonged extraction with hot water, potash, acetic acid, and alcohol. In the elementary analyses of this substance sulphur was not found. In another specimen, in which the extraction with potash was omitted, a small percentage of sulphur (0·3) was found. It is doubtful, however, whether this is contained in the elastin molecule or in proteïd matter mixed with it; the authors incline to the former view.

The elastin was subjected to treatment with boiling water, to which a trace of hydrochloric acid had been added; another portion to artificial gastric digestion, and a third portion to artificial pancreatic digestion. In all three cases, two products were obtained, which are named *protoelastose* and *deuteroelastose*, terms symmetrical with those of the corresponding proteoses. No trace of any hetero-product was found; the protoelastose has the characters and composition of Horbaczewski's hemielastin. The question whether true peptone is formed on energetic digestion has yet to be investigated. The original paper gives full details of the separation, reactions, and analysis of these substances. W. D. H.

Myosin and Myosinoses. By W. KÜHNE and R. H. CHITTENDEN (*Zeit. Biol.*, **25**, 358—367).—The primary products of digestion of fibrin, egg albumin, globulin, caseïn and vitellin have been previously studied; the ultimate product is peptone, and the intermediate substances, albumoses, globuloses, &c., may be conveniently included under the generic term proteoses. The present paper relates to the proteoses obtained in the digestion of myosin.

Myosin was extracted from muscles by the use of ammonium chloride solutions; from such extracts, the myosin was precipitated in a gelatinous form by dialysing away the salts, it was then submitted to elementary analysis. Some was submitted to gastric digestion, and then the insoluble residue to pancreatic digestion. But in the latter case, the formation of peptone was so rapid that no myosinoses were obtainable. In the case of gastric digestion, however, considerable quantities of proto- and deutero-myosinose were obtained, but only small quantities of heteromyosinose. These products were separated from one another by the methods the authors have already described in the case of other proteoses.

Protomyosinose only differs from protoalbumose in its reactions, in that nitric acid does not precipitate it from solutions free from salt. *Deuteromyosinose*, like deuteroalbumose, is not precipitated by copper sulphate in the cold; after boiling and subsequent cooling, however, a precipitate forms. It is precipitated by saturation with salts, but with greater difficulty than deuteroalbumose is. Both these albumoses in an aqueous solution are alkaline in reaction. The following table contrasts their percentage composition with that of myosin.

	Myosin.	Protomyosinose.	Deuteromyosinose.
C	52·79	52·43	50·97
H	7·12	7·17	7·42
N	16·86	16·92	17·00
S	1·26	1·32	1·22
O	21·97	22·16	23·39

W. D. H.

Artificially prepared Nucleïns. By J. Pohl (*Zeit. physiol. Chem.*, **13**, 292—297).—Liebermann (Abstr., 1888, 510) has shown that a substance having the properties of nucleïn may be artificially prepared from metaphosphoric acid and white of egg. White of egg contains, however, at least two proteïds (globulin and albumin) and the present research relates to nucleïn prepared artificially from pure proteïds; namely, (1) serum albumin freed from globulin by magnesium sulphate; and (2) varieties of albumose obtained by the fractional precipitation of a solution of commercial peptone by ammonium sulphate. Nucleïn from serum albumin so prepared contains about 5·5 per cent. of phosphorus; from one variety of albumose, 4·8; from another, 6·5. Although these artificial nucleïns resemble native nucleïn in their solubilities, they differ from it in the fact that substances of the uric acid group (xanthine and hypoxanthine) cannot be obtained from them on decomposition. These substances also do not form insoluble compounds with metaphosphoric acid. Guanidine hydrochloride, however, gives with sodium metaphosphate a crystalline precipitate which contains 22·3 per cent. of phosphorus; thus corresponding with the formula CN_3H_5,HPO_3. Certain vegetable bases (strychnine nitrate, quinine hydrochloride) form similar compounds.

W. D. H.

Action of Salts on the Proteïds of Serum. By S. Lewith (*Arch. exper. Path. Pharm.*, **24**, 1—16).—These experiments are similar to those of Kauder with ammonium sulphate (*Arch. exper. Path. Pharm.*, **20**, 411), who determined the amount of that salt necessary to precipitate the globulin and albumin of serum. Halliburton (*J. Physiol.*, **5**, 152) has made similar experiments, although not quantitative ones, with a large number of different salts. Salts which were found to produce no precipitation of the proteïds even when added to saturation were potassium sulphate, nitrate, and chlorate; ammonium chloride, nitrate, and acetate; calcium acetate; barium chloride, nitrate, and acetate; magnesium chloride, nitrate, and acetate. Those which were found to produce a greater of less precipitation were potassium chloride and acetate; sodium chloride, sulphate, nitrate, chlorate, phosphate, and acetate; calcium chloride and nitrate; magnesium sulphate. With three of these salts, Halliburton obtained, however, negative results, namely, potassium chloride, sodium sulphate, and sodium phosphate. In the present research, a somewhat higher temperature was used than in Halliburton's work, and this probably accounts for the discrepancy: the precipitate produced was, however, small in all three cases.

The following table gives the results of the quantitative estimation of the amount of salt necessary to produce precipitation of the two proteïds of serum:—

Salt.	Percentage of salt necessary to produce				Result of saturation.
	Precipitation of globulin.		Precipitation of albumin.		
	Begins.	Ends.	Begins.	Ends.	
Sodium sulphate	11·4	—	—	—	Incomplete precipitation of globulin.
Ammonium sulphate	14·2	23·1	33·6	47·2	Complete precipitation of both.
Sodium acetate	14·6—15	—	—	—	Nearly complete precipitation of globulin.
Sodium nitrate	43—46	—	—	—	Do. do.
Magnesium sulphate	16·9	25·7	—	—	Complete precipitation of globulin.
Potassium acetate	17—22	35·2	64·6	88·1	Complete precipitation of both.
Sodium chloride	21·8	—	—	—	Incomplete precipitation of globulin.
Potassium chloride	25·9	—	—	—	Do. do.

The solubility of the salts is by no means parallel to the power they have in precipitating the proteïds. The sulphates and acetates seem to be the most powerful in this direction, then the chlorides, and lastly the nitrates.

W. D. H.

Action of Salts on Proteïds. By F. Hofmeister (*Arch. exper. Path. Pharm.*, **24**, 247—260).—This is a research of similar nature to that of Lewith (see preceding Abstract). Instead of using serum, however, a solution of globulin prepared from white of egg was employed; and all observations were made using the same strength of globulin solution, in order to compare them more justly with one another. Lewith used serum containing very varying percentages of globulin and albumin. The number of salts employed was very numerous, and the results are given in tabular form similar to that quoted in the preceding Abstract. The salts are then arranged in groups according to certain properties; and it is found (although not without exceptions) that purgative power, difficulty of diffusion, and power of precipitating globulins go together.

W. D. H.

Physiological Chemistry.

Can the Mucous Membrane of the Stomach decompose Bromides and Iodides? By E. DRECHSEL (*Zeit. Biol.*, 25, 396—399).—Külz (Abstr., 1887, 508) has found by Rabuteau's (quinine) method of separating the free acid in gastric juice that he obtains quinine hydrochloride: in artificial gastric juice to which the bromides of the alkali metals had been added, that quinine hydrobromide was also formed, and in experiments on dogs he also considered he had proved the existence of free hydrobromic or hydriodic acids in the gastric juice after the administration of a bromide or iodide respectively. But there is a factor in the case which he overlooked, and that therefore renders his deductions invalid: this is the old question, how many salts are contained in a solution formed by mixing solutions of two salts with different bases and acids? When equivalent quantities of solutions of such salts as mercuric chloride and sodium nitrate are mixed, doubtless there are only two salts in the mixture; but in other cases there would be four salts: chlorides and nitrates of both metals.

So in a mixture of sodium bromide and free hydrochloric acid, there would also be sodium chloride and free hydrobromic acid; and hence in a simple mixture like this, by treatment with quinine the hydrobromide and the hydrochloride of that alkaloïd would both be formed. Hence the action of the gastric mucous membrane is not necessarily proved to be that of bringing about a decomposition of the molecules of the bromide or iodide used.

This theoretical objection to Külz's conclusions was put to the test of experiment, and it was found that hydrobromic and hydriodic acids could be recognised by treating mixtures of either the bromide or iodide of potassium or sodium and weak hydrochloric acid with quinine as in Rabuteau's method. The question raised by Külz is therefore still unanswered. W. D. H.

Tension of Oxygen in Blood and in Solutions of Oxyhæmoglobin. By G. HÜFNER (*Zeit. physiol. Chem.*, 13, 285—291); compare Abstr., 1888, 1214).—One point not worked out in the earlier research is the influence of the concentration of the oxyhæmoglobin solution in the dissociation that takes place. The following table illustrates the results now obtained bearing on this point as well as the influence of fever temperature; t, p, and v represent respectively temperature, pressure, and volume of oxygen before, and t' p', and v' after the shaking.

The limiting pressure of dissociation is thus higher at this temperature than in the previous research. In researches 4 and 5 the initial pressure was lower than in the others. The last four researches illustrate the effect of concentration. The solution with higher concentration still gives off oxygen, whilst one of half the concentration and at about the same temperature does not.

	Percentage of oxyhæmoglobin.	t.	t'.	$p'-p$.	$v'-v$.
1.	11·06	39°·0	38°·5	1·13	0·31
2.	11·06	39·0	38·5	1·58	0·41
3.	12·97	39·0	38·3	0·13	0·09
4.	16·51	39·1	38·5	11·16	2·67
5.	16·51	39·4	38·9	10·31	2·47
6.	16·63	40·0	39·25	0·97	0·33
7.	8·32	39·6	39·1	−0·80	−0·15
8.	16·84	39·25	38·7	1·16	0·35
9.	8·42	39·7	39·1	−0·10	0·01

If one can apply results obtained with solutions of oxyhæmoglobin outside the body to the solving of problems occurring in the red corpuscles of the blood, the best means of rendering breathing possible in high altitudes would be to increase the richness of the blood in hæmoglobin. W. D. H.

Blood Tablets and Thrombosis. By M. Löwit (*Arch. exp. Path. Pharm.*, **24**, 188—220).—The blood tablets of mammalian blood seem to be absent from the blood of birds, amphibians, reptiles, and fishes. By certain methods of microscopical staining with gentian violet, which are fully described, it is found that the fibrin network and the blood tablets stain similarly, whilst the white blood corpuscles remain unaffected or are only lightly stained. The tablets are therefore regarded as a most important precursor of fibrin, and are considered to consist chiefly of a globulin which is readily changed into or takes part in the formation of fibrin. The colourless plugs sometimes found in veins (thrombi) are also considered to be chiefly composed of blood tablets. The spindle cells of the blood of Batrachians and birds are not the equivalent of blood tablets, as some have supposed (Eberth and Schimmelbusch, *Virchow's Arch.*, **108**, 36[illegible]), but are merely varieties of white blood corpuscles. W. D. H.

Influence of Starvation on the Glycogen of the Liver and Muscle. By G. Aldehoff (*Zeit. Biol.*, **25**, 137—162).—The question has been investigated by others previously, and references to their work are given. It was judged necessary to reopen the question, as in the previous work on the subject the method of Külz (Abstr., 1887, 494) had not been employed. This is a method which is believed to give more trustworthy results from a quantitative point of view than any other. Experiments were made on frogs, rabbits, cats, horses, pigeons, and fowls. The quantitative results are given in tabular form, and the following are the general conclusions that are drawn:—

In the fowl, the glycogen, under the influence of starvation, disappears not only in the heart muscles but also in the muscles of the limbs and other parts, much more slowly than in the liver. This is opposed to Luchsinger's statement (*Dissert.*, *Zurich*, 1875) that the heart muscles are richer in glycogen during inanition than those of the limbs and other parts of the body; but agrees with the statement of Weiss, that the muscle-glycogen does not disappear so quickly as that in the liver, when insufficient carbohydrate food is given; the same statement holds for most of the other animals (pigeons, rabbits, cats, and horses) used in the research. The muscle-glycogen of summer and winter frogs remains fairly constant during inanition, or varies within narrow limits; the glycogen of the liver, however, disappears much more quickly in summer frogs than in winter frogs; in the latter, after abstinence from food for two months, relatively large quantities of glycogen are still to be found in the liver.

In the hearts of two horses, after a nine days' fast, 0·82 and 0·58 per cent. of glycogen respectively was found; and in a cat which had been without food for a fortnight, the heart still contained 0·44 per cent. of glycogen. In the skeletal muscles of the horse, larger percentages still were found (0·098—1·34).

Luchsinger considers that glycogen is not the direct source of energy in contracting muscle, but this is in no way proved by his researches, for it is doubtful whether he could ever have obtained muscles free from glycogen. Estimations of glycogen by weighing and by the polarimetric method correspond with one another very well.

W. D. H.

Effect of Muscular Work on the Glycogen in the Muscles. By E. MANCHÉ (*Zeit. Biol.*, 25, 163—179).—Weiss (*Sitzb. d. k. Akad. der Wissensch.*, Abth. 64) stated that on contraction the amount of glycogen in the muscles diminishes. Weiss used Brücke's method of estimating the glycogen: this is a method which does not give such good results as that of Külz; for this reason, among others, it was deemed advisable to repeat the experiments. In the present research, Külz's method of estimating the glycogen was used. The experiments were performed on frogs, and the following table illustrates the results obtained:—

	Weight of glycogen in limb at rest.	Weight of glycogen in limb which was made to contract from 23—65 minutes.	Loss of glycogen per cent. in tetanised limbs.
	gram.	gram.	
1........	0·1277	0·1114	12·76
2........	0·2287	0·1942	15·09
3........	0·2267	0·1917	15·44

In other words, the limbs which were stimulated to contract, lost from 12 to 15 per cent. of their glycogen in an hour, and thus Weiss's statement was confirmed.

Chandelon (*Pflüger's Archiv*, 13, 626) came to the conclusion that section of the nerve of a muscle caused an increase in the glycogen of the muscle. These experiments were repeated on rabbits, using Külz's method of analysis as before; the following table illustrates the results obtained:—

	Operation of cutting one sciatic nerve performed.	Increase (per cent.) of glycogen on operated side as compared with the normal.
1	5 days before death	6·25
2	7 " "	26·67
3	20 " "	33·33
4	2 " "	8·33
5	2 " "	10·00

As Chandelon states, the paralysed muscles contained a greater quantity of glycogen; this is probably explained by the fact that the intact muscles of the other limb had been contracting since the operation, and thus the glycogen in them was lessened.

Other experiments of Chandelon's were also repeated and fully confirmed; namely, those which illustrate the fact that ligature of the artery supplying a muscle leads to a decrease of its glycogen. The loss of glycogen was greatest in those cases where œdema followed the operation; the saturation of the tissues by lymph leads probably to saccharification. W. D. H.

Source of the Glycogen of Muscle. By C. Schmelz (*Zeit. Biol.*, **24**, 180—207).—This research, like those related in the two preceding Abstracts, consisted mainly of a repetition of the work of previous investigators. Various criticisms are passed on the methods adopted by them; and the estimations in the present experiments were made by Külz's method, or by the polarimeter (Cramer, *Zeit. Biol.*, **24**, 67); these two methods giving approximately equal results. The net result of the experiments, however, is merely to confirm the results arrived at by Brücke's seemingly less exact method.

Minkowski (*Arch. f. exp. Path. Pharm.*, **23**, 139) and Laves (*Inaug. Dissert.*, *Königsberg*, 1886) stated that after extirpation of the liver, the amount of glycogen in the muscles markedly diminishes; they consider that the muscular glycogen chiefly originates in the liver. This diminution was also found to be the case in the present research; moreover, feeding on cane-sugar produced no marked increase of the muscle-glycogen either in normal animals or in those in which the liver had been removed. W. D. H.

Secretion of Lime by Animals. By R. Irvine and G. Sims Woodhead (*Proc. Roy. Soc. Edin.*, **127**, 308—316).—Dana and J. Y. Buchanan have stated their belief that the calcium carbonate excreted by polyps, &c., is absorbed as sulphate, and converted first into sulphide and then to carbonate. The authors, therefore, experimented with fowls, shutting them up so that they could obtain no lime other than that given to them as sulphate—the hens continued to lay eggs with normal shells. They also show that fowls are unable to store up in their gizzard more lime as carbonate than is sufficient for the formation of the shells of two or three eggs, and that if lime is not procurable, either they will lay soft eggs, or will cease to lay; there is also a discussion as to the various parts of the bird which take part in the excretion of lime. E. W. P.

Proteïds in Milk. By J. SEBELIEN (*Zeit. physiol. Chem.*, **13**, 135—180).—See p. 450.

Guanine in the Excrement of Spiders. By C. WEINLAND (*Zeit. Biol.*, **25**, 390—395).—Will and Gorup-Besanez have described guanine in the excrement of the spider, in the organ of Bojanus of the mussel, and in the green glands of the crayfish. Voit was not able to find it in the organ of Bojanus, but he found it in the flesh of pigs, and also in the swimming-bladder of the *Argentina sphyræna.* The present research is concerned with spiders; the excrement was collected and found to consist of roundish particles 4—10 mm. across, and of a reddish-yellow colour. From this, crystals of guanine were prepared which gave the reactions of that substance as described by Capranica (*Zeit. physiol. Chem.*, **4**, 233). W. D. H.

Cystin. By RADZIWILLOWICZ (*Chem. Centr.*, 1888, 1415, from *Berlin. klin. Wochensch.*, **25**, 835—836).—In order to separate cystin from animal excreta, the author recommends extraction of the strongly ammoniacal liquid with amyl alcohol, evaporation and treatment of the residue with water. He thus isolated 0·1 milligram from 2 c.c. of solution, and confirmed its presence with potassium mercuric iodide, iodine in potassium iodide or phosphotungstic acid. Its toxicological action appears to be qualitatively the same with all animals, although differing in degree, not only with the different species but also with different members of the same species. Spectroscopical investigation shows that blood impregnated with cystin remained longer arterial, and its action appears to tend to the suppression of consumption of oxygen in the system. J. W. L.

Relation between the Total Sulphuric Acid of the Urine and that Existing as Ethereal Sulphates in Rest and Work. By S. SHER (*Diss. for M.D. St. Petersburg*, No. 4, 1888—1889).—The total sulphuric acid (*a*) and that existing in the form of ethereal sulphates (*b*) in the urine of 26 persons of different classes (doctors, soldiers, prisoners, peasants, &c.), was estimated by day and by night, in work and at rest. It was found that *a* was less during rest than during work, that *b* was also less during rest, and that the ratio between *a* and *b* was less during rest than during work.

Exceptions to these rules occurred when the work was excessive and exhausting. The mean quantities obtained were as follows:—REST by day, *a* 1·4128, *b* 0·1733, ratio 8·1; by night, *a* 1·3343, *b* 0·1601, ratio 8·3; during the 24 hours, *a* 2·7471, *b* 0·3334, ratio 8·2.

WORK by day, *a* 1·6176, *b* 0·1803, ratio 8·9; by night, *a* 1·3556, *b* 0·1408, ratio 9·6; during the 24 hours, *a* 2·9732, *b* 0·3211, ratio 9·2. T. M.

Pepsin in Normal and Pathological Urine. By E. STADELMANN (*Zeit. Biol.*, **25**, 208—231).—A proteolytic ferment acting like pepsin in an acid medium has been found by many observers in urine. Neumeister (Abstr., 1888, 516) brought forward a proof that this is pepsin, when he showed that in Carnivora injection of primary albumoses into the circulation caused the appearance of deuteroalbumose in the urine; and deuteroalbumose when injected was similarly converted into true peptone.

In the present research, the question whether the ferment is pepsin or another ferment something like pepsin was investigated by performing experiments with the ferment outside the body on fibrin; and the results may be thus summarised:—

(1.) The ferment is true pepsin, as by its action all the products of peptic digestion are formed: protoalbumose, heteroalbumose, deuteroalbumose, and peptone. (2.) If, however, the solution contain but little ferment, the only products of digestion are acid-albumin and small quantities of the primary (proto- and hetero-) albumoses; and, indeed, these products can be obtained by the action of 0·25 per cent. hydrochloric acid without any pepsin on raw fibrin; the same strength of acid has no action on boiled fibrin; but 1 per cent. hydrochloric acid acts energetically by itself on boiled fibrin, forming even deuteroalbumose and peptone.

The influence of small quantities of various salts on tryptic digestion has been investigated by Nasse (*Pflüger's Archiv*, **11**), Heidenhain (*ibid.*, **10**), and A. Schmidt (*ibid.*, **13**). This same question is here investigated for peptic digestion. A number of specimens, each containing the same amount of artificial gastric juice and fibrin, were taken, with different amounts of various salts, and the time noted in which solution of the fibrin occurred. A concentration equal to 0·02 per cent. of various urates was found to exert inhibiting influence on the action of pepsin; much smaller percentages (0·004) of sodium sulphate, potassium sulphate, ammonium sulphate, and magnesium sulphate produced the same effect, whilst sodium chloride and sodium phosphate only exerted a similar action when present to the extent of 0·01 per cent.

The urine of various patients was investigated as follows: The urine was divided into three parts: (1) was diluted with 0·25 per cent. hydrochloric acid in the proportion of 1 of urine to 3 of dilute acid; (2) fresh, raw fibrin was added to extract the ferment, the fibrin was then washed and digested in 0·25 per cent. hydrochloric acid; (3) was the control specimen; it was treated as in (1), but was also boiled, fibrin being then added to each. Trypsin was sought for but never found. In fever patients, pepsin seems never absent from the urine; this includes typhoid fever, in which some have failed to find the ferment. Also in severe cases of stomach disease, including cancer, pepsin was often found. No diagnostic value can therefore be attached to the presence or absence of pepsin in the urine in cases of disease. W. D. H.

Formation of Volatile Fatty Acids in the Ammoniacal Fermentation of Urine. By E. SALKOWSKI (*Zeit. physiol. Chem.*, **13**, 264—274).—The peculiar smell of ammoniacal urine is chiefly due to the formation of volatile fatty acids.

A quantity of normal urine was divided into two parts, one part was distilled with strong sulphuric acid, the other was allowed to undergo the ammoniacal change, and then similarly distilled. The distillates were then titrated with $\frac{1}{4}$ normal sodium hydroxide solution. As a mean of eight analyses, the distillate of 300 c.c. of fresh urine contained acid equivalent to 2 c.c. of the alkaline solution, and of the stale urine, acid equivalent to 12·2 c.c. of the same solution; that is, it has increased more than sixfold. Traces of hydrochloric acid were found in both distillates, but this error is probably a constant one.

Reckoning 1500 c.c. as an average day's urine, the volatile acid per diem would be equivalent to 0·15 gram of acetic acid (a number probably a little too high), this is increased to 0·915 gram on the occurrence of putrefactive changes. In different specimens, the stronger the alkalinity of the urine the greater the amount of volatile acids obtained.

This acidity is not due to carbonic anhydride obtained by decomposition of ammonium carbonate; the ammonium carbonate in some experiments being first removed by barium hydroxide; and fresh urine mixed with ammonium carbonate gives the same amount of acidity in the distillate as a similar specimen to which ammonium carbonate was not added. The acids present appear to be acetic, propionic, and butyric. Recent researches seem to have established the fact that normal urine contains carbohydrates, and by means of the furfuraldehyde colour reaction with α-naphthol (Udránszky) these can be tested for. This reaction is, however, very weak in stale urine, hence the conclusion is drawn that the fatty acids are formed from the carbohydrates during the ammoniacal fermentation. Uric acid is found only in traces in putrid urine: ceratinine is, however, fairly abundant. Acetone is apparently unaltered by the ammoniacal fermentation; phenol and cresol are increased in quantity; the power of reducing copper oxide or silver oxide in alkaline solutions is fairly strong in putrid urine. W. D. H.

Evolution of Hydrogen Sulphide in Urine and the Behaviour of Sulphur in the Organism. By E. SALKOWSKI (*Chem. Centr.*, 1888, 1471, from *Berlin klin. Wochensch.*, **25**, 722—726).—The author considers that the evolution of hydrogen sulphide from urine is to be traced to the action of bacteria on the neutral sulphur compounds contained in the urine. It accordance with this, it was found that when nutritive solutions containing suitable thiosulphates were inoculated with urine already containing hydrogen sulphide, large quantities of hydrogen sulphide were liberated, showing the reducing power of such bacteria. Similar experiments on sulphates were attended with a like result. No trace of thiosulphates could, however, be detected in healthy urine.

Experiments made to determine the ultimate disposal of flowers of sulphur introduced into the intestinal canal showed that a part was absorbed, and of this, one part went to form sulphuric acid, whilst the remainder was separated as neutral sulphur compounds ("neutraler Schwefel"). During the hydrogen sulphide fermentation, only a part of the sulphate was reduced; how large this proportion was could not be ascertained. J. W. L.

Physiological Effect of Amyl Nitrite. By T. L. BRUNTON and T. J. BOKENHAM (*Pharm. J. Trans.* [3], **19**, 491).—The authors have found that officinal nitrite of amyl is uncertain in its action by reason of the absence or small proportion present of the active constituent, the loss being due either to its volatility or to some chemical change in the liquid. The freshly made nitrite was alone trustworthy; specimens a few days old having been found ineffectual in producing the usual physiological results. It is suggested that the freshly prepared nitrite should be put up for use in small glass capsules. The authors infer from physiological experiments, which are detailed in the paper, that the preparation is indebted for its medical efficacy less to either one or other of the two amyl nitrites than to the isobutyl nitrite which is known to be present in the ordinary "amyl nitrite." The great importance of an investigation that would determine the physiologically active ingredient, and secure its presence in determinate quantity in the officinal preparation, is pointed out. R. R.

Formation of Adipocere. By K. B. LEHMANN (*Bied. Centr.*, 1889, 66).—Horse-flesh was placed in a flask and exposed to a continuous stream of a pure river water. After seven months had elapsed, it was found that the fatty acids had increased 100 per cent. as compared with another similar piece of flesh which had been preserved in alcohol.
E. W. P.

Chemistry of Vegetable Physiology and Agriculture.

Influence exerted by Salicylic Acid on the Proportions of Glycerol and Alcohol formed in Wines. By L. WEIGERT (*Chem. Centr.*, 1885, 1511, from *Mitt. Chem.-physiol., Versuchs-Stat., Klosterneuburg bei Wien*, **5**, 54—58).—Experiments conducted by the author on the influence exerted by salicylic acid on the rate of fermentation of must, show that the addition of 20—40 grams of the former per hectolitre of the latter retards, but does not ultimately prevent, the fermentative process. The influence exerted is not always the same; in two cases, in which 20 grams of salicylic acid per hectolitre was employed, 10·46 volume per cent. of alcohol and 4·8 per cent. of extract, and 8·37 volume per cent. of alcohol and 2·89 per cent. of extract were obtained. In another comparative experiment, in which 40 grams of salicylic acid per hectolitre was employed, 6·16 volume per cent. of alcohol and 11·5 per cent. of extract and 7·64 volume per cent. of alcohol and 3·6 per cent. of extract were obtained. The proportion of glycerol formed is not altered by the addition of salicylic acid.
J. W. L.

Asparagine and Tyrosine in Dahlia Bulbs. By H. LEITGEB (*Chem. Centr.*, 1888, 1397, from *Mit. bot. Inst. Graz*, **1**, 215—236).—The author has found that the presence of considerable quantities of these substances may be overlooked when extracted from the bulbs with alcohol, owing to the presence of a viscid liquid substance which prevents them from crystallising. J. W. L.

Juice of Bassia Latifolia. By E. HECKEL and F. SCHLAGDENHAUFFEN (*Compt. rend.*, **108**, 103—105).—The dried juice of *Bassia latifolia* forms a rosy-white, somewhat hard and compact mass, resembling gutta-percha, but becoming soft and even sticky when kneaded. At 105°, it loses 60 per cent. of water. In order to remove woody fibre, &c., it is treated with warm water acidified with sulphuric acid, well squeezed, and dried on a water-bath. It is pale brown, hardens after some days, and becomes covered with a white efflorescence readily soluble in chloroform, carbon bisulphide, and hot alcohol, but almost insoluble in cold alcohol. From hot solutions, it separates in a gummy mass, which is easily powdered when dry. Sulphuric acid colours the substance yellow and then brown, and the colour is not altered by chloroform, but if ferric chloride is added to the mixture the upper layer becomes rose-coloured and afterwards blue; this reaction is not due to the presence of cholesterin. Concentrated nitric acid produces no picric acid, and it is not affected by hydrochloric acid or by fused potash. When heated, it decomposes without forming any crystals. The substance has the composition $C_8H_{12}O$. The portion insoluble in alcohol or acetone has the consistency of gutta-percha, but is much more adhesive and hardens more easily. It is not likely to replace gutta-percha, but a mixture of equal parts of the two substances may be used for galvano-plastic moulds, and softens very readily in warm water. The ash of the substance contains a small quantity of sodium chloride, calcium phosphate, and a large proportion of calcium sulphate. C. H. B.

Analyses of Fruits from the Southern States, with reference to their Food Values. By C. L. PARSONS (*Amer. Chem. J.*, **10**, 487—488).—König, in his summary of fruit analyses, has but one analysis of oranges. The examination of eight varieties of Florida oranges, as well as pomegranates and persimmons, is now described, and the results given in a table. The flavour and general edibility of Florida oranges varies nearly with the percentage of cane-sugar; this varies from 0·84 and 0·97 in bitter-sweet and sour oranges, to 8·07 in the Mandarin orange. H. B.

Leguminosæ in Acid Soils. By P. DE MONDESIR (*Compt. rend.*, **108**, 62—64).—It is generally supposed that the presence of calcium carbonate in a soil is essential to the proper growth of leguminosæ which can be used as fodder. The author finds, however, that lupins, clover, and other leguminosæ will grow luxuriantly in the acid soils in the department of La Manche, provided that the soils are mixed with phosphates or with phosphates and potassium chloride. No improvement was obtained by mixing the soil with lime without phosphates. The superphosphates, which are themselves acid, act even more beneficially than the normal phosphates. It follows from these results that calcium carbonate is not essential, but in presence of phosphates and potassium salts, leguminosæ can obtain sufficient calcium from the compounds of the latter with the humous substances which are present in the soil. C. H. B.

Phosphates and Cereals. By J. RAULIN (*Compt. rend.*, **108**, 64—66).—The author has repeated the experiments made in 1877 (Abstract, 1888, 85). 200 kilos. of phosphoric anhydride per hectare being added in the form of natural phosphates the first year, and 40 kilos. per hectare in the following year. Similar plots were treated with only 40 kilos. of phosphoric anhydride per hectare in the form of soluble or precipitated phosphates, the same amount being added each year. The results show that fossil phosphates can be used with the same success as precipitated or soluble phosphates, provided that in the first year the fossil phosphates are added in five or six times the usual quantity. The experiments were made with maize and wheat, and the results were most strongly marked in the case of maize.

C. H. B.

Analysis of a Soil from Washington Territory. By E. A. SCHNEIDER (*Amer. J. Sci.*, **36**, 236—247).—The author has examined a soil of the following composition from Washington Territory, which is derived from a rock of the composition given below:—

	Insoluble in HCl.	Insoluble in Na_2CO_3.	SiO_2 soluble in Na_2CO_3.	Organic matter.
Rock	75·41	63·84	1·57	—
Soil..........	71·42	63·69	7·73	3·52

	SiO_2.	P_2O_5.	SO_3.	H_2O.	K_2O.	Na_2O.	CaO.
Rock	50·85	0·76	0·05	0·34	1·13	2·37	9·33
Soil.......	58·16	0·43	0·07	1·77	1·68	2·56	4·57

	MgO.	FeO.	Fe_2O_3.	Al_2O_3.
Rock	5·57	7·11	10·03	12·54
Soil	1·99	—	10·59	15·03

The results, except the first three, in each case are by fusion of the rock and soil. By sifting, the soil was divided into particles above 2 mm. cube, between 2 mm. and 0·6 mm., and below 0·6 mm. the latter constituting the bulk of the sample; this was mechanically analysed by Hilgard's method and 14·46 per cent. of brownish-yellow clay was obtained; 17·38 per cent. of brick-red sediment with hydraulic value less than 0·25 mm.; 51·17 per cent. of light chocolate stuff between 0·25 and 8 mm. h.v., and 16·86 per cent. of greyish-black sediment resembling the mother rock, with hydraulic value 8 to 64 mm. Each of these and the siftings above 2 mm. were analysed, both by fusion and by extraction with hydrochloric acid; the results are tabulated in the original. The coarsest particles approach nearest to the mother rock in composition, the lime and phosphoric acid are lowest in the clay, but when the clayey water was evaporated down instead of separating in the ordinary way, the percentage of these constituents in the residue was CaO 2·60, P_2O_5 0·65, as compared with CaO 0·41 and P_2O_5 0·11 in clay separated in the ordinary way. There is a great difference between the amount of the various constituents dissolved by hot or by cold hydrochloric acid, and the variation is different for each constituent and in different soils. The author points out that plants probably derive their nutrition from the finest particles of the soil, and, there is good reason to suppose, by the help of carbonic and feeble organic acids; therefore he does not consider chemical analysis as suitable for deciding as to the fertility of a soil, because although the larger proportion of the valuable constituents may be so locked up in the larger particles as to be inaccessible to the plants, yet they would succumb to the attacks of boiling hydrochloric acid, and then from the analytical results, these imprisoned constituents would be erroneously registered as useful to vegetation. D. A. L.

Algerian Soils. By A. LADUREAU (*Compt. rend.*, **107**, 1154—1155).—The soil of Algeria is generally deficient in phosphates. In the department of Algiers, the quantity of phosphoric anhydride per kilo. varied from 0·30 to 1·97 grams, the mean being 0·76; in the department of Oran, the limits are 0·23 and 1·37, the mean being 0·54; in the department of Constantine, the mean is 0·69, and the limits 0·30 and 1·25. The general mean is 0·68. C. H. B.

Action of Ferrous Sulphate in Various Soils. By P. M. DELACHARBONNY and L. DESTREMX (*Bied. Centr.*, 1889, 9—14).—Wheat was sown on soils containing quantities of iron varying from 1·740 to 4·321 per cent.; it was observed that the sulphate was productive of increased yield only when the iron of the soil was present in small quantities, the increase ceasing when the percentage of ferric oxide reached 3 per cent., and was detrimental when the percentage was 4 per cent. In a second experiment, when potatoes were the crops (the land being deficient in lime, lime was added in the form of sulphate and carbonate) the same results as to yield were noted. The same results were likewise observed when lucerne and hay were grown. Ferrous oxide appears to be a good manure for pastures in which much moss is present, and may be applied at the rate of 300 kilos. per hectare, or more if necessary; it may be applied dry, or dissolved in water in the ratio of 5 kilos. per hectolitre, and in the month of March.

E. W. P.

Comparative Manurial Value of the Nitrogen in Sodium Nitrate and Ammonium Sulphate. By BAESSLER (*Bied. Centr.*, 1889, 14—18).—Potatoes being the crop experimented on, and the soil sandy, it was found that ammonium sulphate, even when in combination with sodium nitrate, did not produce an increased yield commensurate with the extra expense; on the other hand the sodium nitrate was very effective. In 1888, oats were grown on humous sand, which had previously received 40 kilos. of phosphoric acid per hectare, after which sodium nitrate and ammonium sulphate were added; in this case, both manures produced a like increase of the grain, but the nitrate brought a greater yield of straw. The good action of the sulphate is ascribed to the wet weather. E. W. P.

Bat's Guano from Cuba. By A. PETERMANN (*Chem. Centr.*, 1888, 1438, from *Bull. Stat. agr. Gembloux*, 1888, **42**, 1—5).—The analysis of two specimens gave the following percentage results:—

	P_2O_5.	N.	K_2O.
I.	6·2	8·0	1·0
II.	11·8	2·0	1·7

A third specimen, also from Cuba, consisted almost entirely of potassium sulphate. The magnitude of these deposits is not known to the author. J. W. L.

Analytical Chemistry.

Draught Arrangement for Water-baths. By C. WINKLER (*Ber.*, **21**, 3563—3567).—The arrangements for keeping water-baths supplied with water and the draught cupboards in which they are placed are described with sketches.

Volumetric Estimation of Sulphur by means of Barium Chloride. By C. and J. J. BERINGER (*Chem. News*, **59**, 41—42).—The authors have made numerous experiments with solutions of 500 c.c. each, containing 10 c.c. of acetic acid and 10 grams of sodium acetate, in some cases with the addition of varying quantities of sulphuric acid, whilst in other cases 20 c.c. of sulphuric acid and varying quantities of different salts were added. In most cases, the sulphuric acid could be readily titrated with barium chloride, even in the presence of 5 grams of sodium, ammonium, zinc, ferric, or copper chloride, or of 5 grams of potassium nitrate or nitrite, or of 1 gram of calcium chloride, but with ferrous chloride the results were low, and with sodium phosphate or arsenate high, therefore, if present, the former must be oxidised, and the latter precipitated by means of ferric chloride. For estimating sulphur, the mineral or other substance is dissolved in water; if necessary being first oxidised with nitric acid, or by fusion with 5 grams of nitre, or with fusion mixture. The solution is mixed with acetic acid and sodium acetate, so that no free mineral acid is left in the solution, which is then made up to half a litre, and while steadily boiling is titrated with barium chloride, until a test quantity just shows a precipitate with sulphuric acid. The method gives good results. As much as 100 c.c. of acetic acid and 50 grams of sodium acetate have been employed in experimental solutions without impairing the results. Titrations in the cold are altogether unsatisfactory. D. A. L.

Estimation of Hydrogen Sulphide. By L. L. DE KONINCK (*Zeit. angew. Chem.*, 1888, 311).—The author published, in 1870, a method for the determination of hydrogen sulphide, which consisted in absorbing it by a solution of silver nitrate and oxidising the washed silver sulphide by bromine-water, when, after filtering from silver bromide the sulphuric acid was obtained in a solution free from non-volatile substances. He now replaces the silver nitrate by a solution of mercuric cyanide mixed with ammonium chloride. Such a solution gives, with hydrogen sulphide, a flocculent precipitate easily collected and washed. This dissolves readily and completely when warmed with bromine-water. The mercuric bromide produced being soluble as well as volatile, the advantage of the former method is attained without filtration. The single test determination reported, made on a measured volume of pure hydrogen sulphide, gave a very satisfactory result. M. J. S.

Estimation of Nitrogen by Kjeldahl's Method. By L. L'Hote (*Compt. rend*, **108**, 59—62).—The results obtained by Kjeldahl's method were compared with those obtained by means of soda-lime.

	Kjeldahl.	Soda-lime.
Caseïn	13·32	9·24—9·56
Dried blood	11·83	11·47
Powdered horn	13·66	13·46
Wheat flour (1)	2·22	1·84
" (2)	2·38	2·05
Vegetable soil (St. Pierre)	0·0870	0·0730
" " (Sèvres)	0·3720	0·3180

The substance was heated with concentrated sulphuric acid, mercury, and mercuric oxide or anhydrous cupric sulphate, and was then mixed with sodium hydroxide and sulphide. C. H. B.

Note by Abstractor.—No mention is made of the addition of potassium permanganate, and the omission of this part of the process would account for the low results, since it is known that the addition is essential in the case of substances which are not readily oxidised. C. H. B.

A Source of Error in the Estimation of Nitrates in Soils. By M. Giunti (*Chem. Centr.*, 1888, 1496, from *Staz. sperim. agrar. ital.*, **15**, 5—15).—The experiments carried out by the author show that, during the time occupied in extracting the nitrates from soils prior to their determination, the quantity of nitrates is reduced considerably, owing to the micro-organisms; at temperatures varying between 24° and 27°, the diminution amounted to a quarter to one-half of the quantity of nitrates present per 24 hours, whilst at a temperature of 15° to 17°, it amounted to nearly as much, although at first it was less. The author has made comparative experiments with different soils, and, in addition to the ordinary method, has made comparative determinations after sterilising with chloroform. In the latter case, no diminution of the amount of nitrates occurred at the end of six days. He recommends, therefore, sterilisation of the soil before extracting the nitrates. J. W. L.

Estimation of Nitrates in Natural Waters. By L. Spiegel *Ber.*, **21**, 3568).—A claim to priority (compare *Zeitsch. f. Hygiene*, **2**, 163) as regards the use of diphenylamine for this purpose (compare Hooker, this vol., p. 312).

Calculation of Phosphoric Acid Estimations. By W. MIELCKE (*Zeit. angew. Chem.*, 1888, 288).—A table giving the percentage of phosphoric anhydride for every 2 milligrams of magnesium pyrophosphate between 0·04 and 0·32 gram, when 0·5 gram of substance is employed. M. J. S.

Direct Estimation of Phosphoric Acid as Tricalcic Phosphate. By H. TZSCHUCKE (*Zeit. angew. Chem.*, 1888, 383—385).—To the phosphate solution, there is added so much hydrochloric acid that calcium chloride produces no precipitate, then calcium chloride, and, lastly, an excess of ammonia. The mixture is immediately diluted with twice its volume of cold water, filtered at once on a rapid filter, and the precipitate washed with cold water. The excess of calcium chloride must not be large, and warming is to be avoided. Substances which already contain sufficient calcium have simply to be dissolved in hydrochloric or nitric acid, and precipitated by ammonia. If sesquioxides are present, the phosphoric acid combined with them must be determined separately. In the case of impure substances, the results are admittedly only approximate, but the facility of the determination gives it a certain value. M. J. S.

Estimation of Phosphoric Acid in Basic Slag. By M. A. v. REIS (*Zeit. angew. Chem.*, 1888, 354—362).—The methods proposed for this purpose are already very numerous. The mode of dissolving the substance has been varied according to the views held respecting the presence and value of the iron phosphide. The author has not met with this compound in the slag, and regards its occurrence as so rare that it need not be taken into consideration. He has made comparative experiments on the following methods of effecting solution:—Klein's fusion method (Abstr., 1886, 740); Kosmann's aqua regia treatment (Abstr., 1881, 489); treatment with nitric acid (Jensch); Brunnemann's process with aqua regia and sulphuric acid (Abstr., 1887, 527); Klein's, with hydrochloric acid (Abstr., 1886, 835); the same as used by Thilo and by Kennepohl without removal of silica (Abstr., 1888, 321); Vogel's cold treatment with hydrochloric acid; Müller's, with hydrofluoric acid; Mohr's, with dilute sulphuric acid (Abstr., 1887, 864); and that of Ende and Loges with concentrated sulphuric acid (Abstr., 1887, 527). The results from all these methods agreed within 0·15 per cent., showing that the simplest of them, the treatment with hydrochloric acid without removal of silica, may be adopted when the phosphoric acid is thrown down by molybdate. Of methods of determination, the following were tested:—A, weighing as magnesium pyrophosphate after precipitation with molybdate; B, precipitation by molybdate at 90° from a solution containing 20 per cent. of ammonium nitrate, and weighing, after drying at 100—110°; C, determination as molybdenum phosphomolybdate by igniting the precipitate thrown down at about 40° (Meineke); D, Korschelt's potassium molybdate method; E, Thilo's ammonia titration method (Abstr., 1887, 526), which, for its convenience and rapidity, the author prefers to all others, where extreme accuracy is not wanted. The most suitable indicator is azolithmin. The change of colour is somewhat gradual, but the reddish-violet tint corresponding to the point of neutrality is easily recognised after practice; F, Schindler's titration with lead acetate (Abstr., 1888, 753, 757); G, determination of the ammonia in the precipitate, according to Isbert and Stutzer (Abstr., 1888, 194); K, Mallot's uranium titration method (Abstr., 1887, 1063); I, Mohr's uranium method (*loc. cit.*); L, direct precipitation by magnesia mixture, after adding citric acid (see Vogel, Abstr., 1888, 991). Following Vogel's instructions exactly, the results came out too high, the precipitate being contaminated with silica, lime, and iron. The filtration, moreover, is very tedious. The following improved process is recommended:—10 grams of the powdered slag is boiled with 50 c.c. of concentrated hydrochloric acid; 50 c.c. of concentrated sulphuric acid is then added, and the mixture heated until white fumes appear. After dilution, it is again boiled until all the iron is in solution, then cooled and made up to 504 c.c. 32 c.c. of the filtered liquid is then precipitated according to Vogel's directions. Each centigram of pyrophosphate corresponds to 1 per cent. of phosphoric acid. The whole determination requires 2½ hours. M, precipitation by molybdate in citric acid solution (Werenskjold). The reagent used is prepared by dissolving 300 grams of ammonium molybdate to 1 litre, adding half a litre of 50 per cent. citric acid solution, heating, adding half a litre of nitric acid (1·4), boiling until any traces of phosphoric acid present are precipitated, and then oxidising the reduced molybdic acid by a few c.c. of hydrogen dioxide. The reagent and the phosphate solution should be boiling when mixed, and the mixture kept for 5 or 10 minutes at 100°. The weight of the precipitate, multiplied by 0·03933, gives that of the phosphoric anhydride. N, ignition of the precipitate obtained as in B. The results are more regular than those obtained by drying at 100°. With the exception of D, G, and I, which are condemned, these methods all give fairly concordant results; L is the best for accuracy, E for rapidity. M. J. S.

Decomposition of Insoluble Silicates. By A. Johnstone (*Chem. News*, **58**, 310).—A small quantity of the silicate is placed on a layer of ammonium fluoride in a platinum crucible or on a piece of platinum foil and heated before the blowpipe; when most of the fumes have passed away, a little more fluoride is pressed into the mass and the whole again heated. After repeating this operation, usually five or six times, the silicates are sufficiently decomposed for the identification of the bases. Felspars, mica, garnet, zircon, &c., have been successfully treated by this method. D. A. L.

Estimation of Carbonic Anhydride in the Air for Hygienic Purposes. By G. Lunge and A. Zeckendorf (*Zeit. angew. Chem.*, 1888, 395—399).—The authors adopt the principle of Angus Smith's minimetric method, but instead of observing the first appearance of turbidity in a solution of an alkaline earth, they employ a dilute standard solution of sodium carbonate coloured with phenolphthaleïn, and ascertain the volume of air required to produce decoloration by the conversion of the normal into the hydrogen carbonate. They recommend an india-rubber hand-pump delivering 70 c.c. at each compression and furnished with valves. This delivers the air into a bottle of 110 c.c. capacity in which it is shaken with 10 c.c. of the soda solution, prepared by diluting a decinormal solution (to which 1 gram of phenolphthaleïn per litre has been added) 50-fold with boiled water. With these conditions, air containing 0·3 per cent. of carbonic anhydride requires two fillings of the pump, whilst 0·03 per cent. requires 48 fillings. These, and the intermediate values, were ascertained by empirical experiment, and are not applicable to apparatus of other dimensions. M. J. S.

Electrolytic Detection of Mercury. By C. H. Wolff (*Zeit. angew. Chem.*, 1888, 294—296).—The solution to be tested is passed slowly through a vertical tube containing the electrodes. The positive electrode is a spiral of stout platinum wire lying close to the walls of the tube. The negative electrode is a spiral of steel pianoforte wire, which has been first coated with copper and then silvered. If the solution contains organic matter, this is to be destroyed by hydrochloric acid and potassium chlorate. It is then acidified with 3 or 4 per cent. of sulphuric acid and passed three times through the tube at the rate of 12 or 15 drops per minute. The steel spiral is then removed, dried by dipping in alcohol and ether, and sealed up in an elongated glass bulb with drawn-out neck. After heating so as to drive the volatilised mercury into the narrow neck, the lower end of the bulb is cut off, the spiral removed, and a crystal of iodine introduced. By careful heating, the vapour of the iodine is passed over the mercury and converts it into iodide. As little as 0·01 milligram of mercury in 100 c.c. can be thus detected. If the quantity is somewhat larger, the portion of the tube containing the sublimate may be introduced into a short, wide test-tube, bedded in sand in a crucible, and be sublimed on a microscopic cover-glass. M. J. S.

Analysis of the Raw Materials and Products of the Iron Industry. By C. Meineke (*Zeit. angew. Chem.*, 1888, 252—261; compare p. 310).—*Precipitation by Ammonia.*—This is chiefly of service for the separation of the iron-group from calcium and magnesium. Blum (Abstr., 1888, 324) has called attention to a possible error arising from the dissociation of ammonium chloride on boiling, but the author shows by numerous test analyses of solutions of known composition, as well as by comparison with the carbonate and acetate methods of separation, that boiling for only a short time invariably leaves some calcium and generally magnesium in the iron precipitate. Moreover, he does not find alumina redissolved even when the boiling is continued until the smell of ammonia is no longer perceptible. An attempt was made to determine calcium by adding to the acid solution a known excess of oxalic acid, then precipitating by ammonia and titrating the excess with permanganate; but more oxalic acid passes into the precipitate than corresponds with the calcium present, in consequence, seemingly, of the formation of a double oxalate.

Neither Bloxam's phosphate method, nor that depending on the precipitation of the iron by barium carbonate, effects a complete separation of the manganese. Mercuric oxide separates iron and manganese imperfectly, but it can be used with great convenience for the determination of the alkalis in silicates decomposable by hydrochloric acid (such as blast-furnace slags). After the evaporation to render silica insoluble, the unfiltered hydrochloric acid solution is mixed with excess of mercuric oxide, and is evaporated to dryness and ignited gently. The aqueous extract will then contain nothing but the alkalis with a little calcium. The latter is separated by adding a few drops of ammonium oxalate, and the smallness of the amount of ammonium salts in the filtrate renders the treatment of the alkalis extremely easy. Alumina when present as sulphate or fluoride is not precipitated by mercuric oxide.

Precipitation by Zinc Oxide.—The sesquioxides can be completely separated from manganese, nickel, and cobalt by zinc oxide. The process of Mathesius consists in oxidising with bromine, evaporating to dryness, taking up with hydrochloric acid, nearly neutralising with ammonia, and precipitating with zinc oxide. After partial filtration, the manganese is precipitated by Wolff's method with bromine and a current of air containing ammonia. The precipitate contains zinc as well as other impurities to the extent of several per cent. After re-solution and reprecipitation, zinc is no longer present, but the presence of other oxides raises the result beyond admissible limits.

Precipitation by Nitroso-β-naphthol.—This method proves very advantageous for the separation of iron, copper, and cobalt from manganese. The iron precipitate is free from manganese. Traces of iron, however, pass into the filtrate and are found in the manganese precipitate, which is further liable to be contaminated with silica and nickel. A great advantage of this method is that it accurately separates iron and alumina, the latter not being precipitated by nitroso-β-naphthol. It can be thrown down by ammonia from the filtrate as usual, and if but little manganese is present, the copious addition of ammonium chloride prevents it from precipitating with the alumina. The determination of calcium and magnesium is not interfered with by the nitroso-β-naphthol. Phosphoric acid will be entirely precipitated with the iron if acetic acid is the only free acid. M. J. S.

Volumetric Estimation of Cobalt in presence of Manganese, Nickel, &c. By N. McCulloch (*Chem. News*, **59**, 51—52).—Cobalt in the presence of cyanides reduces chromic acid in accordance with the equation $6Co(CN)_2 + 24KCN + 2CrO_3 + 3H_2O = 3K_6Co_2(CN)_{12} + Cr_2O_3 + 6KHO$, and the resulting potassium cobalticyanide is a stable compound of constant composition. On this basis, the author has devised the following method for the estimation of cobalt in the presence of nickel, manganese, lead, arsenic, or phosphorus; copper must be absent and iron is best eliminated. Standard solutions of dichromate and potassium cyanide in suitable proportions, and a few drops of ammonia, are boiled in a flask fitted with a double-bored cork carrying a thistle funnel dipping into the liquid and a tube for the escape of steam; the hot solution to be examined is then poured down the funnel, and the whole treated with warm, concentrated ammonium chloride solution and boiled to expel volatile cyanides. To prevent the formation of ferrous cobaltocyanide and double cyanide of iron and nickel in the subsequent treatment with ferrous salt, nickel sulphate solution is added until no further precipitate is formed, but not in great excess. The contents of the flask are poured into excess of hot standard ferrous ammonium sulphate solution, acidified with a few drops of hydrochloric acid, and titrated with dichromate in the usual way. The percentage of cobalt is calculated from the dichromate reduced in the first instance. A correction, which should be ascertained by blank experiments, must be made for the dichromate reduced by boiling with the cyanide and ammonia. The author strongly recommends the method. D. A. L.

Estimation of Chromium, Iron, and Manganese by means of Hydrogen Peroxide. By A. CARNOT (*Compt. rend.*, **107**, 997—1000 and 1150).—Chromic acid in an acid solution is reduced by hydrogen peroxide, but in alkaline solutions chromic salts are oxidised to chromates by this reagent. A dilute solution of a chromium salt is heated to 100°, mixed with a few cubic centimetres of hydrogen peroxide, then with excess of ammonia, and again heated to boiling. The solution at first becomes turbid and brown, but the colour rapidly changes to pale-yellow owing to the formation of ammonium chromate. If any chromic oxide remains unoxidised, it is allowed to subside and is redissolved in acid and again treated in the same way. After boiling to expel excess of hydrogen peroxide, the chromic acid formed may be estimated volumetrically by hydrogen peroxide (this vol., p. 311). The solution from this operation may be mixed with sodium or ammonium acetate and the chromium precipitated with sodium phosphate.

After boiling with hydrogen peroxide and ammonia, and separation of the metals precipitated by ammonia, the chromate may be reduced by hydrogen sulphide and the chromium precipitated by adding ammonia.

In the case of mixtures of chromates and chromic salts, the chromic acid is first estimated volumetrically by hydrogen peroxide, and the total chromium in the same solution is precipitated as phosphate or hydroxide. In the case of solutions containing chromium mixed with iron or aluminium, the former is oxidised to chromic acid, which is estimated by hydrogen peroxide, and in the same solution the chromium and iron or chromium and aluminium are precipitated together, the aluminium or iron being estimated by difference.

If an ammoniacal solution of a manganese salt is mixed with hydrogen peroxide and boiled, a precipitate is obtained of the composition Mn_6O_{11}, but it can only be purified from other bases by repeated re-solution and reprecipitation. The manganese in this precipitate can, however, be more readily determined volumetrically by means of standard oxalic acid, sulphuric acid, and potassium permanganate, $O_5 = Mn_6$. C. H. B.

Estimation of Titanium in Natural Silicates. By P. HOLLAND (*Chem. News*, **95**, 27—29).—In preliminary experiments, the author satisfied himself that titanium oxide does not suffer loss when it is treated with hydrofluoric acid in presence of sulphuric acid, although the loss is great when none of the latter acid is present (Riley, this Journal, 1859, 13), and that titanic oxide may be completely precipitated after fusion with potassium hydrogen sulphate. He finds the following method gives good results:— 2 grams of titaniferous rock or mineral is moistened with dilute sulphuric acid in a platinum crucible, and 5 grams of hydrofluoric acid is gradually added. The crucible is now covered and heated in an air-bath, starting at 100° but subsequently raising the temperature until the residue appears dry; concentrated hydrochloric acid is added and the crucible is again heated. Any undissolved titanic oxide is collected on a filter, ignited, fused with potassium hydrogen sulphate, dissolved, and the filtered solution added to the hydrochloric solution, which has been oxidised by a few drops of chlorine-water, and the combined solutions are made up to half a litre and divided into two portions. In one, the alumina, ferric, and titanic oxides are precipitated together by means of ammonium acetate, care being taken to remove all the alumina from the solution by further precipitation. The united precipitates are weighed, finely powdered, and fused with potassium hydrogen sulphate, quickly extracted with water at 80° containing a little sulphuric acid, made slightly alkaline with ammonia and boiled for 20 minutes. The precipitate is dried, ignited, re-fused, re-treated, then ultimately weighed as titanic oxide. In the other portion of the solution, the iron is estimated, and the amount of alumina is ascertained by difference from the weight of the combined alumina, ferric and titanic oxide precipitate. This method does not answer in the presence of phosphoric acid. Ignited titanic oxide is insoluble in hydrochloric acid, but when it is ignited in the presence of alumina it becomes almost completely soluble in that solvent; for this reason, Roussel's process for estimating titanic oxide does not answer if his directions are exactly followed; it is better to treat the precipitate of alumina, titanic acid, and sulphur (obtained by boiling the acid solution with sulphurous acid and sodium sulphate and thiosulphate) with carbon bisulphide and then with dilute sulphuric acid to dissolve the alumina. D. A. L.

Detection of Antimony in Minerals. By A. JOHNSTONE (*Chem. News*, **58**, 296—297; **59**, 15).—The mineral is heated on charcoal before the blowpipe or in an open tube in the usual way, and the white sublimate obtained is treated with a drop of ammonium sulphide; a change in colour from white to orange is a sure indication of the presence of antimony, as antimonious oxide is converted into the orange sulphide by this treatment. D. A. L.

Volumetric Estimation of Antimonic Acid. By A. JOLLES (*Zeit. angew. Chem.*, 1888, 261).—The antimony in antimonic acid can be very conveniently determined by titration with potassium manganate after reduction by sulphurous acid. The antimoniate is made strongly acid with hydrochloric acid, a concentrated solution of sodium sulphite is added, the excess of sulphurous anhydride is boiled

off, the solution is made up to a definite volume (about 0·2 gram in 100 c.c.) and is titrated by manganate in the manner described on p. 311.
M. J. S.

Tartar Emetic. By W. R. DUNSTAN and L. E. BOOLE (*Pharm. J. Trans.* [3], **19**, 385—387).—The authors point out various sources of error in the process prescribed by the British Pharmacopœia for the determination of antimony in tartar emetic. They advocate a volumetric method, depending on titration with a solution of iodine immediately after the addition of sodium hydrogen carbonate; the method is accurate. When alcohol is added to an aqueous solution of tartar emetic, that substance is precipitated in the anhydrous state.
R. R.

Decomposition and Estimation of Iodoform by Silver Nitrate. By GRESHOFF (*Rec. Trav. Chim.*, **7**, 342).—Silver nitrate acts readily on iodoform at ordinary temperatures as follows:—$CHI_3 + 3AgNO_3 + H_2O = 3AgI + 3HNO_3 + CO$. The reaction takes about an hour and a half for its completion, and the nitric acid set free can then be titrated.
H. C.

Analysis of Alcohols. By C. GIRARD and X. ROCQUES (*Compt. rend.*, **107**, 1158—1159).—When aldehyde is mixed with an alcoholic solution of metaphenylenediamine hydrochloride, the liquid becomes orange-red, and if agitated in presence of air the colour deepens, and an intense fluorescence is developed. This coloration is not affected by acetic acid, but changes to pale yellow and the fluorescence disappears on addition of ammonia. The compound formed is stable and remains in the retort when the alcohol is distilled.

200 c.c. of alcohol of 50° is mixed with 3 grams of metaphenylenediamine hydrochloride, boiled for half an hour in a flask attached to a reversed condenser, allowed to cool, and the pale yellow liquid, when agitated repeatedly, becomes dark coloured and fluorescent. 125 c.c. of the alcohol is distilled off rapidly and amyl alcohol is estimated in the distillate by Savalle's method. If the amyl alcohol is only present in small quantity the whole of it passes over with the 125 c.c.
C. H. B.

Estimation of Alcohol in Essential Oils. By H. HAGER (*Chem. Centr.*, 1888, 1512—1513, from *Pharm. Zeit.*, **33**, 650—651).—Since glycerol, containing 20 per cent. of water, mixes completely with alcohol but does not dissolve the essential oils, the following method, based on this principle, is recommended. Into a graduated tube 8—10 cm. long and 7—9 mm. wide, 1·5—3 cm. of glycerol is introduced, and after noting the volume, 2—3 c.m. of the essential oil is added and the volume again read off. After shaking and subsequent separation of the liquids, the increase in the volume of the glycerol is noted. Instead of measuring the liquids, the determination may be made gravimetrically, the essential oil being absorbed by means of blotting-paper from the surface of the glycerol layer, and the latter weighed.
J. W. L.

Estimation of Glycerol in Wine. By L. WEIGERT (*Chem. Centr.*, 1888, 1511, from *Mitt. chem.-physiol. Versuchs-Stat., Klosterneuburg bei Wien*, **5**, 59—62).—The following method is recommended:—100 c.c. of wine (sour, not sweet) is concentrated on the water-bath to 3—5 c.c., 3—5 grams of slaked lime is added, and then 50—80 c.c. of 90—96 per cent. alcohol, the mixture being then heated on the water-bath until the alcohol has boiled a few minutes. The solution is then filtered, treated a second time with 43—50 c.c. of the alcohol, and the whole brought on to the filter and washed with 50—80 c.c. of alcohol. The filtrate is concentrated on the water-bath, preferably in a 230—250 c.c. flask, to a syrup, 10—20 c.c. of absolute alcohol and 15—30 c.c. of ether added, and after the solution has cleared, the ether layer is poured off into the weighing glass. The residue is again treated with a mixture of alcohol (1 part) and ether (1½ part), and the extract added to the first. The ether and alcohol are evaporated off, and the glycerol remaining finally weighed.

In the case of sweet wines, no calcium hydroxide is employed, but in other respects the procedure is similar. The glycerol should always be tested for sugar. In judging a wine, in regard to the proportion subsisting between the glycerol and alcohol, the presence of acetic acid, or the addition of salicylic acid, whether the proportion of nitrogen varies much from the average, or whether the wine has been strongly sulphured, should always be taken into account.

J. W. L.

Safranine as a Reagent for Grape-sugar. By L. CRISMER (*Chem. Centr.*, 1888, 1510, from *Pharm. Zeit.*, **33**, 651).—If 2 to 3 c.c. of a 1 : 1000 solution of safranine is heated in a test-tube with a few drops of a solution of grape-sugar and 2 to 3 c.c. of soda, the safranine becomes reduced, and the solution is rendered colourless and opalescent, owing to the precipitation of the decolorised dye. At the surface, the colour of the dye rapidly reappears, owing to reoxidation. The author recommends this reaction for the detection of grape-sugar in solutions, such as urine, since the safranine is not reduced by uric acid, creatinine, chloral, chloroform, hydrogen peroxide, or hydroxylamine salts, all of which reduce Fehling's solution. Egg-albumin reduces safranine slowly, but completely. J. W. L.

Detection of Salicylic Acid in Beer. By G. H. HOORN (*Rec. Trav. Chim.*, **7**, 341).—The author tested various samples of beer for salicylic acid by two methods; the first being by acidifying the beer with sulphuric acid, extracting with a mixture of ether and light petroleum, and evaporating the extract; the second by distillation of the beer after acidifying with sulphuric acid. By the first, salicylic acid could not be detected, but by the second it was detected in the later, but not in the first portions of the distillate.

It has also been ascertained that the coloration produced by ferric chloride in salicylic acid solutions is due to a volatile compound, which is also formed when the beer is distilled with sulphuric acid.

H. C.

Estimation of Salicylic Acid. By L. WEIGERT (*Chem. Centr.*, 1888, 1511, from *Mitt. chem.-physiol. Versuchs-Stat., Klosterneuburg bei*

Wien, 5, 54—58).—The author recommends shaking 50 c.c. of wine with an equal volume of chloroform, after which the chloroform layer is separated and passed through a dry filter. 30 c.c. of this is treated with 10 c.c. of ferric chloride (freshly prepared solution 1 : 1000), and shaken up well. For quantitative determinations, ether should be used in place of chloroform in a Schwarz's extractor. J. W. L.

Estimation of Foreign Acids in Artificial Salicylic Acid. By E. E. EWELL and A. B. PRESCOTT (*Pharm. J. Trans.* [3], **19**, 328—330).—Salicylic acid, manufactured from ordinary phenol, necessarily contains a greater or less quantity of homologous compounds, derived from the higher phenols. In 1878, Williams proposed a method of estimating these foreign acids, based on the less solubility of calcium salicylate. This method the authors find untrustworthy, at least on the data known at present. They give details of two new processes; one being the determination of the saturating power of the acid, in which 1 gram is titrated with centinormal alkali and phenolphthaleïn as indicator, and thus 1·8 per cent. of the other acids (calculated as hydroxytoluic acid) may be detected; the other, a plan by distilling with lime, by which salicylic acid and its homologues are converted into phenols, the amount of the respective phenols being estimated by known methods. R. R.

Estimation of Citric and Tartaric Acids when Mixed. By J. S. WARD (*Pharm. J. Trans.* [3], **19**, 380).—The author finds that quantitative determinations of mixtures of citric and tartaric acids give too low results in each case. He adopted certain modifications in the analytical process, obtaining results which, although constant, were still too low; whence he infers that calcium tartrate, in the presence of a citrate, is not completely precipitated in 12 hours, and that calcium citrate is slightly soluble in boiling water. R. R.

Tests for Tannic and Gallic Acids. By S. G. RAWSON (*Chem. News*, **59**, 52—53).—When ammonium chloride and ammonia are added to solutions of tannic acid, a white precipitate is formed which rapidly becomes red. In solutions containing 1 part of tannic acid in 5,000 of water, the precipitation is slow, and it is best to drop in the ammonium chloride and ammonia so as to form a layer on the top, then at the point of contact a distinct white line appears, even in solutions containing 1 in 20,000, whilst by holding against a black surface 1 in 50,000 may be detected. When solutions of gallic acid are treated in a similar manner, no precipitation occurs, but the liquid becomes red in strong solutions, and with dilute solutions a greenish-coloured ring forms, even when the dilution is 1 in 100,000. A red coloration is produced in solutions of either of these acids by chlorine-water and ammonia, and by potassium ferricyanide and ammonia. With the latter reagents a 1 in 10,000 solution of tannic acid becomes distinctly red, and the redness produced in a 1 in 30,000 solution is seen by looking down the test through the column of liquid, whilst by comparing with a blank, a yellowish-brown coloration may be detected in a 1 in 100,000 solution. D. A. L.

Detection of Iron in Oil. By B. EMDE (*Zeit. angew. Chem.*, 1888, 362—363).—In dyeing with alizarin on alumina mordants, the presence of traces of iron is highly injurious. To detect it in "Turkey-red oil," the oil is shaken in a cylinder with dilute sulphuric acid containing a little potassium ferrocyanide. After adding ether, it is again shaken. The whole of the iron present in the oil will then appear as a blue layer between the aqueous and ethereal liquids.

M. J. S.

The Reichert-Meissl-Wollny Method of Analysis as applied to Italian and Mixed Butters. By C. BESANA (*Bied. Centr.*, 1889, 61—65).—The analyses made, according to the above process, of a large number of Italian butters, showed that the melting point varied from 33—37·7° (one case 40·5°), and that the quantity of decinormal alkali necessary for saponification varied from 30·19 c.c. to 21·8 c.c., but that for the greater majority of samples 30 c.c. to 28 c.c. was sufficient, the remaining samples being too unusual to be taken into consideration. Besana, therefore, concludes that 28·8 c.c. may be taken as a fairly accurate factor in all necessary calculations when dealing with pure butter: further various samples of artificial butter (margarine, &c.) were examined, and 0·3 c c. is taken to be their equivalent of decinormal alkali.

To estimate the percentage of margarine, added to genuine butter in a sample of mixed butter, the following formulæ are employed:—

$$100 = b + m \text{ and } t = \frac{bt'}{100} + \frac{mt''}{100},$$

from which follows—

$$b = \frac{100(t - t'')}{t' = t''},$$

where b = percentage of pure butter; m = percentage of added fat: t = c.c. of decinormal alkali; as shown by titration of sample; t' = c.c. of decinormal alkali required for pure butter (*i.e.*, 28·8), and t'' = c.c. of decinormal alkali required for added fat (*i.e.*, 0·3). The author adds that for t', the figures 21·8, 30 2, and 27 may be employed according to opinion, in which case the maximum and minimum quantities of admixture will be obtained.

E. W. P.

Estimation of Free Caustic Alkali in Soap. By J. A. WILSON (*Chem. News*, **59**, 40).—Soap made by the cold process may contain both free alkali and free fat, consequently when dissolved in alcohol to titrate the free alkali, the latter immediately saponifies the free glycerides and vitiates the results. For this reason, the author prefers to titrate the total alkali with normal acid and methyl-orange, and to estimate in another portion the alkali required by the fatty acids of the soap. Silicates, carbonates, or borates interfere with the results, but can be easily estimated by other means.

D. A. L.

Detection of "Saccharin." By S. C. HOOKER (*Ber.*, **21**, 3395).—The reaction described by Börnstein (Abstr., 1888, 760) for the detection of saccharin cannot be depended on, as the result seems to be the same when resorcinol alone is heated with concentrated sulphuric acid.

F. S. K.

Detection of "Saccharin." By E. Börnstein (*Ber.*, **21**, 3396). The author points out that although many organic compounds can be made to yield a fluorescent solution by suitable treatment with resorcinol and sulphuric acid, yet this reaction can be employed for the detection of "saccharin," because extremely small quantities of this substance are sufficient to give a distinct reaction (compare Hooker, preceding Abstract). In testing for "saccharin" in foods, 0·005 gram of the dry residue is treated with twice its weight of resorcinol and 2 to 3 drops of concentrated sulphuric acid; if "saccharin" is present, a distinctly fluorescent solution is obtained, whereas with resorcinol alone several decigrams must be employed before the fluorescence can be observed. The green coloration which appears at the moment when the solution is made alkaline is only shown in the case of two substances besides "saccharin," namely, phthalic anhydride and phthalimide.

F. S. K.

Estimation of the Alkalinity of the Blood. By J. B. Haycraft and R. T. Williamson (*Proc. Roy. Soc. Edin.*, **127**, 396—399).—Zuntz's method (*Centr. med. Wiss.*, **51**, 1867) is the only one whereby the alkalinity of blood may be estimated quantitatively, but it is unfitted for clinical purposes, as a large amount of blood is required. The authors, requiring a method necessitating only a very small quantity of blood, experimented with many indicators, but none were found to be so effective as litmus. They prepared a series of red litmus-papers (acidified with a small quantity of oxalic acid) and glazed them by dipping into liquid paraffin oil. A single drop of blood produces a neutralising effect after a short time, as the plasma does not percolate through the glaze rapidly. After moistening with the blood, the paper is washed in distilled water and then pressed between folds of blotting-paper. The amount of alkali which will turn the red paper blue being previously known, the alkalinity of the blood can therefore be easily ascertained. The authors, however, are of opinion that, because of the difficulty of percolation above referred to, the alkalinity will not be quite identical with the amount of alkali, but as this error is uniform the usefulness of the series of litmus-papers will not be impaired for physiological purposes.

E. W. P.

Furfuraldehyde Reactions. By L. v. Udránszky (*Zeit. physiol. Chem.*, **13**, 248—263).—This has been the subject of two previous communications by the author (Abstr., 1888, 863 and 878). It has been already noted that commercial amyl alcohol cannot be used in certain researches, especially for the separation of pigments in acid liquids, as on the addition of acid it undergoes a partial decomposition resulting in the formation of a brown deposit. This is because it contains furfuraldehyde. Attempts to obtain the alcohol free from that impurity by means of animal charcoal were unsuccessful; it was, however, obtained from potassium amyl sulphate. This was dissolved in warm alcohol, and a large excess of ether added; from this solution crystals of the salt crystallised out, and were purified from all but traces of furfuraldehyde by repeated recrystallisation. The salt was then saponified by sodium hydroxide, decomposed by 10 per cent. sulphuric acid, and heated on the water-bath for five hours; the alcohol was then obtained by distillation. The properties of the alcohol so obtained are described. Quantitative estimations of the amount of furfuraldehyde in the commercial preparations of the alcohol were also made: from 0·028 to 0·074 of the coloured product were obtained. The pure amyl alcohol is very useful as a means of separating pigments, and for extracting small quantities of alkaloïds in medico-legal investigations. The colour reactions, including spectroscopic appearances of the furfuraldehyde in amyl alcohol, may be used for the detection of the latter substance in spirituous liquors.

W. D. H.

Volumetric Determination of Uric Acid. By A. M. GOSSAGE (*Proc. Roy. Soc.*, **44**, 284—285).—Haycraft's method, in which uric acid is precipitated with silver nitrate in the presence of sodium carbonate and ammonia, and the precipitate treated with ammonium thiocyanate, is compared with that of Salkowski, in which the excess of silver nitrate is determined, phosphates being previously removed with magnesia mixture. Haycraft's results are always higher than Salkowski's, as the former assumed that the precipitated urate contains one atom of silver in the molecule, whereas the proportion of silver is always larger. If Haycraft's results are divided by 2, they agree in some cases with those of Salkowski, in others they are lower.

H. K. T.

Estimation of Proteïds with Special Reference to Milk. By J. SEBELIEN (*Zeit. physiol. Chem.*, **13**, 135—180).—Milk contains three proteïds, caseïn, lactalbumin, and traces of lactoglobulin. In order to test the method adopted for the quantitative estimation of the total proteïds and of the individual proteïds, a number of preliminary experiments were made with solutions of (1) pure caseïn containing small quantities of calcium chloride and sodium phosphate, (2) lactalbumin, and (3) egg albumin. Ritthausen's copper sulphate method of precipitating total proteïds was first investigated in the following way: the total nitrogen in the proteïd solution, in the precipitate, and in the liquid from which the precipitate had been filtered off, was estimated by Kjeldahl's process. The two first named had practically the same amount of nitrogen in them, whilst the filtrate was free from nitrogen. Lead acetate was similarly tested; some proteïd was left in solution, and the nitrogen in the precipitate plus that in the filtrate gave too high a result. Tannic acid was found to precipitate all proteïds completely; the precipitate must, however, not be washed with hot water or with spirit, as it is partially soluble in both those reagents. Albumoses are only incompletely precipitated by tannic acid, and peptone is soluble in excess of the reagent. The properties of phosphomolybdic acid are much the same, except that it causes a more complete precipitation of both albumoses and peptone.

The question whether albumoses and peptone occur in milk was then investigated. Saturation with ammonium sulphate completely precipitates all proteïds but peptone, which if present, may be identified in the filtrate by the biuret reaction (Kühne), or better still by the precipitate it gives with tannic acid. Peptone is, however, absent in milk, and also in colostrum, and in whey; the whey-proteïd of Hammarsten is thus not of the nature of peptone. It is, however, present in kephir, and in "long-milk" (a preparation made from milk in Upper Scandinavia). Other portions of milk were precipitated with tannic acid, and the filtrate was found to contain only such small quantities of nitrogen as would be accounted for by the urea, hypoxanthine, and other non-proteïd constituents; albumoses are absent therefore.

The method of estimating the total nitrogen in the precipitate produced by tannic acid, and multiplying this by 6·37 to obtain the total proteïd, is recommended as the most accurate method in quantitative investigations of proteïds, and is stated to produce less error than the more usual methods involving the washing, drying, weighing, and incineration of proteïd precipitates.

In order to estimate the caseïn and lactalbumin separately, rennet and various salts added to saturation have been recommended; these were all tested, and magnesium sulphate was found to be the best; it precipitates all the caseïn and the trace of lactoglobulin which is seemingly disregarded, and leaves all the albumin in solution. Sodium chloride was also found to precipitate all the caseïn. The albumin has been estimated by others, by weighing the precipitate produced by boiling after the separation of the caseïn. But boiling was found to be a very incomplete method of precipitating it; much nitrogen occurring in the filtrate after its removal. It is suggested that boiling lactalbumin and other proteïds split them (as Hammarsten found with fibrinogen) into an insoluble proteïd which is precipitated, and a soluble one which is left in the filtrate. It was found that solutions of pure caseïn when heated do not coagulate, but become opalescent, becoming clear again, however, on cooling. With regard to colostrum, many contradictory statements are quoted as to the relative amount of caseïn and albumin. By the present method it is found that the amount of these two proteïds is very variable; that the quantity of globulin is very considerable, and that the non-proteïd nitrogenous constituents are more abundant than in milk.

The following method was adopted in the analysis:—(1.) Total nitrogen first estimated in the colostrum. (2.) Proteïd nitrogen estimated in the tannic acid precipitate. (3.) Nitrogen in the precipitate produced by saturation with magnesium sulphate (caseïn + globulin). (4.) Caseïn-nitrogen estimated in the precipitate produced by adding acetic acid to milk. (Approximate.) (5.) Globulin nitrogen; two estimations: maximal, obtained by the difference of (3) and (4); minimal, estimated in the precipitate produced by magnesium sulphate after separating the caseïn by saturating with sodium chloride. (6.) Albumin-nitrogen, estimated in the precipitate produced by adding tannic acid to the filtrate after the separation of the proteïds, precipitated by magnesium sulphate saturation. (7.) Non-proteïd nitrogen is the difference between (1) and (2).

The following table gives the results in the analysis of five specimens of colostrum:—

	(1.)	(2.)	(3.)	(4.)	(5.)	(6.)	(7.)
1...	1·232	1·025	0·887	—	0 100	0·138	0·207
2...	2·506	2·269	2·02	0·56	0·248 1·46	0·25	0·237

Estimation of Albumin in Urine. By A. Christensen (*Lancet*, 1, 1889, 189, from *Virchow's Archiv*, **115**, 128—143).—This new method is considered more accurate than Esbach's. The latter plan consists merely in the complete precipitation of the albumin by picric acid, and the use of a tube so graduated that the depth of the deposit at the end of 24 hours indicates so many grams of albumin per litre of urine. This was found to be variable in its results when compared with those of coagulation by heat and nitric acid, for very slight changes of temperature influence the extent to which the precipitated albumin will "settle." The new method proposed consists in the use of tannic acid as the precipitant, and the suspension of the precipitate in the urine by means of mucilage. This mixture is then, after being diluted with water, poured into a vessel of certain capacity, which is placed over a white surface on which black lines are drawn. The amount of the "emulsified" urine necessary to obscure the lines will be in inverse ratio to the quantity of albumin in the urine, a quantity easily estimated by the employment of a suitably graduated burette. The principle is the same as that introduced by Panum for the determination of the quantity of cream in milk, and can no doubt be made available for clinical work. The results obtained are given in tables, but so far as can be gathered from these the advantage of the plan over that of Esbach (a far simpler method) does not seem very great; neither plan is quite accurate. W. D. H.

General and Physical Chemistry.

Relations between the Specific Rotatory and the Refractive Power of Chemical Compounds. Part II. By I. KANONNIKOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 686—693; compare this vol., p. 326). —In a former paper, the author has shown that very simple relations exist between the rotatory (α) and refractive (ϕ) powers of compounds of the same class, inasmuch as $\alpha = A\phi - B$, A and B being constants varying with each substance. Moreover, it was found that B/A = const. = 23·57, and $[\alpha]_D = A \times 5·6 = B/4·2$. With regard to the questions as to whether the value B/A has a special or a general significance, and whether it is possible to calculate the sp. rot. power from these constants A and B in the case of other substances, the author finds that the first relation holds good in the case of substances of perfectly unlike constitution:—

	A.	B.	B/A.
Nicotine	9·66	227·72	23·56
Tartar emetic	30·75	725·35	23·58
Quinic acid	7·40	174·56	23·59

The value B/A is found to change only with the nature of the solvent. Thus we have for solutions in ethyl alcohol—

	A.	B.	B/A.
Camphor	10·73	276·95	25·81
Russian turpentine	5·40	137·00	25·37
Coniine	2·65	69·80	26·34
Nicotine	20·77	537·50	25·87
Brucine	10·88	280·88	25·81
Menthol	10·61	273 00	25·73
		Mean	25·82

For solutions in chloroform, we have—

	A.	B.	B/A.
Camphor	31·12	1009·00	32·42
Terpene	30·80	999·79	32·46
Coniine	16·06	522·15	32·51
Menthol	61·43	1994·10	32·46
		Mean	32·46

The ratio $\alpha = A\phi - B$ then becomes $\alpha = A(\phi - c)$, where B/A = c = 23·57 for water, 25·82 for alcohol, and 32·46 for chloroform. These values are independent of the length of the rotating column.

The second question arises: What relation exists between the constants A and B and the sp. rot. power of active bodies? It is found that here again the relation varies with the nature of the solvent only, and that the general expression is—

$$[\alpha]_D = Ax \text{ and } [\alpha]_D = B/y.$$

Thus, for water $x = 5{\cdot}6$ and $y = 4{\cdot}2$, for alcohol $x = 5{\cdot}16$ and $y = 5{\cdot}00$, and for chloroform $x = 1{\cdot}78$ and $y = 18\ 21$.

It is remarkable, however, that the numbers calculated and found are sometimes identical, sometimes connected by a simple ratio, represented by such numbers as $\frac{1}{2}$, $\frac{1}{3}$, $\frac{3}{2}$, 2. The author proposes to investigate the influence of the chemical nature and properties of different compounds on the ratio B/A, and the cause of the variation above mentioned in the calculated rotatory power.

B. B.

Molecular Refraction. By W. SUTHERLAND (*Phil. Mag.*, [5], **27**, 141—155).—Newton's formula $(n^2 - 1)/d = c$, connecting index of refraction and density, Gladstone's $(n - 1)/d$, and Lorenz's $(n^2 - 1)/(n^2 + 2)d$, deduced theoretically from the assumption that in a medium composed of ether and molecules, light is propagated with a mean velocity but periodically varying amplitude of vibration, agree differently with experimental results. Thus Lorenz's formula holds good for both the liquid and gaseous states, but fails when change of density is produced by change of pressure, whilst Gladstone's meets the last requirement but fails to bridge over the great gap in density between liquid and vapour. Ketteler's theoretical formula, $(n^2 - 1)(v - \beta) = c(1 + ae^{-kt})$, where v = molecular domain and β = the true volume of the molecule, gives for compressibility results inferior to those obtained by Gladstone's formula. Lorenz's formula is derived by assuming a mean wave-length in the mixed medium, but this is erroneous, since the wave-length, as well as the amplitude, must vary as we pass from ether to matter. The author treats the velocities separately, and obtains a theoretical explanation of Gladstone's law. If the atoms are small and numerous, a ray will travel a certain mean distance in the atoms, which will represent a given loss of time and will be proportional to the length of path (s), the mean sectional area of the atom (a), and the number of atoms in unit volume d/m. If v is the velocity of light in free ether, V that in the atom, and l the mean distance through the atom, the loss of time in the atom will be $l/V - l/v$, and the total loss $= \frac{kslad}{m}\left(\frac{1}{V} - \frac{1}{v}\right)$, but this is equal to $\frac{s}{v'} - \frac{s}{v}$, where v' is the mean velocity of light in the medium, hence

$$\left(\frac{v}{v'} - 1\right)\frac{m}{d} = kla\left(\frac{v}{V} - 1\right),$$

that is, $(n - 1)m/d = kla(N - 1) =$ const., where n is the refraction index of the medium and N that of the atom. This is Gladstone's law. In the above considerations, the loss of time has been supposed to be due to the path through the atoms only. But the wave-point on issuing from the atom is a curved surface, and tends to recover its plane form in the intermediate ether, causing a further retardation, which is proportional to the length of path and is a function of the density, and as it vanishes with the density can be expressed by $s(bd + cd^2)$, where b and c are constants. The equation now becomes $(n - 1)m/d = la(N - 1) + m(b + cd +)$. In order to test this formula, the values at 10° and 20° (liquid) and at 100° (gaseous), determined by Lorenz (*Ann. Phys. Chem.* [2], **11**) for ethyl oxide, ethyl acetate, ethyl iodide, chloroform, and carbon bisulphide are examined. For this purpose, the above equation can be written

$$\frac{n - 1}{d} = \left(\frac{la(N - 1)}{m} + b\right) + cd.$$

c and the constant bracketed term can be determined from the values at 10° and 20°, and the bracketed term should agree with the value for the gas since cd vanishes, d being small. This is found to be the case, except for ethyl iodide.

Since Lorenz's formula gives the same value for liquids and vapours, and since for vapours $(n^2 - 1)/(n^2 + 2)d = \frac{2}{3}(n - 1)d$, it follows that the value of $(n - 1)/d$ for a vapour is $\frac{3}{2}$ of Lorenz's formula applied to the liquid. This fact is useful where a measurement at only one temperature is available, but may not always hold good.

H. K. T.

Spectral Analysis of Cadmium. By A. Grünwald (*Monatsh.*, **9**, 956—1034; compare Abstr., 1888, 389, 882).—The details of an analysis of the spectrum of cadmium by the method which has already been described by the author are here given. It is shown that cadmium contains condensation forms of the primary elements "*b*" and "*c*." The first is present in four different chemical conditions, namely, in the same condition as in helium, in that in which it occurs in free hydrogen, in that of combined hydrogen, as in water-vapour, and in a more condensed form than this latter. "*c*" occurs in two conditions: as found in oxygen, magnesium, and carbon, and in a less condensed state than the above.

In both zinc and cadmium "*b*" occurs in a more condensed condition than in water-vapour, the condensation for zinc being $\frac{5}{4}$ and for cadmium $\frac{7}{6}$. As zinc and cadmium occur in the same group in the periodic system, the first, however, in the fifth, the second in the seventh horizontal line, the author was led to believe that there might be some relation between the degrees of condensation in which "*b*" exists in elements belonging to the same group of the periodic system, expressible by "*b*" $\frac{n}{n - 1}$, where n is the number of the horizontal line in which the element having the above condensation form occurs. This has been confirmed for a number of elements. The opinion is also stated that the primary element "*c*" of oxygen is a definite condensation form of "*a*" of hydrogen.

The author replies to objections raised against his method, and expresses his firm conviction as to the general accuracy of his results.

H. C.

Gadolinium. By L. de Boisbaudran (*Compt. rend.*, **108**, 165—168).—Crookes's observations on the spectra of the fluorescences led him to conclude that Marignac's *gadolinium* is a mixture of 61 parts of yttria with 39 parts of samaria.* The term *yttria*, according to Crookes, denotes a mixture of earths which give different fluorescence spectra, and which form a family of very closely related substances, the equivalent of the metals oscillating about 89°. They all, however, give the same spark spectrum.

The author has previously shown that the principal fluorescence formerly attributed to yttrium is really due to $Z\alpha$ and $Z\beta$, which have atomic weights not less than 163, and therefore much higher than the atomic weight of yttrium. $Z\beta$ is probably identical with terbium. Moreover, it is not easy to see how a mixture of 61 parts of yttria ($Yt = 89$) with 39 parts of samaria ($Sm = 150$) could give an atomic weight of 156·75, which was found by Marignac to be the atomic weight of the metal in gadolinia.

The fluorescence of the earth formerly known as yttria is, when samaria is absent, practically identical with the fluorescence of a mixture of $Z\alpha$ and $Z\beta$, both of which have an atomic weight higher than that of yttrium and do not give the yttrium spark spectrum. Pure yttria shows the fluorescences of $Z\alpha$ and $Z\beta$ very feebly, but gives a magnificent spark spectrum. The author applies the term yttria to the non-fluorescent substance which gives the well-known yttrium spark spectrum, and is the oxide of a metal with an atomic weight of about 89.

Comparison of the spark and fluorescence spectra of Marignac's gadolinia with those of mixtures of yttria with varying proportions of other rare earths, leads to the conclusion that it contains a distinct oxide *gadolinia*, with the following impurities:—

Di_2O_3.	$Z\beta_2O_3$.	Yt_2O_3.	Sm_2O_3.	$Z\alpha_2O_3$.	CaO.
0·24	4·70	0·15	4·40	0·13	0·07

The small quantities of $Z\beta$ and samaria still remaining must be regarded as the residue of impurities which would be completely removed by appropriate fractionation. The greater part of the gadolinia has resisted a fractionation sufficient to remove almost all the yttrium and $Z\alpha$, and hence, if it is still compound, it must contain hitherto unknown elements which are extremely difficult to separate.

C. H. B.

Chemical Theory of the Galvanic Element. By F. Exner and J. Tuma (*Monatsh.*, 9, 903—943).—The authors show that the results obtained by Ostwald (Abstr., 1888, 886) with dropping electrodes of mercury are untrustworthy, inasmuch as two sources of error remain unnoticed, the first being chemical action of the electrolyte on the mercury, and the second the subsequent occurrence of polarisation. It was found experimentally that the first in the case of dilute sulphuric acid makes as large a difference as 0·84 Daniell on the result, and the second 0·8 to 1·2 Daniell. The two being, however, of opposite sign, tend to neutralise one another. These errors also occur in the observations of Moser and Miesler (Abstr., 1888, 209, 392).

---

* The statement as to gadolinium made at the commencement of this paper entirely misrepresents Crookes's views on the subject (compare *Proc. Roy. Soc.*, 40, 502, and *Chem. News*, 54, 39).—Ed.

An arrangement is then described in which these sources of error are eliminated, the mercury being allowed to drop into a cylinder of filter-paper, wetted with and connected by a damp thread to the solution in which dips the metal under examination. A number of metals in different solutions were examined, and in every case, with the apparent exception of carbon and platinum in concentrated nitric acid, the metal was found to be negatively charged. The exception is ascribed to the formation of nitrous acid in solution. It also appears that the numbers obtained for metals in acids are identical with those for the same metals in salts of the same acids.

Details of experiments on the potential differences in galvanic cells and voltameters are also given. H. C.

Electric Conductivity of Fused Salts. By L. POINCARÉ (*Compt. rend.*, **108**, 138—141).—The addition of a small quantity of silver nitrate to any fused nitrate depolarises immediately and completely a silver electrode which is immersed in it. If such an electrode is placed in fused silver nitrate, and then thoroughly washed with water, it remains depolarised for some time when immersed in a fused alkaline nitrate. It is therefore possible in certain cases to simplify the method devised by Bouty and the author for determining the conductivity of fused salts, and it has been applied to fused silver nitrates and mixtures of this salt with other nitrates.

The specific conductivity of fused silver nitrate between 280° and 370° is represented by the expression $Ct = 1·233 [1 + 0·0025(t - 350°)]$. Experiments with five mixtures through a somewhat wide range of temperature give results which are represented by the formula—

$$C''_t = \frac{pc_{350} + qc'_{350}}{p + q}\left[1 + \frac{p^{\alpha} + q\beta}{p + q}(t - 350)\right],$$

in which p and q are the volumes, and not the weights of the respective salts, and α and β the coefficients of variation with the temperature. The conductivity of ammonium nitrate is given by the equation $\gamma_t = 0·400 [1 + 0·0073(t - 200)]$.

In the case of the nitrates of sodium, potassium, silver, and ammonium, the coefficients of variation with the temperature are inversely as the sp. gr. of the corresponding salts. The molecular conductivities of the potassium and ammonium salts, 0·0397 and 0·0420 respectively, are almost identical, whilst those of silver nitrate, 0·0537, and sodium nitrate, 0·0602, show considerable differences. It is noteworthy that the first two give solutions with normal properties, whilst the solutions of the second two show abnormal behaviour.

C. H. B.

Abnormal Electromotive Forces. By E. F. HERROUN (*Phil. Mag.* [5], **27**, 209—233).—The author investigates those cells in which the electromotive forces do not agree with the theoretical values as deduced from thermochemical data. The method consists in passing a current between electrodes immersed in solutions of their salts separated by a porous cell, and noting the changes of temperature in the solutions. The results lead to the conclusion that the electromotive force is derived from the free energy of the chemical process. If a portion of the total energy (as measured by the calorimeter) is negative, this may be supplied at the expense of either the free or bound energy. In the first case there will be a reduction in electromotive force, whilst in the second the effect will be simply thermal. Thus with silver nitrate solution, whilst the total energy is 27600 — 10880 = 16720, the electromotive force corresponds to 27600 thermal units, the —10880 (heat of solution) being supplied by the disappearance of sensible heat. The author questions Helmholtz's view that mercury deposited by zinc, even from its solid salts, can give an electromotive force in excess of thermal values. In the case of hydrated salts, the electromotive force does not incorporate the whole heat of hydration, it is therefore only in the case of salts which do not form hydrates, and consequently only absorb heat during solution, that the electromotive force is equivalent to the heat of formation of the solid salt. It is not yet determined whether there is any relation between that portion of the heat of hydration which is converted into electrical energy and that which runs down into heat. In some cases (zinc-cadmium chloride cell) the degradation of energy increases with the dilution of the salt solution. The above makes it apparent that no cell can give an electromotive force in excess of the free energy of the reaction, and negatives the possibility of the conversion directly of sensible heat into electrical energy. Low electromotive forces are in many cases due to the formation of films, or sub-salts, on the surface of the metals, thereby leading to a different thermochemical reaction. H. K. T.

Electrolysis of Copper Chloride. By F. QUINCKE (*Ann. Phys. Chem.* [2], **36**, 270—272).—According to Faraday's law, the quantities of different substances separated at the electrodes are in the ratio of their chemical equivalents. Therefore in the case of compounds of the higher and lower oxides of a metal, different quantities of the metal will be separated at the cathode for the same amount of anion set free at the anode, so that the chemical equivalent must have more than one value.

The only direct experimental proof of this result, not obviously vitiated by secondary actions, was given by Buff, who passed a current through a copper voltameter and a tube containing fused copper chloride connected in series, so that both were traversed by the same current. He found that the diminution in weight of the copper anode in the copper sulphate was about half as much as the diminution of the anode in the fused chloride, but was unable to obtain any accurate determination of the increase in weight of the anode in the fused chloride.

The author has repeated this experiment, and finds that no definite conclusions can be drawn from it, as the copper electrode in the fused chloride was found to dissolve gradually when the battery was cut out of the circuit, owing to the production of a current of sufficient strength to be indicated by an ordinary tangent galvanometer. This current was very irregular, and the author attributes it to inequalities in the temperature of different portions of the fused salt.

G. W. T.

Heat Conductivity of Mixtures of Ethylic Alcohol and Water. By H. HENNEBERG (*Ann. Phys. Chem.* [2], **36**, 146—164).—In 1880, Weber showed that the ratio of heat conductivity to the specific heat of unit volume was the same for all the liquids experimented with. In 1885 (*Berlin Monats.*) Weber obtained another and more complex law, namely, if k is the heat conductivity of the liquid, c its specific heat, and ρ its density, μ the number of molecules in the state of vapour which make up a single molecule of the liquid, λ^3 the volume of such a molecule, then the quantity $\frac{k}{c\rho} \cdot \frac{\lambda}{\sqrt[3]{\mu}}$ is constant for all liquids of similar chemical constitution.

The author transformed this expression by means of the relation $\lambda / \sqrt[3]{\mu} = \sqrt[3]{m/\rho}$, where m is the mass of a molecule of the liquid: a relation which is obtained immediately, since if N is the number of molecules of liquid in unit volume, $\rho = \mathrm{N}\mu m$ and $\mathrm{N}\lambda^3 = 1$.

He then found that although the values of the heat conductivity were in all cases included between the values for pure water and pure alcohol respectively, the heat conductivity of the mixtures did not obey either of Weber's laws, from which he considers it probable that such mixtures consist each of one or more chemical compounds, and that the compounds occurring in the different mixtures are not identical.

G. W. T.

Specific Heats of Gases at Constant Volume. By J. JOLY (*Proc. Roy. Soc.*, **45**, 33—36).—Two equal thin metallic spheres are suspended from a delicate balance in separate steam calorimeters, their thermal capacities being made equal by the addition of copper wire, so that the condensation on each is equal, and the balance remains in equilibrium. Air is now forced into one, and their specific heats again compared by means of the formula $\mathrm{S} = \frac{w\lambda}{\mathrm{W}(t_2 - t_1)}$, where λ is the latent heat of steam, w the weight of steam condensed, W the weight of gas, and t_2, t_1 the extremes of temperature. Concordant results are obtained which are slightly above the value usually assigned. The results show that the specific heat is quite independent of the compression of the air. The reason of the excess over the theoretical value is not apparent.

H. K. T.

Heats of Formation of several Organic Acids. By I. OSSIPOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 650—652).—The following preliminary values were found as the heats of combustion of—

Sorbic acid............	726·6— 731·3 Cal.
Terebic acid...........	791·0— 787·6 „
Cinnamic acid.........	1032·6—1024·3 „
Atropic acid..........	1042·4—1043·2 „

B. B.

Heats of Combustion of Stilbene and the Isomeric Nononaphthenes. By I. Ossipoff (*J. Russ. Chem. Soc.*, 1888, **20**, 645—650).—The heats of combustion of stilbene and the two isomeric nononaphthenes, C_9H_{18}, obtained by Markownikoff from Caucasian petroleum, were determined by means of the "calorimetric bomb." The results obtained are—

Stilbene, m. p. 124—125°.......	1771·7 Cal. const.	volume.
	1773·3 „ „	pressure.
Nononaphthene, b. p. 135—136°.	1380·9 „ „	volume.
	1383·4 „ „	pressure.
Isononaphthene, b.p. 150—151°	1381·7 „ „	volume.
	1384·2 „ „	pressure.

B. B.

Dilatation and Compression of Air. By C. Antoine (*Compt. rend.*, **108**, 141—144).—A mathematical paper not admitting of useful abstraction.

Velocity of Sound in Vapours and the Determination of the Vapour-density. By W. Jaeger (*Ann. Phys. Chem.* [2], **36**, 165—213).—The velocity of sound in a perfect gas is given by the equation $V = \sqrt{gk\frac{R}{d}T}$, where g is the acceleration of gravity, k the ratio of the specific heat at constant pressure to the specific heat at constant volume, T the absolute temperature, R the gaseous constant for air, and d the relative density of the gas.

The author makes use of this relation to determine the densities of the superheated vapours of ether, alcohol, and water at various temperatures. He also determines the ratio of the specific heats for these three vapours, and finds that in ether vapour $k = 1·097$, for alcohol vapour $k = 1·133$, and for steam $k = 1·33$. G. W. T.

Vapour-density Determinations. By T. W. Richards (*Chem. News*, **59**, 87—88).—The author points out that when using apparatus in which vapour-densities are measured by the fall of a column of mercury in an attached barometer tube, errors due to cooling in the unheated parts of the apparatus may be eliminated by reducing the extent of those parts, and an apparatus for the purpose is described. D. A. L.

Relation between the Solubility of Salts and their Melting Points. By A. Etard (*Compt. rend.*, **108**, 176—178; comp. Abstr., 1888, 548).—The solubility of many salts increases with the temperature up to the melting point of the anhydrous salt, and beyond this point a given quantity of water can dissolve an unlimited quantity of the salt.

Potassium nitrate:—Between 0° and 10° the line of solubility is slightly curved, but beyond 10° the solubility is represented by the following expressions:—From 10° to 69°, $y = 17{\cdot}0 + 0{\cdot}7118t$; from 69° to 125°, $y = 59{\cdot}0 + 0{\cdot}375t$; from 125° to 338°, $y = 80{\cdot}0 + 0{\cdot}0938t$.

Sodium nitrate:—From −15° to 64°, $y = 36{\cdot}0 + 0{\cdot}2784t$, and from 64° to 313°, $y = 58{\cdot}0 + 0{\cdot}1686t$.

Potassium chlorate:—From 0° to 42°, $y = 2{\cdot}6 + 0{\cdot}2000t$; from 42° to 171°, $y = 11{\cdot}0 + 0{\cdot}3706t$, and from 171° to 359°, $y = 59{\cdot}0 + 0{\cdot}2186t$.

Silver nitrate:—From 55° to 198°, $y = 81{\cdot}0 + 0{\cdot}1328t$.

Barium nitrate:—From 0° to 210° $y = 4{\cdot}5 + 0{\cdot}2000t$.

The curve of solubility being the locus of the melting points of mixtures of the anhydrous salts and water, the solubilites at temperatures between 200° and 450° were determined by observing the temperatures at which the salt melted in mixtures of the salt and water of known composition. C. H. B.

General Law of Diminution of Volume of Salts by Solution in Water.

By A. Heritsch (*Ann. Phys. Chem.* [2], **36**, 115—122, and *J. Russ. Chem. Soc.*, 1888, **20**, 632—645).—If δ is the diminution of volume due to the formation of 100 grams of solution, p the percentage weight of the salt, it can be shown that $\delta = C(100 - p)p$, where C is a constant for a given temperature. This expression attains a maximum for $p = 50$. Also since $(100 - p)p > \frac{(100 - 2p)2p}{2}$, it follows that contraction must always take place during solution, which is in agreement with experiment.

The author has determined the coefficient C for the chlorides of sodium, potassium, ammonium, aluminium, strontium, barium, calcium, magnesium, and zinc; the nitrates of sodium and potassium, the sulphates of potassium, sodium, ammonium, magnesium, and zinc; the bromides of ammonium and potassium; the carbonates of sodium and potassium; potassium acetate, magnesium and potassium sulphates, potassium hydroxide, potassium oxalate, tartaric acid, citric acid, phosphoric acid, copper sulphate, lithium chloride, and ammonium nitrate.

Except in the case of the last two, he finds the formula to be true. In the case of these two salts, δ is greater for weak than for strong solutions. The author attributes this to dissociation taking place after a certain amount of dilution. G. W. T.

Influence of Temperature on Evaporation and on the Diffusion of Vapours.

By A. Winkelmann (*Ann. Phys. Chem.* [2], **36**, 93—114).—If D_0 and D_t are the coefficients of diffusion of a pair of gases at 0° and t° respectively, and A is the coefficient of expansion of a gas, the relation between D_t and D_0 may be expressed by an equation of the form—

$$D_t = D_0 (1 + at)^m.$$

The author finds the following values for the constant m—

Gases.	m.
Air and carbonic anhydride	1·968
Oxygen and hydrogen	1·755
Oxygen and nitrogen	1·792
Steam and carbonic anhydride ...	1·972
Steam and hydrogen............	1·712
Steam and air	1·774

Now if η_0 and η_t are the viscocity coefficients of a gas at 0° and t° respectively—

$$\eta_t = \eta_0(1 + at)^n.$$

Also by the kinetic theory of gases—

$$D_t = D_0(1 + at)^{n+1},$$

which gives $m = n + 1$.

The theoretical value of n is 0·5, but its value as determined by the most trustworthy experimental methods approaches more nearly to unity. This may be explained by supposing that the length of the free path of the molecules increases with the temperature. Stefan and O. E. Meyer have attributed this to a closer approach of the mutually impinging molecules at higher than at lower temperatures.

The values obtained for the constant m if they are trustworthy, therefore, show that the molecule of water behaves like the molecules of oxygen and nitrogen, and that the radius of the sphere of mutual action diminishes less rapidly with increasing temperature in the case of water molecules than in the case of molecules of carbonic anhydride. The author suggests that it would be of interest to investigate vapours of complex molecular structure, to see whether, as would be anticipated, the constant m has relatively high values in such cases.

G. W. T.

Gradual Chemical Change. By W. H. PENDLEBURY and M. SEWARD (*Proc. Roy. Soc.*, **45**, 124—126).—Mixtures of chloric and hydrochloric acids and of potassium chlorate and hydrochloric acid were made, potassium iodide added, and the rate at which iodine was set free determined by means of sodium thiosulphate. The rate of liberation of iodine represents the velocity of reaction of the acids, the decomposition of the potassium iodide being comparatively instantaneous. With variation of chloric acid, the rate varies, (1) directly, as a participant in the reaction, (2) with a small acceleration proportioned to the amount present. With variation of hydrochloric acid there is observed (1) a secondary (accelerative) effect on the decomposition of chloric acid by itself, and (2) an effect both primary and secondary on the decomposition of chloric acid with hydrochloric acid. With potassium chloride present there is a small accelerative effect proportional to its quantity. Temperature and velocity are related, so that the latter increases in geometric progression when the former increases in arithmetical progression. H. K. T.

Reduction-velocity of Alkaline Copper Solutions. By F. URECH (*Ber.*, **22**, 318—319).—The author gives a table showing that the formula $kw^y = u^x . t$ where k = constant (compare *Ber.*, **17**, 495), can be employed for the comparison of analogous reactions and for calculating the coefficients appertaining thereto. If m is the number of molecules of copper sulphate acting on one molecule of dextrose, the differential velocity formula under the simplest conditions is $kuv^m . dt = -du = ku^n dt$ for $v = u$, and integrated $kt = lgu_0 - lgu$. The experimental results previously published (*loc. cit.*) do not agree with this integral formula, but it is shown by a table that by introducing a term (d) for correction of time, the results agree somewhat better with the integral formula $k(t + d) = lgu_0 - lgu$, where $d = 6$, although several influences cannot as yet be formulated.

F. S. K.

A General Method of Estimating the Basicity of Acids. By F. Fuchs (*Monats.*, 9, 1132—1142).—Sodium hydrosulphide and potassium hydrosulphide can both exist in aqueous solution, and are perfectly stable when the solution is surrounded by an atmosphere of hydrogen sulphide. Making use of the well-known fact that hydrogen sulphide can be turned out of combination by even the feeblest acids, the author explains a method of determining the basicity of an acid by estimating the amount of hydrogen sulphide a known weight (0·05—0·06 gram) of the acid can liberate from an alkaline hydrosulphide, the amount set free being ascertained either by absorbing the gas in soda and subsequent neutralisation with acetic acid and titration with iodine, or by allowing the gas to react with mercury and directly measuring the volume of hydrogen set free.

G. T. M.

Prout's Hypothesis, especially with reference to the Atomic Weights of Carbon and Oxygen. By J. A. Groshans (*Rec. Trav. Chim.*, 7, 358—364).—The author shows that isomeric organic compounds, containing carbon, hydrogen, and oxygen, which have the same molecular weight but different composition, belong to one of seven general series, the molecular weights in each of which are given by $14n + 2x$, where x is any unit less than 7. He argues from the equality in the molecular weights of such compounds of different composition, that the atomic weights differ by some multiple of that of hydrogen, so that $C + 4 = O$ and $4C = 3O$, and hence that $C = 12$ and $O = 16$.

H. C.

Sublimation Apparatus. By J. W. Brühl (*Ber.*, 22, 238—240).—The author describes, with the aid of a diagram, an apparatus designed for purifying substances by sublimation. The apparatus employed for substances melting at a comparatively low temperature, consists of a flat, circular, brass box (B), supported on a iron tripod and provided with an inlet and an outlet tube so that it may be kept cool by means of a constant stream of water. In the centre of this box there is a perforation shaped like the segment of a cone, the base being downwards. The crucible containing the substance is placed in the hole in the box (B) and a flat, well-fitting, glass bell-jar is placed on the box; as the only part of the crucible in contact with (B) is a very narrow circular surface, a very small flame is sufficient to heat the crucible. The crucible should be made of some metal which is a good conductor of heat; if the glass cover is moderately flat almost the whole of the substance condenses on the cool brass surface. This apparatus can also be suitably employed for fractional sublimation.

Another form of apparatus for substances melting at a moderately high temperature, consists of an ordinary flat, porcelain plate, in the centre of which a small circular hole is made to hold the crucible, and a flat, well-fitting, glass bell-jar cover. The plate is kept cool by a circular piece of asbestos card, which is placed in the hollow of the plate, and a square, somewhat larger piece which rests directly on the tripod; both layers of asbestos are pierced in the centre and soaked in cold water before the commencement of the operation. F. S. K.

Apparatus for Crystallising at a Low Temperature and in Absence of Moisture and Air. By J. W. Brühl (*Ber.*, 22, 236—238).—The apparatus described, a diagram of which is given, was employed by the author for crystallising substances at a low temperature in a perfectly dry atmosphere or in absence of both moisture and air. The apparatus can also be employed for saturating liquid with gaseous substances at a low temperature and separating the solid products in a pure condition.

The liquid is placed in a thick, wide glass tube (B), the lower extremity of which is funnel-shaped and connected with a narrow glass tube (*b*), the upper end being covered with a very small, shallow, glass bell-jar, and made air-tight by means of a thick ring of soft india-rubber which surrounds the tube (B). The bell-jar is provided with a tubulus and india-rubber cork, through which passes a chloride of calcium tube; the latter is either closed by means of a pinch-cock (*p*), or, if a gas is to be passed into the apparatus, it is connected with the conducting tube. The receiver (B) is surrounded by a small inverted bell-jar (A) containing the freezing mixture. The narrow tube (*b*), with which (B) is connected, passes somewhat loosely through an india-rubber cork in the tubulus of the bell-jar (A), as does also a tube, bent at a right angle and provided with a pinch-cock, through which the freezing mixture can be run off at the end of the operation. A platinum cone, pierced with a small hole, is placed in the funnel-shaped portion of the tube (B), and the narrow tube (*b*), in connection with (B), is drawn out to a smaller diameter and connected by india-rubber tubing with a glass tube (D), provided with a stopcock (*h*). The lower extremity of (D) passes through an india-rubber cork, fitting into a small flask (E), which is provided with a tubulus. The apparatus is employed as follows:—The stopcock (*h*), being closed, a few drops of the liquid are placed in (B) to make the platinum cone adhere to the glass, and the whole of the liquid is then poured in; the bell-jar cover (C) is made air-tight, and the receiver (B) and the portions in connection therewith are lowered into the vessel (A), so that when the freezing mixture is placed in (A) only the bell-jar cover remains above the surface. When the separation of crystals is at an end, the calcium chloride tube is closed by the pinch-cock (*p*), the cock (*h*) is opened, and the whole apparatus is exhausted as completely as possible by connecting the tubulus of (E) with the pump. Dry air can then be passed through the apparatus by slowly opening the pinch-cock (p). If oxygen is to be excluded, the apparatus is filled with some indifferent gas before the commencement of the process, and, when the operation is at an end, the same gas can be passed through the apparatus by connecting the conducting tube with the calcium chloride tube. F. S. K.

Inorganic Chemistry.

Preparation of Hydrogen. By J. HABERMANN (*Zeit. anal. Chem.*, **28**, 88).—A granulated alloy of tin and zinc, containing about 83 per cent. of the latter, prepared by adding zinc to molten tin as long as it dissolves, is recommended for use in Kipp's apparatus. The pieces retain their shape and size after all the zinc is dissolved out, and therefore have no tendency to fall through into the lower bulb.

M. J. S.

Preparation of Oxygen. By C. F. GÖHRING (*Chem. Zeit.*, **12**, 1659—1660).—It is proposed to prepare oxygen by adding potassium permanganate to hydrogen peroxide made alkaline with ammonia.

D. A. L.

Combustion in Dried Oxygen. By H. B. BAKER (*Proc. Roy. Soc.*, **45**, 1—3).—This paper is a continuation of the author's experiments on combustion in dry oxygen (Trans., 1885, 349). The elements were very carefully purified, especially from occluded hydrogen. Carbon, sulphur, boron, and phosphorus were found to have their combustion arrested in proportion to the dryness of the oxygen. In no case when the materials were carefully dried, did flame appear.

In experiments with amorphous phosphorus, it was found that when heated in nitrogen up to 300°, no change into the ordinary modification took place, whilst in moist oxygen, combustion commenced at 260°, hence amorphous phosphorus burns as such and is not first converted into the ordinary form as is generally supposed.

Carbon burnt in partially dried oxygen mainly gives rise to carbonic oxide even at temperatures at which carbonic anhydride cannot be reduced by carbon. Hence carbonic oxide is the first product in the combustion of carbon, further oxidation, in this particular case, being prevented by the dryness of the oxygen. Carbonic oxide is also produced by the slow combustion of carbon in air at 440°, a temperature too low for a reduction of carbonic anhydride to have taken place.

H. K. T.

Valency of Boron. By G. GUSTAVSON (*J. Russ. Chem. Soc.*, 1888, **20**, 621—623).—Referring to Lorenz's paper (Abstr., 1888, 1246), in which the author says that the product of the action of equivalent quantities of boric anhydride and boron trichloride is not BOCl, "as assumed by Gustavson," Gustavson shows that in his original paper (in Russian), he never said that the compound produced had the composition BOCl, for this would be absurd, as half of the boron trichloride employed was distinctly said to escape on heating. As he obtained substances differing widely in composition, he believed it to be right to assign no formula to the product; Lorenz, on the other hand, although his results varied greatly: $B_2O_3 = 74·8—82·5$ and $Cl = 20·2—24·2$, took the mean result as correct, from which he deduced the formula $B_8O_{11}Cl_2$: this is evidently of no great value.

B. B.

Formation of Carbon Oxysulphide. By C. BÖTTINGER (*Ber.*, **22**, 306).—A claim of priority.

Relative Rates of Dissolution of Gypsum and Anhydrite. By J. F. MCCALEB (*Amer. Chem. J.*, **11**, 31—33).—Owing to the difficulty of pulverising selenite completely, the solvent action of water on the various specimens experimented with was determined by immersing blocks of the minerals. Only a portion, about 6—9 sq. cm., of one smooth surface was exposed, the other parts being covered with a layer of paraffin. The blocks were suspended just below the surface of 4 litres of distilled water in tall jars. The temperature varied from 19° to 32°. The specimens used were as follows:—A, gypsum, "pure" pink, micaceous mass; B, gypsum, "pure" white massive; C. selenite, "pure" honey-yellow crystal; D, anhydrite, "impure" grey massive; E, anhydrite, "pure" greyish massive; F, gypsum and anhydrite mixed, white massive.

Amounts of calcium sulphate in grams dissolved from each square centimetre of surface in one week:—

A.	B.	C.	D.	E.	F.
0·2388	0·2219	0·1177	0·0666	0·0601	0·2184

In order to determine the rate at which the solvent acts as it becomes more nearly saturated, the pieces B, C, D were exposed for a longer time and afforded the following results:—

	1st week.	2nd week.	3rd week.	4th week.	5th week.
B	0·2219	0·4638	0·6788	0·8168	0·8768
C	0·1177	0·2021	0·3250	0·4179	0·4893
D	0·0666	0·0999	0·1514	0·1881	0·2398

J. W. L.

Hydration of Calcium Sulphate. By J. F. MCCALEB (*Amer. Chem. J.*, **11**, 34—35).—In order to determine the rate at which anhydrous calcium sulphate becomes converted into the hydrate, three specimens were experimented upon. D, an impure anhydrite from Salzberg; E, a pure anhydrite from Nova Scotia; G, a pure selenite from Montmartre, which was heated to bright redness.

Portions of 1 gram of these various specimens, in a state of fine division, were moistened on watch-glasses with water and placed under a bell-jar over water. In order to determine the extent of hydration, the watch-glasses and contents were dried over sulphuric acid and weighed, only mechanically admixed water being given off under these circumstances. The results were as follows:—

	1 week.	2 weeks.	3 weeks.
D	0·0209	0·0357	0·0493
E	0·0072	0·0155	0·0234
F	0·0022	0·0048	0·0073

The temperature during this series of experiments varied between 20—25°. Also a number of watch-glasses, each containing 1 gram of anhydrite D, were exposed to moisture in a similar manner, the temperature being about 25—30°:—

	No. of weeks exposed.						
	4.	8.	12.	16.	20.	28.	36.
Water absorbed	0·0308	0·0488	0·0629	0·0700	0·0803	0·0873	0·0949

J. W. L.

Specific Gravity of Calcium Sulphate. By J. F. McCaleb (*Amer. Chem. J.*, **11**, 35—36).—These determinations were made by means of the specific gravity bottle, with a paraffin oil of high boiling point. The specific gravity is stated in reference to water at 15°.

(1) "Plaster of Paris," obtained by heating crystallised selenite to 200°; sp. gr. = 2·577. (2) Same selenite heated to a dull red heat; sp. gr. = 2·911. (3) Same selenite heated to a bright red heat; sp. gr. = 2·890. (4) Same selenite heated on platinum until just melted; sp. gr. = 2·796. (5) Same selenite heated in clay crucible in a blast furnace; sp. gr. = 2·654. (6) Anhydrite (97 per cent. pure); sp. gr. = 2·907. According to Clark, selenite has sp. gr. = 2·30—2·33; anhydrite has sp. gr. = 2·92—2·98. J. W. L.

A Red Copper Slag containing Artificial Cuprite. By J. L. Jarman and J. F. McCaleb (*Amer. Chem. J.*, **11**, 30—31).—The specimen examined was from the Canton copper works of Baltimore. It is very hard and tenacious, breaks with conchoidal fracture and splintery edges, and contains minute beads of copper disseminated through its mass. It is opaque with dark scarlet colour. Sp. gr. = 3·486. H = 4·8.

The analysis gave the following figures:—

SiO_2.	Cu_2O.	Al_2O_3.	FeO.	CaO.	MgO.	K_2O.	Na_2O.
38·039	47·489	2·001	2·829	2·525	0·404	0·549	5·920

Under the microscope it appeared as a transparent matrix of a pale-yellow colour, in which minute transparent crystals of a cochineal colour, mostly of cubical and rectangular forms, were observed.

Treated with 8 per cent. nitric acid in a very finely pulverised condition, 46·29 per cent. was dissolved, and of this 43·49 per cent. was cuprous oxide. The resulting pale-yellow powder contained no red fragments. From this it appears that the red particles consist of cuprous oxide, and they appear to be in the form of the native cuprite (Brown, *Amer. J. Sci.*, **32**, 379). The yellow powder is insoluble in aqua regia and sodium hydroxide; sp. gr. = 2·31; H = 4·8, fusible without change of colour, but in the oxidising flame it forms a blue glass.

The analysis gave—

SiO_2.	Al_2O_3..	FeO.	CaO.	MgO.	Cu_2O.	K_2O.	Na_2O.
69·22	4·84	5·74	3·33	0·89	5·65	0·61	10·34

J. W. L.

Affinity of the Heavy Metals for Sulphur. By E. Schürmann (*Annalen*, **249**, 326—350).—An investigation of the action of solutions of various metallic salts on 16 metallic sulphides led to the following results :—Palladium sulphide is not attacked by any of the metallic salts, and palladium dichloride decomposes all metallic sulphides. Manganese sulphide is the least stable of the 16 sulphides examined. Arranged in the order of their affinity for sulphur, the metals form the following series :—Pd, Hg, Ag, Cu, Bi, Cd, Sb, Sn, Pb, Zn, Ni, Co, Fe, As, Tl, Mn. In each natural family of elements, the affinity to sulphur increases with the atomic weight. Family IV is an exception to this law, as the affinity of sulphur to tin is greater than its affinity to lead. The members of family III have less affinity to sulphur than their neighbours in family IV, and these again than the corresponding elements with a slightly higher atomic weight in family V. W. C. W.

Interaction of Chromic Acid and Hydrogen Peroxide. By Berthelot (*Compt. rend.*, **108**, 157—161).—When hydrogen peroxide is added to a solution of a dichromate acidified with a strong acid, the blue compound is formed and a slow evolution of oxygen begins almost immediately, the chromium being reduced to the form of a chromic salt. The ratio of the oxygen liberated from the chromic acid to that liberated from the peroxide is 1 : 1 when the hydrogen peroxide is added to the chromium solution, and 3 : 5 if the order of addition is reversed. Decomposition takes place more rapidly in presence of nitric acid than in presence of sulphuric acid.

When the dichromate solution is acidified with a feeble acid, such as acetic or phosphoric, it first acquires, according to the degree of concentration, a violet or purple colour, which is due to a mixture or compound of the perchromic acid and a brown substance. The oxygen ratios are the same as with the strong acids. With still feebler acids, such as boric or hydrocyanic, the brown substance alone is formed, and the rate of decomposition is very slow. The phenomena are, in fact, similar to those observed with hydrogen peroxide and a solution of pure chromic acid.

If the peroxide is added to a moderately strong solution of chromic acid, the liquid is at first blue and then becomes violet, brown, or even green, but with very dilute solutions at a temperature not exceeding 10°, mere traces of perchromic acid are formed, and the brown substance is the chief product. The same results are obtained with potassium dichromate, which has been mixed with an exactly equivalent quantity of hydrochloric or sulphuric acid.

The action is most regular with a solution of pure potassium dichromate, which may be regarded as a mixture of normal chromate with chromic anhydride. If a solution of this salt containing a gram-molecule in 16 litres is mixed with an equivalent quantity of a solution of hydrogen peroxide which contains a gram-molecule in 2 litres, the liquid darkens in colour, rapidly becoming a very deep brown, and oxygen is liberated with effervescence, but during this reaction, the liquid contains mere traces of perchromic acid. After some time, the liquid becomes clear and has its original tint; it then contains neither hydrogen peroxide nor reduced chromium oxide. In the calorimeter, the temperature rises gradually, and after four minutes the reaction is practically complete, the heat liberated being +20·8 Cal., a number almost identical with the heat liberated by the decomposition of hydrogen peroxide, namely, +21·6 Cal. Indeed, if the final reading is taken 19 minutes after mixing, the total heat liberated is 21·4 Cal.

The same quantity of potassium dichromate will decompose in the same manner an unlimited quantity of hydrogen peroxide.

The brown intermediate product is probably a compound of hydrogen peroxide with chromic oxide: it decomposes rapidly, with regeneration of chromic acid, liberation of oxygen, and formation of water. As the thermal measurements show, the heat liberated by the reaction is identical with that liberated by the decomposition of hydrogen peroxide.

The brown colour of the intermediate product points to the formation of chromium chromate, which is probably combined with hydrogen peroxide, thus: $(n + 2)CrO_3 + 6H_2O_2 = nCrO_3,Cr_2O_3,3H_2O_2 + 3H_2O + 3O_2$. The peroxide then oxidises the chromium chromate with reproduction of chromic acid and formation of water.

A solution of normal potassium chromate containing a gram-molecule of the salt in 4 litres, at first shows no change when mixed with hydrogen peroxide, but after some time decomposition takes place in the same manner as with the dichromate, although very much more slowly. After the decomposition, all the chromium is still present as chromate. This reaction may be explained by the fact that in solution, potassium chromate is partially dissociated into potassium dichromate and potassium hydroxide, the latter accelerating the decomposition.

Unlimited decomposition, the formation of an unstable intermediate compound, and the liberation of heat owing to the decomposition of some endothermic compound, are characteristic of all the so-called "actions of presence." C. H. B.

Phosphotungstic Acid. By C. H. Brandhorst and K. Kraut (*Annalen*, **249**, 373—380).—The sp. gr. at 20° of solutions of sodium phosphotungstate, $2Na_2O,P_2O_5,24WO_3 + 27H_2O$, is shown in the table (p. 470).

Phosphotungstic acid is obtained in the free state by adding to a solution of the acid sodium salt, in half its weight of water, one-tenth its volume of strong hydrochloric acid. The free acid is extracted from the mixture by ether free from alcohol. It can also be obtained by adding strong nitric acid to a solution of the sodium salt. The precipitate is redissolved in water, and reprecipitated by nitric acid

Percentage.	Sp. gr. crystallised salt.	Sp. gr. anhydrous salt.
5	1·04	1·044
10	1·084	1·092
15	1·131	1·143
20	1·181	1·199
30	1·299	1·333
50	1·64	1·734
64	1·998	—

three times. Finally it is recrystallised from a mixture of nitric acid and water. The crystals belong to the rhombic system, and contain 93 mols. H_2O, the formula being $48WO_3,2P_2O_5 + 93H_2O$. Acid sodium phosphotungstate dissolves precipitated barium carbonate, forming a crystalline salt of the composition

$Na_2O,2BaO,P_2O_5,24WO_3 + 46H_2O$. W. C. W.

Mineralogical Chemistry.

Pyrolusite from Augusta Co., Virginia. By J. L. JARMAN (*Amer. Chem. J.*, **11**, 39—40).—The larger portion of the ore of the Crimora mine consists of psilomelane, with about one-third as much pyrolusite. The following analysis was made of portions from a fine mass of the ore weighing upwards of 50 lbs. It consists of a network of fibrous crystals, closely matted; colour, grey; streak, black; H. = 2·7; sp. gr. 4·69; infusible—

J. W. L.

Beryllonite. By E. S. DANA and H. L. WELLS (*Amer. J. Sci.*, **37**, 23—32).—The authors give a more complete account of the new mineral recently described by E. S. Dana (this vol., p. 355). The first specimens were discovered in 1886 near Stoneham, Maine. The specimens are mostly fragments of crystals. Well-formed crystals are rare. Twins are common, the twinning plane being a prism of about 60°. The measured angles and optical characters conform to the orthorhombic system, the axial ratio being $a : b : c = 0·57243 : 1 : 0·54901$. The crystals are remarkable for the number of planes that they present. The mineral is colourless to white, and transparent. It has a hardness of 5·5 to 6, and a sp. gr. of 2·845.

An interesting feature is the presence of large numbers of liquid inclusions. In many of the cases, they are filled with water and liquid carbonic anhydride, and frequently also there is gaseous carbonic anhydride. Analysis gave the following results:—

P_2O_5.	BeO.	Na_2O.	Ignition.	Total.
55·86	19·84	23·64	0·08	99·42

It is thus evident that the mineral has the composition indicated by the formula $NaBePO_4$, a formula that is analogous to that of triphylite and lithiophilite. In form, the mineral seems to be related to herderite, the only other phosphate in which beryllium is known to exist. B. H. B.

Occurrence of Hanksite in California. By H. G. HANKS (*Amer. J. Sci.*, **37**, 63—66).—The author describes some magnificent crystals recently discovered at Borax Lake. He is of opinion that instead of being a rare mineral, hanksite will be found in great abundance, and will be proved to play an active part in the metamorphoses that produce gaylussite, thinolite, and perhaps borax. (Compare Abstr., 1886, 315). B. H. B.

Sperrylite, a New Mineral. By H. L. WELLS and S. L. PENFIELD (*Amer. J. Sci.*, **37**, 67—73).—This mineral is essentially an arsenide of platinum. It was found at the Vermilion mine, in the district of Algoma, Province of Ontario, Canada. The colour of the mineral is nearly tin-white, its hardness is between 6 and 7, and its sp. gr. is 10·602. Analysis gave the following results:—

As.	Sb.	Pt.	Rh.	Pd.	Fe.	SnO_2.	Total.
40·98	0·50	52·57	0·72	trace	0·07	4·62	99·46

The composition is consequently represented by the formula $PtAs_2$, a small portion of the platinum and arsenic being replaced respectively by rhodium and antimony. In composition, the mineral is nearer Wöhler's laurite, ($RuS_2 + \frac{1}{20}Ru_4O_5$), than any other mineral now known. It is possible that Wöhler's formula is slightly incorrect. The composition of the mineral corresponds with that of the artificial platinum arsenide made by Murray.

The crystalline form of sperrylite is shown by Penfield to be isometric. Simple cubes are common; octahedra are exceptional, whilst the majority of the crystals show combinations of the cube and octahedron. The mineral is named after F. L. Sperry, by whom the material for investigation was furnished. B. H. B.

Bertrandite from Pisek. By C. VRBA (*Zeit. Kryst. Min.*, **15**, 194—201).—On crystals of bertrandite from Pisek in Bohemia, the author has observed the following planes: $0P$, ∞P, $\infty\breve{P}\infty$, $\infty\bar{P}\infty$, $3\breve{P}\infty$, $2\breve{P}\infty$, $\infty\breve{P}3$, and $\frac{4}{9}\breve{P}\infty$; the last plane is new. The axial ratio is $a : b : c = 0·7191 : 1 : 0·4206$. The sp. gr. of the mineral was found to be 2·5986. Analysis gave the following results:—

SiO_2.	BeO.	H_2O.	Fe_2O_3.	Al_2O_3.	Total.
49·90	42·62	7·94	trace	trace	100·46

The formula therefore is $H_2Be_4Si_2O_9$. The analytical results are in accord with those obtained by Penfield (this vol., p, 24) in his examination of bertrandite from Colorado. B. H. B.

Composition of Tourmalin. By P. JANNASCH and G. CALB (*Ber.*, **22**, 216—221).—The analyses of the following samples of tourmalin are given below: I. Tourmalin from Snarum (black, sp. gr. at 22° = 3·134). II. Alabaschka (black, dark blue in thin layers, sp. gr. at 22° = 3·138). III. Piedra blanca (black, sp. gr. at 23° = 3·173). IV. Tamatawe (black, sp. gr. at 20·5° = 3·195). V. Mursinsk (black, sp. gr. at 20° = 3·210). VI. Ohlapian (black, sp. gr. at 25·3° = 3·084). VII. Buchworth (Australian, black, sp. gr. at 23·5° = 3·173). VIII. Barrado Perahy (Brazilian, green, sp. gr. at 23° = 3·029). IX. Brazilian (green):—

IX.	2·35	0·47	0·32	0·60	trace	3·18	3 23

From these analyses, the author deduces the general formula $R_9BO_2(SiO_4)_2$. A. J. G.

Minerals of the Pacific Coast. By W. LINDGREN (*Zeit. Kryst. Min.*, **15**, 333—334, from *Proc. California Acad. Sci.*, 1887).—A variety of chlorite, similar to koschubeite, occurs with chromite in the serpentine of the Green Valley in the American River cañon. It is of a blood-red colour, and is found in crusts of small, thin, hexagonal tablets, as well as in compact masses with a finely fibrous structure and a pale purple colour. Its hardness is 2, and sp. gr. 2·69. On analysis, it gave the following results:—

SiO_2.	Cr_2O_3.	Al_2O_3.	FeO.	NiO.	MgO.	CaO.	H_2O.	Total.
31·74	11·39	6·74	1·23	0·49	35·18	0·18	13·04	99·99

These figures prove the mineral to be similar to koschubeite. The high percentage of chromium is remarkable. Optically, the mineral is positive, with an axial angle of about 3°. Associated with this mineral is an emerald-green garnet in small dodecahedra exhibiting distinct double refraction. B. H. B.

New Mineral from Franklin, New Jersey. By G. A. König (*Zeit. Kryst. Min.*, **15**, 334, from *Proc. Acad. Nat. Sci. Philadelphia*, 1887, 310—311).—This new mineral, named *bementite* after C. S. Bement, forms pale greyish-yellow masses resembling pyrophyllite. Its sp. gr. is 2·981. Analysis gave the following results:—

SiO_2.	MnO.	FeO.	ZnO.	MgO.	H_2O.	Total.
39·00	42·12	(3·75)	2·86	3·83	8·44	100·00

B. H. B.

Spessartine. By W. C. Robinson (*Journ. Anal. Chem.*, **1**, 251).—The author has analysed two varieties of spessartine with the following results:—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	Total.	Sp. gr.
I.	38·24	19·62	2·27	13·60	25·30	0·53	99·56	4·23
II.	40·92	9·24	1·13	9·28	38·34	trace	99·01	4·12

I. From Fairmount Park, Philadelphia; II. From Avondale, Pennsylvania. B. H. B.

Iron Ores of the Penokee-Gogebic Series of Michigan and Wisconsin. By C. R. Van Hise (*Amer. J. Sci.*, **37**, 32—48).—The author describes at length the character of the iron ores, the shape of the deposits, their relation to the rocks surrounding them, the nature of the rocks of the iron formation above the ore horizon, and the character of the formation above and below bearing iron. The shape of the deposits and their relations to the strata of the iron-bearing formation are such as to exclude the idea of original sedimentation in place, and they cannot be considered as the result of oxidation of iron carbonate in place alone. It is, however, certain that the iron carbonates formed the source whence the iron oxides for the ores were derived. The ores are thus necessarily concentrations of iron oxide, combined, perhaps, with iron oxide furnished by oxidation of carbonate in place. These conclusions accord with those of S. F. Emmons as to the origin of the silver-lead deposits of Leadville, Colorado. He finds that the ore did not form in pre-existing cavities, but by a gradual displacement of the rock materials by substances brought in solutions, and that these solutions did not come from below but from above. A like origin is more common among ore-deposits than has been believed. B. H. B.

Rocks of Pigeon Point, Minnesota. By W. S. Bayley (*Amer. J. Sci.*, **37**, 54—63).—At Pigeon Point, a bright red rock occurs along the borders of a large mass of olivine gabbro that forms the main portion of the point. Similar rocks have been observed at various places in the Lake Superior region, but no careful study has been made of them. The author shows that this red rock is not an altered gabbro nor an altered sedimentary rock as hitherto thought, but is the result of the solidification of a magma, which, under certain conditions, gave rise to a rock with the characteristics of a granophyre. The various phases of the red rock possess the same mineralogical composition and present gradation in structure from the granular (analysis I) to the porphyritic (analysis II) with granophyric ground-mass.

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	BaO.	MgO.
I.	72·42	0·40	13·04	0·68	2·49	0·09	0·66	0·15	0·58
II.	74·00	0·34	12·04	0·78	2·61	0·05	0·85	0·12	0·42

	K_2O.	Na_2O.	H_2O.	P_2O_5.	Cl.	Total.	Sp. gr.
I.	4·97	3·44	1·21	0·20	trace	100·33*	2·620
II.	4·33	3·47	0·86	0·06	trace	99·93	2·565

The two rocks are obviously parts of the same mass. They both contain a sodium potassium felspar, and thus should be classed among the quartz-keratophyres. Upon the contact of the quartz-keratophyres with an olivine-gabbro, is a series of rocks having a composition intermediate between that of the keratophyre and that of the gabbro. These may be regarded as the results of contact action at great depths.

B. H. B.

Relation between Solfataras and Acidic Eruptive Rocks.

By A. de Lapparent (*Compt. rend.*, **108**, 149—151).—Solfataras are most abundant in volcanic districts which are characterised by the occurrence of acidic eruptive rocks in considerable masses. They are rare in the Sandwich Islands and in the neighbourhood of Vesuvius and Etna, where the rocks are mainly basic, but abound in the Chilian Andes, California, the district of the Yellowstone River, Java, and New Zealand, where the rocks are acidic.

There are no traces of solfataras in the Eifel and very few in Auvergne, but in Transylvania the solfataras which gave rise to the metalliferous deposits were formed in the midst of andesite, rhyolite, and other acidic rocks.

The solfataras seem to result from the gradual evolution of gases which were at one time incorporated with the lavas and are now being given off. Acidic rocks are very refractory, and by reason of their imperfect fluidity would retain to a very great extent the gases by which they were permeated at the time of eruption, and to which, as a matter of fact, their mobility is usually due. The presence of these gases in the lavas will retard the formation of crystals, and hence promote the growth of the large crystals which characterise this class of rocks.

Organic Chemistry.

Soluble Prussian Blue. By C. E. Guignet (*Compt. rend.*, **108**, 178—181).—Ordinary soluble prussian blue is a compound of prussian blue with potassium ferrocyanide. It is easily obtained by gradually adding to a boiling solution of 110 grams of potassium ferricyanide a hot solution of 70 parts of crystallised ferrous sulphate. The mixture is boiled for two hours, filtered, and the precipitate washed until the washings become dark blue. It is then dried at 100°, and has a fine deep-blue tint, and is very soluble in water. Admixed potassium ferrocyanide can be removed by washing with alcohol of 40 per cent. The compound is precipitated from its solution by sodium sulphate, sodium chloride, &c., but when the salts are removed by washing it redissolves. With salts of lead, zinc, and other metals, it yields, as Wyrouboff observed, a series of well-defined blue compounds.

Colloidal prussian blue was obtained by Graham by dialysis. Pure soluble prussian blue is obtained by suspending purified prussian blue in a saturated solution of oxalic acid, filtering, and allowing the mixture to remain for two months. Prussian blue is completely precipitated, and the liquid is quite colourless. After thorough washing with dilute alcohol, the precipitate is readily soluble in pure water. The same result is obtained in a very short time by precipitating the oxalic acid solution with strong alcohol or by a concentrated solution of sodium sulphate, and washing the precipitate with dilute alcohol. Ammonium oxalate or tartrate can be used instead of oxalic acid.

If the oxalic acid solution is boiled, insoluble prussian blue is precipitated, a result due to the action of the acid and not to the rise of temperature. Dilute sulphuric acid has the same effect at the ordinary temperature, and the precipitate does not dissolve even after long washing. The soluble and insoluble modifications have the same composition.

When prussian blue is heated with water and molybdic anhydride, it yields a deep-blue solution which is not affected by boiling or by gelatin. It is precipitated by sulphuric or nitric acid, but if the precipitate, which retains a small quantity of molybdic anhydride, is well washed with dilute alcohol, it dissolves in pure water. Ammonium molybdate and tungstate will also dissolve prussian blue.

When prussian blue is treated with concentrated sulphuric acid, it yields a soft, white mass like starch-paste, and if the temperature rises is partially decomposed. Hydroferrocyanic acid is liberated and partially dissolves in the excess of sulphuric acid. If the liquid is filtered through glass-wool and the filtrate cooled, it deposits the acid in long needles. The same result is obtained with lead or copper ferrocyanide.

If prussian blue which has been treated with sulphuric acid, is treated with absolute alcohol, it re-acquires its blue colour and dissolves in the alcohol. The same solution is obtained by dissolving solid prussian blue in a mixture of equal volumes of sulphuric acid and alcohol. When mixed with water or with a large excess of strong alcohol, the solution yields a precipitate of ordinary prussian blue, which retains sulphuric acid even after prolonged washing with dilute alcohol. Ethyl hydrogen sulphate does not dissolve prussian blue, and hence the phenomena just described cannot be attributed to the formation of this compound. C. H. B.

Relative Stability of the Alkyl Bromides. By F. LENGFELD (*Amer. Chem. J.*, **71**, 40—66).—The stability of alkyl bromides when in solution with various reagents has been determined.

With sodium hydroxide, potassium hydroxide, and ammonia, the relative stability is (in order of increasing stability), ethyl, propyl, butyl, isoamyl, isobutyl, isopropyl.

With nitric and sulphuric acids, the order of increasing stability is isopropyl, ethyl, propyl and butyl (about equal), isoamyl, isobutyl, ethylene.

With argentic nitrate and argentic nitrate and nitric acid, the order of increasing stability is isopropyl, ethyl, propyl, isoamyl, isobutyl, ethylene.

Experiments carried out on the influence of light on the stability of alkyl bromides in contact with sodium hydroxide showed that it was without influence on the result.

With dilute sodium hydroxide, *n*/40 and less, the velocity of changes is inversely as the concentration.

The action of sodium hydroxide on the bromides dissolved in methyl alcohol is slower than in propyl alcohol, and slower in propyl than in ethyl alcohol.

In the case of excess of one reagent over another, similar effects are produced by similar excess of ether reagent. J. W. L.

Analyses of Pure Sherry. By E. BORGMANN and W. FRESENIUS (*Zeit. anal. Chem.*, **28**, 71—77).—The authors, having obtained 18 samples of genuine sherry of various qualities, have analysed them by recognised methods and give the results in a table. The chief feature worthy of notice is the high percentage of sulphates. The universal practice of plastering the must for the manufacture of sherry renders it necessary to adopt for that wine an admissible maximum different from that allowed in unplastered wines. The sulphates found (calculated as potassium sulphate) ranged from 2·5—8·8 grams per litre. The superior brands (with two exceptions) contained more than 4 grams, and the inferior (with one exception) less than 3 grams per litre. The maximum limit of 3 grams proposed by the German Imperial Commission would exclude the finer wines of this class. Plastering increases the proportion of potassium in the wine, but not that of calcium. Phosphoric acid, chlorine, and magnesium appear to rise with increasing sulphates. In most of the samples, a deposition of tartar occurred on keeping. This fact is of interest in connection with the dictum of Blitz, that in judging of a wine containing much sulphates, it is necessary to consider whether at the same time a sufficient amount of hydrogen potassium tartrate is present.

M. J. S.

Boiling Points of Secondary Alcohols with Secondary Radicles: Diisopropyl Carbinol. By G. POLETEÉFF (*J. Russ. Chem. Soc.*, **20**, 672—686).—The author finds that the boiling point of diisopropyl carbinol, as given by Münch (*Annalen*, 180, 331), that is, 131·5°, does not agree with Flavitzky's (*J. Russ. Chem. Soc.*, 1871, 815, and 1887, 369) method of calculating boiling points, and that a higher number might be expected. He very carefully prepared the pure carbinol and determined its physical constants and those of other compounds formed during its preparation. The calcium salt of isobutyric acid was subjected to dry distillation, and *diisopropyl ketone*, $C_7H_{14}O$, was obtained. Its (corrected) boiling point was found to be 123·7°, the sp. gr. = 0·8230 at 0° and 0·8063 at 20° (water at 4° = 1). The molecular refractive power = 55·03—55·24 (calculated 55·37), or for infinite wave-length = 33·46 (calculated 33·58). On reduction with sodium amalgam of 3 per cent., it yields *diisopropyl carbinol*, $C_7H_{16}O$, boiling at 140° (corr.), having the sp. gr. 0·8445 at 0° and 0·8288 at 20°, and the molecular refractive power = 57·64 (calculated 57·37), or for infinite wave-length = 34·82 (calculated 34·89). The *acetate* boils at 160° (corr.), and has the sp. gr. 0·8856 at 0° and 0·8676 at 20·5°. From this, after hydrolysis, the original alcohol was obtained boiling at 140·4°. On oxidation with chromic mixture, the alcohol yields diisopropyl ketone, isobutyric acid, acetone, and some acetic acid (formed from the last). It is shown that the correct boiling point of diisopropyl carbinol, 140°, is in better accord with Flavitzky's theory than that obtained by Münch, namely, 131·5°. B. B.

Butyl Ethers. By E. REBOUL (*Compt. rend.*, **108**, 162—165; compare this vol., p. 366).—*Diisobutyl ether*, $O(CH_2{\cdot}CHMe_2)_2$, is readily obtained by the action of isobutyl bromide on the sodium-derivative of isobutyl alcohol. It is a mobile liquid only slightly soluble in water, and boils at 122—122·5° under a pressure of 760 mm.; sp. gr. at 15° = 0·7616. Concentrated hydrobromic acid converts it into isobutyl bromide boiling at 90—91°. The product of the action of isobutyl iodide on potassium isobutyl-oxide, which was believed to contain diisobutyl ether, is really a mixture of isodibutylene and isobutyl alcohol in nearly equivalent proportions.

Secondary isobutyl ether, $CHMe_2{\cdot}CH_2{\cdot}O{\cdot}CHMe{\cdot}CH_2Me$, is formed, together with isobutylene and the secondary alcohol, by the action of isobutyl bromide on the sodium-derivative of the secondary alcohol. It is insoluble in water and boils at 121—122; sp. gr. at 15° = 0·7652. Hydrobromic acid resolves it into isobutyl bromide and secondary butyl bromide.

Tertiary isobutyl ether cannot be obtained by the action of isobutyl bromide on the sodium-derivative of trimethyl carbinol, nor by the action of tertiary butyl bromide on sodium isobutyl oxide. *Disecondary butyl ether* is obtained in mere traces by the action of the secondary bromide on the sodium-derivative of the secondary alcohol, but the product consists mainly of the secondary alcohol and normal butylene. Secondary tertiary and ditertiary butyl ethers could not be obtained. C. H. B.

Oxidation of Glycerol. By E. Fischer and J. Tafel (*Ber.*, **22**, 106–110; compare Abstr., 1888, 1264).—*Trihydroxyisobutyric acid*, $OH\cdot C(CH_2\cdot OH)_2\cdot COOH$, is obtained when glycerose (250 grams) is mixed with anhydrous hydrocyanic acid (30 grams) and allowed to remain for 12 hours at 50° and a second 12 hours at 60° in a well-closed vessel. After the removal of the excess of hydrocyanic acid, the product is concentrated to 150 c.c., saturated with hydrogen chloride in a freezing mixture, and allowed to remain two days at the ordinary temperature. It crystallises from alcohol in slender, colourless prisms, melts at 116°, and is readily soluble in water, sparingly soluble in alcohol, and almost insoluble in ether, benzene, and chloroform. The *calcium* salt, with 4 mols. H_2O, crystallises in slender, matted needles; the *lead* salt, with 1 mol. H_2O, crystallises in slender, colourless prisms; the normal *barium* salt could not be crystallised; the basic *barium* salt, $C_4H_6O_5Ba$, is precipitated from a hot solution of the acid in slender needles; the *strontium* salt crystallises in slender needles; the *sodium* salt in prisms. On reduction with hydriodic acid and amorphous phosphorus in a reflux apparatus, trihydroxyisobutyric acid is converted into a mixture of acids containing iodine, and these, by further reduction with zinc-dust and dilute sulphuric acid, yield isobutyric acid.

Diiodoisobutyric acid, $C_4H_6O_2I_2$, can be extracted by ether from the product obtained on reducing trihydroxyisobutyric acid with hydriodic acid and amorphous phosphorus. It crystallises from water in long, colourless needles, melts at 127°, and is very readily soluble in alcohol and ether.

In addition to trihydroxyisobutyric acid, a small yield of erythroglucic acid is also obtained on treating glycerose with concentrated hydrocyanic acid. W. P. W.

Extraction of Sorbite. By C. Vincent and Delachanal (*Compt. rend.*, **108**, 147—148).—The fermented juice of *Sorbus aucuparia* is concentrated in a vacuum to one-third of its volume, and 10 grams are heated with excess of sulphuric acid, evaporated to dryness, the residue calcined, and the combined sulphuric acid estimated. The amount of sulphuric acid required to convert into sulphates all the bases in the juice is calculated from this result, and this quantity of acid is added to the concentrated juice, which is then diluted with its own volume of water and twice the volume of alcohol. The calcium and potassium, which interfere with the crystallisation of sorbite, are thus almost completely precipitated in the form of sulphates. The liquid is filtered, the alcohol distilled off, and the residue exactly neutralised with barium hydroxide, evaporated to a syrup, and extracted with boiling alcohol of 95°, which dissolves almost pure sorbite, and leaves in combination with the barium the viscous acid substances which usually interfere greatly with crystallisation. When the alcoholic solution is concentrated, it leaves a syrup which after a few days deposits a large quantity of sorbite in long needles.

Sorbite may be estimated in the form of dibenzoic acetal (following Abstract) in the following manner. The juice is concentrated in a vacuum to one-third its volume, mixed with excess of basic lead acetate, and the filtrate treated with hydrogen sulphide. The filtered liquid is concentrated in a vacuum to a thick syrup, mixed with its own weight of 50 per cent. sulphuric acid, and then with 80 per cent. of benzaldehyde. It rapidly becomes almost solid, owing to the formation of the acetal, which after 24 hours is thoroughly washed with water, dried, and weighed.

In order to separate sorbite from the acetal, the latter is heated with water which contains a few per cents. of sulphuric acid and benzaldehyde, and the liberated benzaldehyde is distilled off in a current of steam. The liquid is then treated with barium hydroxide to precipitate the sulphuric acid, and the barium present in the filtrate in the form of barium benzoate is exactly precipitated by addition of sulphuric acid. The liquid is then cooled, treated with ether in order to remove benzoic acid, and concentrated in a vacuum to a thick syrup, which after some days deposits crystals of sorbite.

C. H. B.

Dibenzoic Acetal of Sorbite. By J. MEUNIER (*Compt. rend.*, **108**, 148—149).—Sorbite when treated with benzaldehyde in presence of sulphuric or hydrochloric acid yields a dibenzoic acetal, $C_{20}H_{22}O_6$, which resembles the dibenzoic acetal of mannitol in constitution and properties. It is a white, confusedly crystalline substance, which melts at about 160°, is insoluble in water and almost insoluble in hot alcohol, but dissolves more readily in boiling benzene, chloroform, and acetic acid.

C. H. B.

Invert Sugar. By E. JUNGFLEISCH and L. GRIMBERT (*Compt. rend.*, **108**, 144—146; compare Abstr., 1888, 1266).—The rotatory power of pure levulose does not agree with that calculated for levulose from measurements with invert sugar, using Tuchschmid's and Tollens' formulæ, and assuming that invert sugar contains dextrose and levulose in equal molecular proportions. The rotatory power of pure levulose is not altered by admixture with pure glucose, and the authors find that the observed differences are due to the action on the levulose of the acids which are used to produce inversion.

The rotatory power of a 10 per cent. solution of pure levulose increases from $[\alpha]_D = -94° 66'$ to $-96° 78'$ when heated for half an hour at 68° with 5 per cent. of hydrochloric acid. With a similar quantity of sulphuric acid, under the same conditions, the rotatory power rises to $-99° 77'$. There is no sensible variation in the results when the liquid is neutralised before the measurements are made. The action of strong inorganic acids on levulose takes place at once at the ordinary temperature, oxalic acid behaves like the inorganic acids when heated, whilst formic and acetic acids of similar concentration do not affect the levulose. The rotatory power of glucose shows no variations of this kind.

The duration of the action of the acids used for inversion has long been known to affect the rotatory power of the product.

Comparative experiments with levulose and invert sugar under the conditions described show that the rotatory power of the levulose in the invert sugar, $[\alpha]_D = -96° 52'$, agrees with that of pure levulose which has been subjected to the same treatment, $[\alpha]_D = -96° 78'$. Clerget's method of inversion by treating with 10 per cent. of hydrochloric acid at 68° for 10 minutes, gives a levulose with a rotatory power of $[\alpha]_D = -101° 30'$, whilst pure levulose treated in the same way has a rotatory power of only $[\alpha]_D = -97° 44'$, which is practically the same as that obtained by treating levulose with hydrochloric acid in the cold.

That these differences are due to the action of the inorganic acids is shown by the fact that if sugar is inverted by treatment with 5 per cent. of acetic or formic acid at 100° for 30 minutes, the rotatory power remains constant even after prolonged heating, and the rotatory power of the levulose which the product contains is identical with that of pure levulose. Addition of hydrochloric acid to this product at once alters the rotatory power of the levulose.

It is evident that the levulose contained in invert sugar which has been prepared in the usual way is not identical with pure crystallised levulose, but is a product of the alteration of the latter by the action of the mineral acids employed. C. H. B.

Fermentation of Galactose, Arabinose, Sorbose, and other Sugars. By W. E. Stone and B. Tollens (*Annalen*, **249**, 257—272).—Most of the results obtained by the authors have already been published (Abstr., 1888, 808). With yeast supplied with suitable nourishment, galactose ferments as completely as dextrose, but less rapidly. Sorbose ferments more slowly and less completely. Arabinose and milk-sugar ferment very slowly and incompletely. Pure yeast does not bring about the fermentation of arabinose.

W. C. W.

Formation of Furfuraldehyde and Non-production of Levulinic Acid from Arabinose: Formation of Furfuraldehyde as a Test for Arabinose: Formation of Arabinose and Xylose from Malt Residues. By W. E. Stone and B. Tollens (*Annalen*, **249**, 227—245).—In addition to the results which have already been published (Abstr., 1888, 1060), the authors have obtained arabinose and xylose from the malt which has been used for brewing. Furfuraldehyde is formed when xylose is boiled with dilute acids.

W. C. W.

Mannose. By E. Fischer and J. Hirschberger (*Ber.*, **22**, 365—376).—The authors have simplified their method for the preparation of mannose (compare Abstr., 1888, 934) as follows:—Mannitol (3 kilos.) is heated at 40—45° with water (20 litres) and nitric acid of sp. gr. 1·41 (10 litres) with constant stirring. In four to five hours, evolution of gas commences, and, as soon as it is found that a small portion of the solution, after neutralising with sodium carbonate, gives a dense, yellowish precipitate with phenylhydrazine acetate, which is generally the case after five to six hours, the operation is brought to an end. The liquid is cooled to about 25° by throwing in ice, then made slightly alkaline with solid sodium carbonate to destroy the nitrous acid, and finally acidified with acetic acid. Phenylhydrazine (1 kilo.), dissolved in dilute acetic acid, is added to the solution, and after an hour's time the separated hydrazone is washed and pressed. About one-quarter of the product is boiled for about 15 minutes with water (5 litres), the filtered solution decolorised by heating with zinc-dust and ammonia, and again filtered; the hydrazone separates in pale yellow plates, and the mother-liquors are employed for recrystallising another portion of the crude product, this process being repeated six or seven times until the whole is purified. The yield of hydrazone is, on the average, 10 per cent. of the mannitol employed.

The pure hydrazone (100 grams) is dissolved in hydrochloric acid of sp. gr. 1·19 (400 grams), and, after keeping for half an hour, the solution is cooled in a freezing mixture, and the crystals separated by filtration. The filtrate is diluted with water (2 vols.), neutralised with lead carbonate, and filtered; the yellow solution is made alkaline with baryta, extracted with ether to remove phenylhydrazine and coloured products, then treated with carbonic anhydride, decolorised with animal charcoal, and concentrated to about 300 c.c. The residue is treated with sulphuric acid to precipitate the barium, neutralised with lead carbonate, filtered, evaporated in a partial vacuum, and again filtered. The filtrate is evaporated to a syrupy consistency, dissolved in absolute alcohol (5 vols.), treated with hydrogen sulphide, and, after separating the lead sulphide, the mannose is precipitated by adding a large volume of ether. It is thus obtained in the form of a colourless syrup containing about 90 per cent. of sugar. 100 grams of the hydrazone yield 60 grams of the syrup.

Mannose is precipitated in amorphous, white flocks when ether is added to an alcoholic solution of the syrup; on keeping under absolute alcohol, the precipitate solidifies to a hard, colourless mass which, however, shows no distinctly crystalline structure. It is hygroscopic, deliquescent, and very readily soluble in water, but very sparingly in boiling absolute alcohol, and insoluble in ether. It does not produce a coloration in the magenta and sulphurous anhydride solution. Alcoholic potash precipitates a flocculent, hygroscopic substance from alcoholic solutions of the sugar; lead acetate and ammonia produce in aqueous solutions a precipitate which becomes yellow on keeping, or when warmed. The specific rotatory power is $[\alpha]_D = 12·96$, and 1 c.c. of Fehling's solution corresponds with 4·307 milligrams of mannose. The quantity of mannose present in the solutions employed for the determination of the rotatory power and reducing power was estimated by means of the phenylhydrazone; as, however, this compound is not quite insoluble in water, there is a slight error in both determinations. Cane-sugar, maltose, raffinose, trehalose, various kinds of molasses, manna, potato-starch, lichenin, gum tragacanth, gum arabic, quince seeds, linseed, fleabane, and Carragheen moss were tested for mannose, but in no case could the presence of this sugar be detected. Salep juice, however, as previously stated by Tollens and Gans, on inverting, yields mannose which can be isolated by means of the hydrazone. The yield of hydrazone is 5 to 6 per cent. of the bulbs employed.

When a dilute solution of mannose is heated at 110° for about four hours, humous substances are formed, and on distilling the filtered solution it yields furfuraldehyde.

Levulinic acid is formed, together with humous substances, when mannose phenylhydrazone is heated with fuming hydrochloric acid.

When mannose (0·25 gram) is heated for three hours with 7·5 per cent. hydrochloric acid (32 c.c.), small quantities of humous substances are formed, but only 0·07 gram of the mannose is decomposed. (Compare Sieben, *Zeit. anal. Chem.*, **24**, 138.)

Mannose (50 grams) dissolved in water (250 grams) was mixed with anhydrous hydrogen cyanide (18 c.c.) and a few drops of ammonia, and kept in a closed vessel at the ordinary temperature; a flocculent substance soon separates, and after three days the reaction is brought to an end by warming at 50° for four hours. The flocculent product seems, from its behaviour towards alkalis and iron salts, to be the amide of mannosecarboxylic acid; it is insoluble in hot water, and, after decolorising with animal charcoal, alcohol precipitates from the solution a white, amorphous powder melting at 182—183° with decomposition. The filtrate from this amide contains considerable quantities of the ammonium salt of the acid.

Barium mannosecarboxylate, $(C_7H_{13}O_8)_2Ba$, is prepared by evaporating the crude product of the action of hydrogen cyanide on mannose until free from hydrogen cyanide, adding water and baryta (80 grams), and again evaporating until the evolution of ammonia ceases. The residue is dissolved in water (4 litres), carbonic anhydride passed through it, the solution decolorised with animal charcoal, and evaporated until the barium salt commences to separate; further small quantities can be obtained by mixing the mother-liquor with alcohol and ether. The yield is almost theoretical. It is a colourless, semicrystalline compound, and is moderately soluble in hot water, but only very sparingly in cold water, and insoluble in alcohol.

The *lactone*, $C_7H_{12}O_7$, is obtained when a hot, aqueous solution of the barium salt is decomposed with the requisite quantity of sulphuric acid. It crystallises in needles, melts at 148—150°, and is very readily soluble in water, but only moderately in absolute alcohol, and insoluble in ether.

A second product, probably *mannosecarboxylic acid*, was sometimes obtained in small quantities in preparing the lactone; this substance has an acid reaction, melts at 167—169° with evolution of gas, and is more readily soluble in alcohol than the lactone.

Heptylic acid (normal) is formed when barium mannosecarboxylate (35 grams) is boiled for five hours with hydriodic acid boiling at 127° (250 grams) and amorphous phosphorus (10 grams). The product is diluted with water, extracted with ether, and the extract shaken with mercury to remove iodine. The oil (27 grams) which is obtained on evaporation is treated in the cold with zinc-dust and dilute sulphuric acid to reduce the iodine-compounds, which are present in considerable quantities, and then distilled with steam. The distillate contains heptylic acid (= 7 grams barium salt) and a neutral oil (2 grams) probably heptolactone.

Mannose is readily oxidised by bromine in aqueous solution; the acid obtained seems to be different from gluconic acid. It is also oxidised by nitric acid, but the acid has not yet been investigated.

The compound described as phenylmannosazone (*loc. cit.*) is identical with phenylglucosazone.

From the authors' experiments, it follows that mannose is the aldehyde of mannitol, and has, therefore, the same constitution as dextrose, with which it is physically isomeric. Since the phenylhydrazones of mannose and dextrose are totally distinct substances, both of which are readily converted into one and the same osazone, $N_2HPh\cdot CH\cdot C(N_2HPh)\cdot [CH\cdot OH]_3\cdot CH_2\cdot OH$, it must be assumed that the isomerism of the two sugars is determined by the carbon-atom which is directly combined with the aldehyde-group. As dextrose has a much greater specific rotatory power than mannose, the former must be looked on as the dextro-, the latter as the lævo-modification of the same system. The compounds which these sugars form with hydrogen cyanide are isomeric, as, probably, are also the corresponding carboxylic acids; as both sugars yield one and the same compound on reduction, some change must occur in the arrangement in space of the $COH\cdot CH\cdot (OH)$-group. The difference in behaviour on reduction seems to show that mannose, in its physical as well as chemical structure, is the true aldehyde of mannitol, whilst dextrose is the aldehyde of a physically isomeric hexahydric alcohol. F. S. K.

Formation of Acrose from Formaldehyde. By E. Fischer and F. Passmore (*Ber.*, **22**, 359—361).—Formose (compare Löw, *J. pr. Chem.*, **33**, 321), as the authors have previously shown, is a mixture of various aldehyde- and ketone-alcohols, which can be separated by means of the osazones.

Pure α-acrosazone can be isolated as follows:—Formaldehyde (100 grams) in 3 per cent. aqueous solution is first treated as described by Löw, the solution is then neutralised with acetic acid, and warmed on the water-bath for four hours with a mixture of phenylhydrazine (100 grams) and 50 per cent. acetic acid (100 grams). The cold solution is filtered, and the residual mixture of osazones dried on porous plates, and then extracted several times, first with cold benzene, and then with ether, to remove resinous products and the more readily soluble osazones. The dirty yellow, crystalline residue (20 grams) is extracted with water (6 litres) to remove phenylformosazone, washed twice with cold, absolute alcohol (10 c.c.), and then boiled twice for a long time with alcohol (10 c.c.). α-Acrosazone (1·1 gram) remains as a yellowish-green powder, and cannot be purified by recrystallisation. It is therefore converted into the osone by warming for one minute at 45° with fuming hydrochloric acid; the cold solution is separated from the phenylhydrazine salt, diluted with water (5 vols.), neutralised with lead carbonate, and filtered. The filtrate is warmed with phenylhydrazine acetate, and the osazone which is formed is obtained pure by recrystallising from a large quantity of hot alcohol. The compound thus prepared has all the properties of α-acrosazone.

The fact that acrose is very nearly related to the naturally occurring saccharoses lends considerable probability to Baeyer's views concerning the formation of grape-sugar in the vegetable kingdom.

F. S. K.

Compounds of Phenylhydrazine with Sugars. By E. FISCHER (*Ber.*, **22**, 87—89; compare Abstr., 1888, 1267).—The author proposes "osone" as a general term for compounds of the type of oxyglucose, and throughout the paper refers to this compound as glucosone.

Glucosone reacts with methylphenylhydrazine in alcoholic solution in the cold, forming *glucosone methylphenylhydrazone*,

$$C_6H_{10}O_5:N{\cdot}NMePh,$$

which crystallises from water in slender, colourless scales, and melts at 171° when rapidly heated; with an excess of the hydrazine in acetic acid solution, however, *methylphenylglucosazone*, $C_{20}H_{26}N_4O_4$, is obtained, and this crystallises from benzene in slender, yellowish-red needles melting at 152° with decomposition. When treated in aqueous solution with solutions of orthodiamines free from acids, glucosone readily yields condensation compounds; thus, with orthotoluylenediamine, it forms *anhydroglucometaparadiamidotoluene*, $C_{13}H_{16}N_2O_4$, which crystallises in colourless, slender needles and melts at a few degrees above 180° with decomposition (compare Griess and Harrow, Abstr., 1887, 930).

Glucosone decomposes into a mixture of humous substances and furfuraldehyde when heated in dilute aqueous solution at 140° for several hours, and into humous substances, carbonic anhydride, and a small quantity of levulinic acid when heated with hydrochloric acid. It is readily reduced by means of zinc-dust and acetic acid at 100°, and is thereby converted into levulose.

Galactosone and *rhamnosone* have been prepared from galactose and rhamnose (isodulcitol) by methods similar to that adopted for the preparation of glucosone. W. P. W.

Synthetical Experiments in the Sugar-group. By E. FISCHER and J. TAFEL (*Ber.*, **22**, 97—101; compare Abstr., 1888, 358).—*α-Acrosone* is obtained when α-acrosazone is rapidly heated to 45° with 20 times its weight of fuming hydrochloric acid (sp. gr. = 1·19), maintained for one minute at this temperature until phenylhydrazine hydrochloride begins to crystallise out, then rapidly cooled to 25° and kept at this temperature for 5 to 10 minutes until the reaction is complete. The product is purified by the method employed in the case of glucosone (oxyglucose) (Abstr., 1888, 1267), and the yield amounts to about 50 per cent. of that theoretically possible. It is a colourless syrup, which solidifies in the cold to a hard, amorphous mass, and in dilute aqueous solution reacts with phenylhydrazine acetate in the cold, forming α-acrosazone. On treatment with orthotoluylenediamine, α-acrosone is converted into a compound, which crystallises in slender needles, becomes brown at 180° and melts at 185° with decomposition, thus closely resembling anhydroglucometaparadiamidotoluene (compare preceding Abstract). When heated in aqueous solution for several hours at 140°, α-acrosone decomposes into humous substances and furfuraldehyde, and when heated with 18 per cent. hydrochloric acid at 100° for six hours it decomposes into humous substances and a small quantity (2½ per cent.) of levulinic acid.

α-Acrose, $C_6H_{12}O_6$, is formed by heating α-acrosone in dilute aqueous solution at 100° with zinc-dust and acetic acid. When the reduction is complete, the solution is freed from zinc by means of hydrogen sulphide, evaporated to dryness in a vacuum, and the residue extracted with absolute alcohol, the concentrated alcoholic solution being finally precipitated by ether. α-Acrose is a sweet syrup which reduces Fehling's solution, yields α-acrosazone on treatment with phenylhydrazine acetate at 100°, and is fermentable by yeast. On reduction with sodium amalgam, it is converted into *acritol*, $C_6H_{14}O_6$, which crystallises in spherical aggregates of thin plates, melts at 164—165°, has a sweet taste, does not reduce alkaline copper solution, is readily soluble in water, very sparingly soluble in alcohol, and, in short, differs only from mannitol in being optically inactive. W. P. W.

Rhamnodiazine. By B. Raýmann and K. Chodoůnský (*Ber.*, **22**, 304—305).—Rhamnodiazine, $C_{18}H_{32}O_8N_2$, is formed when rhamnose is treated with ammonia and ethyl acetoacetate (2 mols.) at the ordinary temperature in methyl alcohol solution. It separates after a few days in long, soft needles, and is purified by recrystallising first from alcohol and then from hot water. It melts at 186° and is decomposed when heated more strongly; it is soluble in alcohol and hot water, but only sparingly so in chloroform, and insoluble in ether, light petroleum, and carbon bisulphide. It dissolves in large quantities in glacial acetic acid, with which it probably combines; the compound is, however, unstable, as rhamnose crystallises from the solution after a short time. It reduces Fehling's solution and a neutral solution of silver nitrate very readily, but ammoniacal silver nitrate solution is only very slightly acted on.

Other glucoses seem to yield similar compounds when treated with ethyl acetoacetate or ketones and ammonia as described above; these substances are not easily obtained in crystals. F. S. K.

Oxidation of Milk-sugar. By E. Fischer and J. Meyer (*Ber.*, **22**, 361—364).—*Lactobionic acid*, $C_{12}H_{22}O_{12}$, is obtained when milk-sugar (1 part) dissolved in water (7 parts) is treated with bromine (1 part) at the ordinary temperature, the mixture being frequently shaken. The bromine dissolves in the course of one to two days and, after keeping for another 48 hours, a stream of air is passed through the solution to drive off most of the free bromine, the remainder being converted into hydrobromic acid by passing hydrogen sulphide into the cooled solution. The quantity of hydrobromic acid present having been ascertained by titrating a portion of the solution with silver nitrate, the calculated quantity of lead carbonate is added, and the hydrobromic acid remaining in the filtered solution is carefully precipitated with silver oxide. The solution is filtered, treated with hydrogen sulphide, and the filtrate evaporated. The acid, syrupy liquid thus obtained is agitated for a long time with large quantities of cold glacial acetic acid to remove reducing substances and other products, the colourless residue, the weight of which is about one-third that of the lactose employed, is dissolved in water and the warm solution precipitated with a hot, concentrated solution of basic lead acetate. The solution of basic lead acetate is prepared by dissolving the neutral salt (2 parts) and lead hydroxide (1 part) in hot water (3 parts) and dissolving the crystals, which separate on cooling, in pure, hot water. The precipitated lead salt is quickly separated by filtration, washed with hot water, and then suspended in cold water and decomposed with hydrogen sulphide. The filtrate is evaporated on a water-bath in a partial vacuum, the residue treated with alcohol and ether to remove acetic acid, and finally dissolved in a small quantity of water and reprecipitated with alcohol and ether.

Lactobionic acid is a colourless, strongly acid syrup, and is very readily soluble in water but only very sparingly in alcohol and cold glacial acetic acid, and is insoluble in ether. It decomposes carbonates, but does not reduce Fehling's solution even on boiling. The *calcium*, $(C_{12}H_{21}O_{12})_2Ca$, *barium*, $(C_{12}H_{21}O_{12})_2Ba$, *cadmium*, and *lead* salts were prepared by warming an aqueous solution of the acid with the corresponding carbonate; they are all insoluble in alcohol, but readily soluble in water excepting the basic lead salt. On evaporating the aqueous solution over sulphuric acid, the salts are obtained in the form of syrups which gradually solidify but do not clearly show a crystalline structure.

Lactobionic acid is decomposed into galactose and gluconic acid when warmed with dilute mineral acids. The pure acid was heated at 100° for an hour with 5 per cent. sulphuric acid; the gluconic acid was then isolated by means of the barium salt, and identified by converting it into the calcium salt (Kiliani, *Annalen*, **205**, 184). The filtrate was evaporated, and the galactose, which crystallised from the solution, identified by converting into the osazone.

The formation and decomposition of lactobionic acid confirm Fischer's conclusions (Abstr., 1888, 1267) with regard to the constitution of milk-sugar.

An acid, isomeric with lactobionic acid, can most probably be obtained from maltose by the process described above; this compound, on inverting, should yield gluconic acid and dextrose. F. S. K.

Derivatives of Trimethylenediamine. By S. Gabriel (*Ber.*, **22**, 224—226).—β-Hydroxytrimethylenediphthalimide (Goedeckemeyer, Abstr., 1888, 1294) is best prepared by heating an intimate mixture of α-dichlorhydrin (13 grams) and potassium phthalimide (37 grams) at 140—150°; as soon as the reaction commences, the mixture is cooled to about 100° and finally heated at about 160—180° for half an hour. The crude product is recrystallised from acetic acid, and washed first with dilute alcohol and then with water. The yield is 50 per cent. of the theoretical quantity. When β-hydroxytrimethylenediphthalimide is heated at 200° with concentrated hydrochloric acid, it yields hydroxytrimethylenediamine hydrochloride, and when treated in like manner with hydrobromic acid of sp. gr. 1·49, it is converted into the corresponding hydrobromide.

β-Bromotrimethylenediamine hydrobromide, $CHBr(CH_2{\cdot}NH_2)_2,2HBr$, is obtained when the preceding compound (15 grams) is heated for four hours at 200—210° with hydrobromic acid (45 c.c.) saturated at 0°; the product is dissolved in cold water, the filtered solution

evaporated to dryness, and the residue recrystallised from dilute alcohol. It crystallises in plates, decomposes at 210—215°, and is readily soluble in water but sparingly so or insoluble in absolute alcohol. The *picrate*, $C_3H_9BrN_2,2C_6H_3N_3O_7$, melts at 215—217° with previous softening, and is soluble in hot water. The *aurochloride*, $C_3H_9BrN_2,2HAuCl_4$, crystallises in plates. The *platinochloride*, $C_3H_9BrN_2,H_2PtCl_6$, crystallises in orange-yellow plates. The *ferrocyanide*, $(C_3H_9BrN_2)_2,H_4Fe(CN)_6$, is a colourless, granular, crystalline salt.
F. S. K.

Action of Sulphurous Anhydride on Tiglic Aldehyde. By F. H. HAYMANN (*Monatsh.*, **9**, 1055—1066; compare Abstr., 1883, 570, and this vol., p. 121).—Excess of sulphurous anhydride was passed into water (50 c.c.) containing tiglic aldehyde (5 grams); the mixture being kept cool by means of ice. The saturated solution was placed in a closely stoppered bottle, well shaken and allowed to remain for three hours at the ordinary temperature, when the solution was neutralised in the cold with barium carbonate; on concentration in a vacuum at a temperature not above 35°, a quantity of barium sulphite separated, and on further concentration, a gummy mass remained, which consisted of a mixture of barium hydroxypentanedisulphonate and barium valeraldehydesulphonate. When the saturated solution was heated in sealed tubes for four hours at 65°, and then treated in a way similar to that above mentioned, the same results were obtained. Hydroxypentanedisulphonate was, however, completely converted into the mono-acid when heated at 100°.

On reduction with sodium amalgam in a solution always containing a small quantity of uncombined sulphuric acid, both valeraldehydesulphonic acid and hydroxypentanedisulphonic acid gave hydroxypentanesulphonic acid, $SO_3H{\cdot}CMeEt{\cdot}CH_2{\cdot}OH$, the latter with formation of sulphurous anhydride. On heating with lime, sodium hydroxypentanesulphonate yielded a mixture of tiglyl alcohol and methylethylcarbin carbinol, $CHMeEt{\cdot}CH_2{\cdot}OH$; whilst sulphovaleric acid was formed on oxidation with bromine-water.
G. T. M.

Metacetone. By E. FISCHER and W. J. LAYCOCK (*Ber.*, **22**, 101—105).—By distilling sugar with lime, Fremy obtained a compound boiling at 84°, which he termed metacetone, and to which he ascribed the formula $C_6H_{10}O$. An examination of the products obtained by distilling sugar with lime under the conditions described by Gottlieb (*Annalen*, **52**, 127) shows that metacetone does not exist, and that Fremy's substance is a mixture of propaldehyde, dimethylfurfuran, and a third hydrocarbon-like compound.

When sugar is distilled with three times its weight of lime, a distillate is obtained which separates into an aqueous and an oily layer. The aqueous layer contains much acetone. The oily layer can be separated into two fractions boiling at 30—115° and 115—280° respectively. The compounds contained in the first fraction were recognised by the hydrazones obtained by treating it with phenylhydrazine, and they comprised acetone, hydrocarbons, and further propaldehyde, dimethylfurfuran, and probably higher and lower homologues of these.

An examination of the "light oil" from wood-tar shows that propaldehyde and dimethylfurfuran are present. W. P. W.

Chlorocrotonic Acids. By A. KOLL (*Annalen*, **249**, 303—326). —By the action of phosphorus pentachloride on the ethylic salt of methylacetoacetic acid, Isbert (Abstr., 1886, 1010) obtained a mixture of ethyl mono- and di-chloromethylacetoacetates and α-methyl-β-chlorotetracrylic acid. The author finds that the yield of acid is considerably increased by adding the ethyl salt of methylacetoacetic acid to an excess of phosphorus pentachloride, warming the mixture at 70°, and when cold, pouring the product into water. *Methyl α-methyl-β-chlorotetracrylate* is a mobile liquid boiling at 158·5° (corr.), sp. gr. 1·131 at 15°. The ethyl, propyl, and isobutyl salts boil respectively at 171—172°, 189—190°, and 201—202°. The copper salt is not crystalline. The ethyl salt is decomposed by a strong solution of potassium hydroxide, yielding alcohol and ethyl methyl ketone. Methyl α-methyl-β-chlorotetracrylate is acted on by sodium ethoxide and propoxide, yielding the *methyl α-methyl-β-ethoxytetracrylate* and *methyl α-methyl-β-propoxytetracrylate* respectively. The former boils at 203—204° and the latter at 215—216°.

α-Ethyl-β-chlorotetracrylic acid is freely soluble in alcohol and ether. It crystallises in colourless needles, melts at 49·5° and boils at 215°. The *methyl* salt boils at 166—167°, sp. gr. 1·087 at 15°. The *ethyl* salt boils at 182—183°, the *propyl* salt at 197—198°, and the *isobutyl* salt at 207—208°. The *zinc* salt, $(C_6H_8ClO_2)_2Zn + 1\frac{1}{2}H_2O$, forms needles, and the magnesium salt, $(C_6H_8ClO_2)_2Mg + 2H_2O$, crystallises in plates. The copper salt is an insoluble amorphous powder. The potassium salt is decomposed by potassium hydroxide at 150°, forming methyl propyl ketone. Sodium methoxide and ethoxide act on the methylic salt of ethylchlorotetracrylic acid, forming the methyl salts of α-ethyl-β-methoxy-, and α-ethyl-β-ethoxy-tetracrylic acids boiling at 188—190° and 208—209° respectively.

The preparation of β-chloroquartenylic acid has been described by Genther and Frölich. The ethyl salt boils at 155—156°. It is converted into *ethyl β-ethoxyquartenylate*, $CH_2{:}C(OEt){\cdot}CH_2{\cdot}COOEt$, by the action of sodium ethoxide. This compound readily crystallises in rhombic plates. It melts at 29·5° and boils at 191—192°.

W. C. W.

Ketosulphides and Ketosulphide-acids. By A. DELISLE (*Ber.*, **22**, 306—309).—The compound obtained by treating ethyl acetoacetate with sulphur dichloride (compare Abstr., 1887, 915) has the composition $C_{12}H_{18}O_6S$, and is identical with the substance prepared by Buchka (Abstr., 1885, 1200) from ethyl sodacetoacetate and sulphur monochloride. It separates from benzene in well-defined crystals melting at 83—84°, but after recrystallising from alcohol it has no well-defined melting point. When treated with reducing agents, hydrogen sulphide is evolved, so that the constitution of this compound is probably $S(O{\cdot}CMe{:}CH{\cdot}COOEt)_2$.

Acetonylphenyl sulphide, $C_9H_{10}OS$, is obtained by gradually adding the calculated quantity of chloracetone to a well-cooled mixture of ether and sodium thiophenoxide (NaSPh), the whole being constantly shaken. It separates from ether in large, well-defined crystals, melts at 34—35°, boils at about 143—145° (15 mm.), and is moderately soluble in alcohol, but only sparingly in light petroleum. It dissolves in concentrated sulphuric acid with a yellowish-red coloration, which turns dark-violet on warming. The *hydrazone* melts at 82—83°.

Phenylacetonylphenylsulphide, $C_{14}H_{12}OS$, prepared in like manner from bromacetophenone and sodium thiophenoxide, crystallises from alcohol in colourless needles or plates, melts at 52—53°, and is very readily soluble in ether and acetone.

Ethyl β-thiophenyllevulinate, $C_{13}H_{16}O_3S$, can be obtained from sodium thiophenoxide and ethyl bromolevulinate as described above; it is a liquid boiling at 196—197° (15 mm.). F. S. K.

Molecular Weight of Pentic Acid. By R. Moscheles and H. Cornelius (*Ber.*, **22**, 243—244; compare Abstr., 1888, 1272).—Determinations of molecular weight by Raoult's method made with ethyl pentate in glacial acetic acid solution gave the numbers: 153, 155, and 158, and thus confirm the formula $OEt{\cdot}C\left<\begin{matrix}CEt{\cdot}CO\\CH_2{-}O\end{matrix}\right>$.

N. H. M.

Ketonic Acids. By J. Seissl (*Annalen*, **249**, 272—303).—*Chlorolevulinic acid*, $C_5H_7ClO_3$, is the product of the action of phosphorus pentachloride on levulinic acid. It is a pale-yellow oil which cannot be distilled. No salts of the chlorinated acid could be obtained by neutralising the acid with bases or carbonates. Chlorine converts levulinic acid into *dichlorolevulinic acid*, $C_5H_6Cl_2O_3$; this is crystalline and melts at 77°. When phosphorus pentachloride acts on ethyl levulinate, a mixture of the ethyl salts of mono- and di-chlorolevulinic acids is formed.

Pyruvic acid is less readily attacked by chlorine at the ordinary temperature than levulinic acid. A mixture of the ethyl salts of mono- and di-chloropyruvic acids is formed by the action of phosphorus pentachloride on pyruvic acid. Under similar treatment, ethyl pyruvate appears to yield a mixture of ethyl tri- and tetra-chloropropionates. W. C. W.

Potassium Antimony Oxalate. By R. Wagner (*Chem. Zeit.*, **12**, 1726).—The crystals of potassium antimony oxalate resemble in form those of oxalic acid; it gives a clear solution with small quantities of hot water, but with much water it is partially decomposed, a basic antimony salt being deposited, whilst an acid salt remains in solution. The finely powdered salt loses 2·5 mols. H_2O at 75°, the rest of its water is given off at 130°, above which temperature further decomposition ensues.

Commercial crystalline potassium antimony oxalate has the composition $Sb_2(C_2O_4)_3 + 3K_2C_2O_4 + 8H_2O$; the salt prepared by Souchay and Lenssen's method has the same composition.

The antimony was estimated both volumetrically and gravimetrically. In the former case, excess of $\frac{N}{10}$ iodine solution was added to the neutral or feeble acid antimony solution, and titrated back with thiosulphate. Acid stannous solutions can be titrated in the same way under certain conditions. D. A. L.

Symmetrical Dimethylsuccinic Acids. By C. A. Bischoff and E. Voit (*Ber.*, 22, 389—391; compare Abstr., 1888, 254 and 1057).—Antidimethylsuccinic acid (m. p. 120°) is obtained, together with the isomeric acid, by hydrolysing ethyl dimethylethenyltricarboxylate, and the two products can be separated by recrystallising from water. Its solubility in water at 14° is 1 : 33·3, that of the para-acid 1 : 97. It is directly converted into pure pyrocinchonic acid when treated with bromine at 130°. The *ethyl* salt is a colourless oil, boils at 221—222°, and is decomposed into ether and the anhydride when heated at a high temperature. The *calcium* salt crystallises with 2 mols. H_2O and is insoluble in cold water. The *silver* salt is anhydrous and unstable. The anhydride, obtained by heating the acid at 200°, melts at 87°, and yields only the anti-acid when treated with water. It is converted into pyrocinchonic acid when heated at 90° with bromine in chloroform solution. The *imide* melts at 106°, and yields only the anti-acid when treated with potash. The *anil* crystallises from hot alcohol in small needles and melts at 146°. The *dianilide*, prepared by treating the chloride with aniline, crystallises from alcohol in colourless needles melting at 222°. It yields the anti-acid only when decomposed with potash.

When paradimethylsuccinic acid is heated at 180—196°, it yields an anhydride which melts at 87°, and is very similar to that obtained from the anti-acid. This anhydride yields a mixture of both acids, the relative quantities of which vary with the length of time during which the original para-acid was heated. When the para-acid is treated with acetic chloride, it gives an *anhydride* melting at 38°, from which only the original acid is obtained.

When the para-acid is heated with ammonia, it yields a mixture of imides which gives the anti-acid together with small quantities of the para-compound. The *imide* prepared by heating the para-ethyl salt with ammonia, crystallises from benzene, melts at 78°, and yields only the para-acid. An anil, melting at 126°, was obtained; it gives about equal quantities of the two acids when treated with alcoholic potash. The *anilide* melts at 235°, and is very similar to the anilide of the anti-acid; it yields only the para-acid when decomposed with alcoholic potash.

The para-acid yields pyrocinchonic acid when treated with bromine. No unsaturated acid, isomeric with pyrocinchonic acid, could be obtained either from the acid itself, or from the anhydride.

When ethyl dimethylethenylcarboxylate is treated with chlorine and the product hydrolysed, pyrocinchonic acid, dimethylethenylcarboxylic acid and the two isomeric dimethylsuccinic acids are obtained.

F. S. K.

Diacetyldicarboxylic Acid (Kepitic Acid) and Diacetyl. By R. Fittig, C. Daimler, and H. Keller (*Annalen*, 249, 182—214).

—Methods of preparing kepitic acid have been described by the authors (Abstr., 1887, 362) and by Wislicenus (*ibid.*, 587).

When an excess of bromine is added to a well-cooled solution of ethyl kepitate in carbon bisulphide and the solution is kept in a cold place for 12 hours, *monethyl dibromokepitate*,

$$COOEt{\cdot}CHBr{\cdot}CO{\cdot}CO{\cdot}CHBr{\cdot}COOH,$$

is deposited in transparent, colourless plates. The compound dissolves freely in chloroform and in water. It decomposes on exposure to the light or to a temperature of 70°. When bromine acts on a warm solution of ethyl kepitate in carbon bisulphide, *ethyl tetrabromokepitate* is formed; this substance crystallises in transparent prisms, soluble in carbon bisulphide. It melts at 119° and is not attacked by a solution of sodium carbonate at the ordinary temperature. Alcoholic ammonia decomposes the compound and yields oxamide and dibromacetamide. The ethyl salt of tetrachlorokepitic acid is formed when chlorine is passed into a boiling solution of ethyl kepitate in chloroform. Hantzsch and Zeckendorf (Abstr., 1887, 727) obtained this compound by acting on ethyl dihydroxyquinonedicarboxylate with chlorine. Ethyl kepitate forms, with 2 mols. phenylhydrazine, a crystalline compound, $C_2(N_2HPh)_2(CH_2{\cdot}COOEt)_2$, soluble in warm chloroform; it crystallises in pale yellow needles and melts between 160° and 180° with decomposition. Kepitic acid yields diacetyl or dimethyl diketone, $CH_3{\cdot}CO{\cdot}CO{\cdot}CH_3$, on dry distillation or on boiling with dilute sulphuric acid. Diacetyl is more conveniently prepared by the methods described by v. Pechmann (Abstr., 1888, 248 and 810). Hydroxylamine acts on diacetyl, forming the dioxime $OH{\cdot}N{:}CMe{\cdot}CMe{:}N{\cdot}OH$, a compound previously described by Schramm (Abstr., 1883, 573) under the name of ethylmethylacetoximic acid. The silver and copper salts of trimethylglyoxaline, $C_6H_9N_2Ag$ and $C_6H_9N_2Cu$, are precipitated when diacetyl is added to silver nitrate or cuprous chloride mixed with a large excess of ammonia. In the presence of a small quantity of ammonia, diacetyl deposits a mirror of metallic silver from a solution of the nitrate.

Dibromodiacetyl, $C_4H_4Br_2O_2$, prepared by adding bromine to a solution of diacetyl in carbon bisulphide, crystallises in flexible plates, melts at 116—117°, and is freely soluble in carbon bisulphide and chloroform. Diacetyl unites with hydrocyanic acid, forming the dicyanhydrin $CN{\cdot}CMe(OH){\cdot}CMe(OH){\cdot}CN$, a hygroscopic substance freely soluble in water, alcohol, and ether. It is decomposed by water at 100° into diacetyl and hydrocyanic acid, and is converted by strong hydrochloric acid at the ordinary temperature into dimethylracemic acid.

Dimethylracemic acid, $COOH{\cdot}CMe(OH){\cdot}CMe(OH){\cdot}COOH$, forms colourless crystals containing 1 mol. H_2O, and bears a close resemblance to racemic acid and also to Böttinger's dimethyltartaric acid. It is very soluble in water. The anhydrous acid melts with decomposition at 178—179°. The following salts were prepared: $C_6H_8O_6K_2$, needle-shaped crystals, freely soluble; $C_6H_9O_6K$, sparingly soluble in cold water. The calcium and barium salts (containing $1\frac{1}{2}$ and 2 mols. H_2O respectively) are obtained as crystalline precipitates on the

addition of calcium or barium chloride to a solution of the normal potassium salt.
W. C. W.

Some Nitramines and their Preparation. By A. P. N. FRANCHIMONT and E. A. KLOBBIE (*Rec. Trav. Chim.*, 7, 343—357).—*Methylurethane*, $NH_2·COOMe$, is obtained by dissolving the methyl salt of the nitro-derivative of ethylenediamidoformic acid (this vol., p. 124) in a strong aqueous or alcoholic solution of ammonia. It crystallises from ether in large plates melting at 55—56°, and boils under a pressure of 760 mm. at 176·5—177·5°. Ethylenedinitramine is simultaneously formed, as also a compound of the nitramine with ammonia, which is insoluble in ether but very soluble in water, and melts with decomposition at about 155—157°. The action of ammonia on the above methyl salt takes place in accordance with the equation $C_2H_4[N·(NO_2)COOMe]_2 + 2NH_3 = C_2H_4(NH·NO_2)_2 + 2NH_2·COOMe$.

By the action of methyl iodide (2 mols.) on ethylenedinitramine (1 mol.), a dimethyl-derivative, $C_2H_4(NMe·NO_2)_2$, is obtained, melting at 137°. A monomethyl-derivative, melting at 121—122°, is formed at the same time. Both these substances can be crystallised from water or absolute alcohol, the latter of the two being the more soluble.

By the action of methyl carbonate (2 mols.) on trimethylenediamine (1 mol.), a white substance is obtained, crystallising from ether, in which it is but slightly soluble, in oblique rhombic plates melting at 74—75°. Analysis shows that it is *methyl trimethylenediamidoformate*, $C_3H_6·(NH·COOMe)_2$. When treated with concentrated nitric acid, it is converted into *methyl trimethylenedinitramidoformate*,

$$C_3H_6[N(NO_2)·COOMe]_2,$$

which crystallises from alcohol in long needles or prisms melting at 89—90°. An aqueous solution of ammonia converts this last compound into a crystalline substance melting at 147°, which, when boiled with alcohol, loses ammonia and yields *trimethylenedinitramine*, $C_3H_6(NH·NO_2)_2$. The melting point of this compound is 67°. It is very soluble in water and alcohol, less so in ether and chloroform. It crystallises in short, thick prisms. When boiled with water containing 2 per cent. of sulphuric acid, it loses nitrous oxide. It has an acid reaction and gives metallic derivatives.

By treating pentamethylenediamine in a similar manner, an analogous series of compounds were obtained. *Methyl pentamethylenediamidoformate* crystallises from water or alcohol in slender needles melting at 114°. *Methyl pentamethylenedinitramidoformate* crystallises from ether and alcohol in small prisms melting at 37°. *Pentamethylenedinitramine* crystallises in oblong plates melting at 59—60°. It is very soluble in water and alcohol, and when boiled with water containing sulphuric acid loses nitrous oxide, giving at the same time an oily substance which is volatile in steam.

By treating monomethylamine with an aqueous solution of methyl chloroformate, methyl methylamidoformate, $NH·Me·COOMe$, is obtained, which, on nitrating, subsequent treatment with ammonia and boiling in alcoholic solution, gives *methylnitramine*, $NHMe·NO_2$. This nitramine crystallises in long, colourless, flat needles melting at 38°. It has a very acid reaction. By the action of methyl iodide and alcoholic potash, it is converted into dimethylnitramine.

Ethylnitramine, $NHEt\cdot NO_2$, may be similarly obtained from ethylamine. By evaporation of the alcoholic solution and cooling, crystals are obtained which melt at 3°.

The authors believe the method used for the preparation of the above nitramines from primary amines to be one of general application. H. C.

Paradiethylbenzene. By A. VOSWINKEL (*Ber.*, **22**, 315—317).—Paradiethylbenzene boils at 182—183°, and when boiled with dilute nitric acid yields parethylbenzoic acid and terephthalic acid.

Cadmium paradiethylbenzenesulphonate, $(C_6H_3Et_2\cdot SO_3)_2Cd + H_2O$, crystallises very readily in flat, colourless prisms, whereas the salt of the corresponding meta-acid is very readily soluble in water. The *sulphonamide*, $C_6H_3Et_2\cdot SO_2NH_2$, crystallises in microscopic needles and melts at 85°.

Tetrabromoparadiethylbenzene, $C_6Br_4Et_2$, crystallises in needles melting at 112°. The *nitro*-compound, $C_6H_3Et_2\cdot NO_2$, is a heavy, brownish liquid boiling at 155° (23 mm.) with partial decomposition. The *amido*-derivative is a bright-yellow liquid boiling at 140—142° (20 mm.); the *hydrochloride*, $C_{10}H_{15}N,HCl$, crystallises in colourless needles and turns reddish-brown on exposure to the air. *Acetoparadiethylanilide*, $C_6H_3Et_2\cdot NHAc$, crystallises in colourless plates and melts at 99°.

Paradiethylphenol, $C_6H_3Et_2\cdot OH$, prepared by melting the sulphonic acid with potash, is a yellowish liquid boiling at 126—127° (17 mm.). It is sparingly soluble in cold water, the solution having a burning taste and a phenol-like odour. Ferric chloride gives no coloration, but bromine-water produces a white precipitate in an aqueous solution.

Paradiethylthiophenol, $C_6H_3Et_2\cdot SH$, prepared by treating the sulphonic chloride with zinc-dust and reducing the salt obtained, is an almost colourless, disagreeably smelling liquid boiling at 113° (18 mm.) F. S. K.

Nitrobromocymene and Nitrochlorocymene. By M. FILETI and F. CROSA (*Gazzetta*, **18**, 290—297).*—*Mononitrobromocymene* from thymol, $C_6H_2PrMeBr\cdot NO_2$ [1 : 4 : 2 : 5], is obtained pure by adding the bromocymene (parapropylmetabromotoluene) (1 part) rapidly to nitric acid of sp. gr. 1·48 (5 parts), cooled to 12—15°, keeping the temperature within these limits whilst the mixture is occasionally agitated; after an hour, the product is poured into water, the oil well washed, and distilled in a current of steam. If no more than 30 grams are operated on at a time, it does not contain either a dinitro-compound or unaltered bromocymene. The pure mononitro-derivative is an oil which is heavier than water; it is rapidly oxidised by boiling with

---

[*] The authors distinguish the bromine and chlorine derivatives obtained by the action of phosphorus perchloride or perbromide on *thymol* as chloro- or bromocymene from thymol, whilst those obtained from *cymene* by the action of bromine or chlorine are designated as chloro- or bromo-cymene from cymene.

nitric acid of sp. gr. 1·39, yielding bromonitrotoluic and melting at 199—200°. It dissolves in nitric acid of sp. gr. 1·52, cooled to 0°, with formation of two dinitro-derivatives.

Dinitrobromocymene (from thymol), $C_6H_2PrMeBr(NO_2)_2[1:4:2:5:?]$, is best prepared by allowing the bromocymene to drop slowly into nitric acid of sp. gr. 1·52 (5 parts), cooled to 0°. The product is then poured into water, the precipitate washed, pressed between filter-paper, and crystallised from alcohol. The crystals are a mixture of two isomeric dinitro-derivatives, which appear to be isomorphous, as they cannot be separated by crystallisation. Attempts to separate them by distillation with steam were equally fruitless. On agitating the finely powdered mixture with ether at the ordinary temperature, evaporating the solution and crystallising the residue repeatedly from alcohol, a compound was obtained with a constant melting point of 125—126°. The other isomeride, which seems to melt at about 94°, is also formed in small quantity along with bromonitrotoluic acid, when the mononitrobromocymene is treated with nitric acid of sp. gr. 1·39, as stated above. It could not be obtained in a pure state, however.

Mononitrochlorocymene (from thymol), $C_6H_2PrMeCl{\cdot}NO_2\,[1:4:2:5]$. This is prepared like the brominated derivative. Like the latter, it yields chloronitrotoluic acid melting at 180—181° when boiled with nitric acid of sp. gr. 1·39.

Dinitrochlorocymene (from thymol). Like the brominated derivative, the chlorocymene yields a mixture of two dinitro-derivatives, which could not be separated; one appears to melt at about 80°, the other was prepared in a pure state by Ladenburg and Engelbrecht by the action of phosphorus pentachloride on dinitrothymol.

Mononitrobromocymene (from cymene), $C_6H_2PrMeBr{\cdot}NO_2\,[1:4:3:?]$, is best prepared by allowing the bromocymene (parapropylorthobromotoluene) to drop slowly into cooled nitric acid, sp. gr. 1·48 (5 parts); the two liquids should be left in contact with occasional agitation for 8 to 10 hours and then poured into water. The product is washed with sodium carbonate solution to remove a little bromotoluic acid formed at the same time, distilled in a current of steam, dried over sulphuric acid in a vacuum, and distilled under diminished pressure (b. p. 210—211° at 100 mm.). It is a red liquid which distils at the ordinary temperature at 289—291° with partial decomposition.

Dinitrobromocymene (from cymene), prepared as already described. The product is a dark-red liquid which, after a time, deposits crystals; these, when separated, pressed, and recrystallised, form bright-yellow prisms which melt at 95—96°. The red oil is an isomeric dinitro-compound containing some of the solid in solution.

Mononitrochlorocymene (from cymene), prepared like the brominated derivative, is a dark-red liquid. The *dinitrochlorocymene* crystallises in bright-yellow prisms which melt at 109—110°. A liquid isomeride seems to be formed at the same time.

There is a marked difference in the action of light on these dinitro-derivatives, those from cymene rapidly becoming red on exposure, whilst the corresponding compounds from thymol are unaffected.

C. E. G.

Oxidation of the Chlorocymene and Bromocymene from Thymol and from Cymene. By M. FILETI and F. CROSA (*Gazzetta*, **18**, 298—313).—In a former paper (Abstr., 1887, 37) the authors showed that the chlorocymene from thymol when oxidised by nitric acid of sp. gr. 1·24 to 1·29, gave metachlorocumic, orthochloroparatoluic, and chloroterephthalic acids, whilst the brominated derivative, with acid of sp. gr. 1·20, gave bromocumic acid, and with acid of sp. gr. 1·29 the same product, together with bromonitrotoluic acid, bromoterephthalic acid, and bromonitrocymene. Acid of sp. gr. 1·39 gave the two acids last mentioned with mere traces of bromocumic acid.

The authors have repeated Landolph's and Gerichten's experiments on the oxidation of the bromo- and chloro-cymenes from cymene (*Ber.*, **5**, 268; **10**, 1249; and **11**, 366), and confirm their results, except that they found that the chlorocymene boils at 216—218° instead of at 208—211°, as stated by Gerichten.

The *bromonitrotoluic acid*, $C_6H_2MeBr(NO_2)\cdot COOH$ [1 : 3 : 6 : 4], is more conveniently prepared by oxidising mononitrobromocymene with nitric acid of sp. gr. 1·39 (preceding Abstract), as in this case no other acid is formed at the same time. The *calcium* salt, with $5H_2O$, crystallises in lustrous, yellowish prisms; and the *magnesium* salt, with $8H_2O$, in large, yellow plates. When reduced with sodium amalgam, it yields *metamidotoluic* acid, which crystallises in long, colourless plates, belonging seemingly to the trimetric system. It melts at 164—165°, and is identical with the acid obtained by Ahrens (*Zeitschr. f. Chem.*, 1869, 104) from metanitroparatoluic acid.

Orthamidometanitroparatoluic acid, $C_6H_2Me(NO_2)(NH_2)\cdot COOH$ [1 : 2 : 4 : 5]. When the bromonitrotoluic acid is heated with alcoholic ammonia at 180° for a day in sealed tubes, it is converted into a mixture of the amido-acid with nitrometatoluidine. These two are separated by evaporating the alcohol, and treating the residue with aqueous ammonia, when the amido-acid dissolves, leaving the nitrometatoluidine. On acidifying the ammoniacal solution, the acid is thrown down as a voluminous, yellow precipitate, which can be purified by crystallisation from dilute alcohol, when it forms long, silky, yellow needles, which contain 1 mol. H_2O, and melt at 235—236°.

The *nitrometatoluidine*, $C_6H_3Me(NO_2)\cdot NH_2$ = [1 : 2 : 5], which may be more conveniently prepared by heating bromonitrotoluic acid with fuming hydrochloric acid at 180°, melts at 135—136°, and is identical with the compound obtained by Beilstein and Kuhlberg from acetometatoluidide. When reduced with tin and hydrochloric acid in the usual way, it yields paratoluylenediamine melting at 64°, and boiling at 273—274°.

Orthobromometamidoparatoluic acid, $C_6H_2Me(NH_2)Br\cdot COOH$ = [1 : 2 : 5 : 4]. When bromonitrotoluic acid is heated at 120° with alcoholic ammonium sulphide for a day in sealed tubes, it is converted into the amido-acid, but at the same time resinous substances are produced, from which it is very difficult to separate it. It is far better to use ferrous oxide as the reducing agent, by dissolving the acid (10 grams) in excess of ammonia, and adding the requisite amount (64 grams) of ferrous sulphate in aqueous solution. The acid is only sparingly soluble in alcohol or ether, and moderately so in alcohol. It crystallises in plates which melt at 186—187°.

Paradibromoparatoluic acid, $C_6H_2MeBr_2\cdot COOH$ [1 : 2 : 5 : 4]. Bromamidotoluic acid dissolved in alcohol is mixed with an alcoholic solution of nitrous anhydride and ether added, until a precipitate begins to form; in a few minutes, the diazoamido-derivative separates as a whitish crystalline powder, which after being repeatedly washed with ether is treated with a solution of hydrogen bromide saturated at 0°, and the mixture gently heated at first and finally boiled. The acid is purified by crystallisation from boiling benzene. It forms long, colourless needles, or short, yellowish prisms which melt at 200—201°.

The *ethyl salt* crystallises in colourless, slender needles, which melt at 49°. This acid is identical with the acid Schultz obtained by oxidising paradibromoparaxylene (*Ber.*, **18**, 1762). He gives the melting point as 195°, as is shown by its yielding paradibromoterephthalic acid by oxidation with potassium permanganate. The true melting point of the last-mentioned acid is 316—317°, and its ethyl salt melts at 124—125°.

Orthobromoparatoluic acid, $C_6H_3MeBr\cdot COOH$ = [1 : 3 : 4], obtained by decomposing the diazoamidobromotoluic acid by boiling it with alcohol, crystallises in slender, colourless needles melting at 140—141°. It is easily soluble in alcohol, ether, and benzene, but only sparingly in water. The acid obtained by Kelbe and Koschnitzky (Abstr., 1886, 884) by oxidising a bromocymene with nitric acid, and described by them as orthobromoparatoluic acid, is either bromonitrotoluic acid or impure metabromotoluic acid, according as the bromocymene employed was derived from thymol or from cymene.

Chlorocymene from thymol, when oxidised with nitric acid of sp. gr. 1·39, yields a mixture of the two isomeric dinitrochlorocymenes already described (preceding Abstract) with chloronitrotoluic and chloroterephthalic acids; these two acids may be easily separated by taking advantage of the insolubility of the chloroterephthalic acid in benzene.

Chloronitrotoluic acid, $C_6H_2Me(NO_2)Cl\cdot COOH$ = [1 : (?) 2 : 5 : 4], crystallises in yellowish, flattened needles which melt at 180—181°. It is insoluble in water, moderately soluble in boiling benzene, soluble in alcohol and ether. The *barium salt* crystallises with 3½ mols. H_2O in yellowish needles; the *magnesium salt*, with 8 mols. H_2O, forms large, yellowish tables.

Chloroterephthalic acid, $C_6H_3Cl(COOH)_2$, obtained by the oxidation of chlorocymene, cannot be purified by crystallisation; it is necessary to first convert it into the methyl salt, purify it, and recover the acid by hydrolysis. The *methyl salt* crystallises from aqueous alcohol in colourless needles which melt at 59—60°; the acid is a white powder consisting of microscopic needles which melt at 300°.

C. E. G.

Behaviour of Phenols and Hydroxy-acids towards the Alkali Hydrosulphides. By F. Fuchs (*Monatsh.*, **9**, 1143—1147). The hydrogen of the hydroxyl of hydroxy-acids and phenols containing neither halogens nor nitro-groups is not displaced by metal on

treatment with an alkaline hydrosulphide; which, however, readily turns out the hydrogen of a carboxyl-group (compare this vol., p. 463).
G. T. M.

Nitrometacresols. By W. STAEDEL (*Ber.*, 22, 215—216).—The nitrometacresol melting at 56°, obtained by nitrating metacresol (compare Abstr., 1883, 662), has the constitution [OH : Me : NO_2 = 1 : 3 : 6], and the nitro-compound (m. p. 129°) produced in the same reaction has the constitution [OH : Me : NO_2 = 1 : 3 : 4]. Salts and alkyl-derivatives of both of these substances have been prepared and will be fully described in a subsequent paper. The ethyl-derivatives yield one and the same dinitro-compound [OEt : Me : $(NO_2)_2$ = 1 : 3 : 4 : 6], from which dinitrotoluidine [NH_2 : Me : $(NO_2)_2$ = 1 : 3 : 4 : 6] was obtained. The nitrotoluidines [NH_2 : Me : NO_2 = 1 : 3 : 6] and [NH_2 : Me : NO_2 = 1 : 3 : 4] were also prepared, and the corresponding nitrotoluenes were obtained from the three nitramido-derivatives.

Paramidometacresol gives a chloroquinoneimide with calcium hypochlorite; the salts and acetyl-derivative were also prepared.
F. S. K.

Constitution of the Anilic Acids. By J. U. NEF (*Amer. Chem. J.*, 11, 17—26).—Hydroxylamine hydrochloride reacts with nitranilic acid, *hydroxyammonium nitranilate*, $C_6O_4(NO_2)_2(NH_4O)_2$, being formed. It is a yellow, crystalline solid, soluble in water. When heated to a high temperature, it explodes. With cold concentrated nitric acid, nitranilic acid is liberated. When boiled with hydroxylamine hydrochloride in excess, it is decomposed.

Sodium nitranilate reacts with bromine-water, bromopicrin, sodium bromide, hydrogen bromide, and oxalic acid being the products. This reaction takes place quantitatively, and must be carried out at 0°.

Methyl- and acetyl-derivatives of nitranilic acid could not be prepared, and the author believes that the anilic acids are derivatives of tetraketohexamethylene.
J. W. L.

Action of Methyl Iodide and Potash on Phloroglucinol. By O. MARGULIES (*Monatsh.*, 9, 1045—1054).—The author has treated phloroglucinol (1 mol.) with potash (6 mols.) and methyl iodide, conducting the experiment in the same way as that adopted by Herzig and Zeisel (Abstr., 1888, 822), and has isolated the following compounds:—

Pentamethylphloroglucinol, $C_6HMe_5O_3$ [Me_2 : Me_2 : Me = 2 : 4 : 6], contains neither hydroxyl- nor methoxyl-groups, thus differing in constitution from the chief product obtained by Herzig and Zeisel (*loc. cit.*) with ethyl iodide. After several recrystallisations from ether, it melts sharply at 80°. *Trimethylphloroglucinol*, $C_6H_3O_3Me_3$, and *bi-secondary tetramethylphloroglucinol*, $C_{10}H_{14}O_3$, are both soluble in potash, and each contains an hydroxyl-group. The former crystallises from methyl alcohol in plates melting at 184°; the latter in small needles melting at 114°.
G. T. M.

Aniline Chlorate and Perchlorate. By C. GIRARD and L. L'HOTE (*Compt. rend.*, 108, 183—185).—When pure aniline is poured into chloric acid, acicular crystals of aniline chlorate separate immediately, and can be dried on porcelain. At about 20°, the salt inflames and leaves a carbonaceous residue. It can also be obtained on a large scale from aniline hydrochloride by double decomposition, provided that the salt is carefully neutralised by agitating it with aniline. 100 grams of the hydrochloride are dissolved in 200 grams of water and mixed with a solution of 82 grams of sodium chlorate in 125 grams of water, and the white, crystalline product is drained on a funnel which is cooled to 0°. It is very soluble in water, and takes fire when brought in contact with fuming nitric acid, Nordhausen acid, or concentrated sulphuric acid, but not with ordinary nitric acid or with strong hydrochloric acid. With the two last mentioned, it yields coloured products.

Aniline perchlorate is obtained in brilliant lamellæ by the direct union of aniline and perchloric acid. It is also formed by adding a solution of 30 grams of sodium perchlorate in 50 grams of water to a solution of 30 grams of neutral aniline hydrochloride in 60 grams of water. It is very stable in the air at the ordinary temperature, but if heated in a tube, it deflagrates and deposits carbon. In contact with fuming nitric acid, it inflames, but ordinary nitric acid and strong sulphuric acid have no action in the cold. On heating, nitric acid forms coloured products, sulphuric acid expels the perchloric acid.

C. H. B.

Dehydrothiotoluidine. By P. JACOBSON (*Ber.*, 22, 330—335).—*Dehydrothiotoluidine*, $C_{14}H_{12}N_2S$, is obtained when primuline (3 grams) (compare Green, *J. Soc. Chem. Ind.*, 7, 179) is heated at 190—200° with phosphorus (1 gram) and hydriodic acid of sp. gr. 1·7 (12 grams). It can also be obtained by heating paratoluidine (100 grams) with sulphur (60 grams) at 180—190° for 18 hours, and then at 200—220° for six hours. The crude powdered product is extracted with hot hydrochloric acid, precipitated from the solution with water, and dissolved in hydrochloric acid; the filtered and diluted solution is neutralised with ammonia, and the precipitated base recrystallised from alcohol. It forms almost colourless needles, melts at 190—191°, and is moderately soluble in hot alcohol, benzene, and ether, but only sparingly in cold alcohol; all the solutions show a blue fluorescence. It dissolves in warm, concentrated hydrochloric acid with an orange coloration, but is precipitated in an impure condition on adding water.

This compound is identical with the "thiotoluidine" described in the German patent No. 35790 (Dahl & Co.), and a base of the same composition can be isolated from the insoluble portion of the melt obtained according to the directions given in the patent.

The phenol, $C_{14}H_{10}NS{\cdot}OH$, is obtained when dehydrothiotoluidine is diazotised and the product boiled with water. It crystallises from alcohol in colourless needles, melts at 255—256°, and is moderately soluble in hot alcohol, but almost insoluble in benzene and ether. The alcoholic solution is colourless, but alkaline solutions show a blue fluorescence. The *acetyl*-derivative, $C_{14}H_{10}NS{\cdot}OAc$, crystallises from alcohol in colourless needles, melts at 131—132°, and is readily soluble in glacial acetic acid and hot alcohol. (Compare also Green, Trans., 1889, p. 228 *et seq.*).

F. S. K.

Metamidoparacresyl Methyl Ether. By L. LIMPACH (*Ber.*, 22, 348—353).—Metamidoparacresyl methyl ether crystallises from hot water, melts at 51·5°, boils at 235°, and is readily soluble in alcohol, ether, and benzene. (Compare Hofmann and v. Miller, Abstr., 1881, 592.) The *hydrochloride*, $C_8H_{11}NO,HCl + H_2O$, crystallises in prisms, and loses its water at 80—90°. The *acetyl*-derivative, $C_{10}H_{13}NO_2$, crystallises in plates, and melts at 110°. The *formyl*-derivative, $C_9H_{11}NO_2$, crystallises from alcohol in prisms, and melts at 86°.

Chlorocresyl methyl ether, [Me : OMe : Cl = 1 : 4 : 3], prepared from the amido-compound by Sandmeyer's reaction, is a yellow oil, boils at 210° (uncorr.), and is insoluble in alcohol, ether, and benzene.

Hydroxycresyl methyl ether, [Me : OMe : OH = 1 : 4 : 3], is obtained by diazotising the amido-compound, boiling the product with potash, and distilling with steam. It is a yellow, aromatic-smelling oil, boils at about 185° with partial decomposition, and is readily soluble in alcohol, ether, and benzene, but only moderately so in water.

The *hydrazine*-derivative, [Me : OMe : N_2H_3 = 1 : 4 : 3], is obtained by diazotising the amido-compound and reducing the diazochloride first in the cold with a solution of hydrogen sodium sulphite and then with warm acetic acid and zinc-dust; the boiling filtered solution is mixed with fuming hydrochloric acid, and the salt which separates is decomposed with soda. It is a crystalline compound melting at 45°.

Homomethylsalicylonitrile, [Me : OMe : CN = 1 : 4 : 3], is prepared from the amido-compound by Sandmeyer's method; the product is distilled with steam and fractionated. It is a yellow oil, which boils at 270°, and is converted into homomethylsalicylic acid when heated with potash. This acid crystallises in needles, melts at 70°, and is soluble in water, benzene, and light petroleum. The *silver* salt, $C_9H_9O_3Ag$, is moderately soluble in water. Since the methyl ether of this acid yields homosalicylic acid when treated with hydriodic acid, the constitution of amidoparacresyl methyl ether is [Me : OMe : NH_2 = 1 : 4 : 3].

Amidoazoparacresyl methyl ether,

$$\overset{4}{OMe}\cdot C_6H_3\overset{1}{Me}\cdot\overset{3}{N}{:}N\cdot C_6H_2\overset{1}{Me}(\overset{4}{OMe})\cdot\overset{3}{NH_2},$$

is obtained when an alcoholic solution of amidocresyl methyl ether hydrochloride (5 grams), and the free base (10 grams) is treated with a solution of sodium nitrite (1·4 grams); hydrochloric acid is added, and the dark-red salt, which separates after a short time, is recrystallised from dilute hydrochloric acid and then decomposed with sodium carbonate solution. It crystallises from dilute alcohol in shining plates, melts at 156° with decomposition, and dissolves in acids with a red coloration.

F. S. K.

Oxidation of Orthophenylenediamine. By O. FISCHER and E. HEPP (*Ber.*, 22, 355—359).—When trianilidonaphthalene, [$(NHPh)_3$ = 1 : 2 : 4], is oxidised it is converted into rosinduline; a full account of the results will be published shortly.

It was observed by Griess (this Journal, 1872, 499) that orthophenylenediamine hydrochloride yields with ferric chloride a ruby-red, crystalline compound which he considered to be the hydrochloride of a base, $C_{12}H_{10}N_4$.. The authors prove that this base has the composition assigned to it by Griess, because, when the ruby-red salt is dissolved in water and the largely diluted solution poured into hot ammonia, diamidophenazine, $C_{12}H_{10}N_4$, separates on cooling in small, yellow needles. (Compare Salkowski, *Annalen*, **173**, 58.) No decomposition takes place as stated by Wiesinger (Abstr., 1884, 1322), and the results obtained by Rudolph (Abstr., 1880, 162) and Wiesinger (*loc. cit.*) are erroneous.

Diamidophenazine, the constitution of which is probably  $\overset{1}{NH_2}\cdot C_6H_3{<}\begin{matrix}N\\|\\N\end{matrix}{>}C_6H_3\cdot\overset{4}{NH_2}$, can be obtained in long, brownish-yellow needles by pouring a boiling, very dilute solution of the pure and sparingly soluble sulphate (prepared by dissolving the precipitated base in very dilute sulphuric acid and crystallising) into hot ammonia. It sublimes in slender, yellow plates when heated carefully in small quantities, and dissolves in concentrated sulphuric acid with a grass-green coloration which turns orange-red on diluting with water. It dissolves in benzene and alcohol with a greenish-yellow fluorescence; alcoholic solutions of the salts show a dark, orange-red fluorescence. The *diacetyl*-derivative, $C_{16}H_{14}N_4O_2$, separates immediately in yellow needles when the base is dissolved in acetic anhydride (10 parts) and the solution warmed. It turns brown when heated at about 200°, melts at about 270°, and is very sparingly soluble in all ordinary solvents, but can be crystallised from 20 per cent. alcohol.

Amidophenazine, $C_{12}H_9N_3$, sublimes in red needles when an intimate mixture of the diamido-compound (1 part) and zinc-dust (4 parts) is carefully heated. It crystallises from alcohol in long, red needles, melts at 265°, and is a strong base. It dissolves in concentrated sulphuric acid, forming an unstable, green salt which, on diluting with water, is converted into a stable, red salt. Dilute solutions of the base show an orange-red, solutions of the neutral salts a saffranine-red fluorescence. The *platinochloride*, $(C_{12}H_9N_3)_2,H_2PtCl_6$, crystallises from boiling water in feathery groups of brownish-red needles, and is very sparingly soluble in cold water.

When amidophenazine is treated with sodium nitrite and dilute sulphuric acid in alcoholic solution, it is converted into phenazine (azophenylene). Phenazine is also formed, together with amidophenazine, when the diamido-derivative (1 part) is distilled with zinc-dust (6—10 parts); it can be isolated by distilling with steam, as amidophenazine does not volatilise. F. S. K.

Benzyl-derivatives of Hydroxylamine. By R. BEHREND and K. LEUCHS (*Ber.*, **22**, 384—386).—When dibenzylhydroxylamine (m. p. 123°), prepared by treating hydroxylamine with benzylchloride according to Schramm's method (Abstr., 1884, 51), is heated at 130° with excess of benzyl chloride, the hydrochlorides of tribenzylamine and dibenzylamine are formed together with benzaldehyde and a basic oil, possibly tribenzylhydroxylamine.

Dibenzylbenzoylhydroxylamine, $BzN(C_7H_7)_2O$, is obtained when the dibenzyl-derivative is treated with benzoic chloride. It crystallises from alcohol in needles, melts at 97°, and is decomposed into dibenzylhydroxylamine and benzoic acid when boiled with alcoholic potash. *Benzoxycarbamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}OC_7H_7$, crystallises from alcohol in needles and melts at 139°.

When benzylhydroxylamine is treated with benzyl chloride (1 mol.) in presence of sodium carbonate, it is partially converted into a compound having the composition of dibenzylhydroxylamine and a neutral oil which seems to consist principally of tribenzylhydroxylamine; the neutral compound reduces Fehling's solution on warming. The dibenzyl-derivative is also an oil, and differs from the isomeric compound referred to above in having more strongly marked basic properties, and in its behaviour towards reagents. The *hydrochloride*, $NH(C_7H_7)_2O,HCl$, is very sparingly soluble in water. F. S. K.

Some Derivatives of Orthazotoluene. By V. POSPÉCHOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 608—610).—In a former paper (Abstr., 1888, 825) the author showed that orthazotoluene melts at 55° and not at 137°. On adding powdered orthazotoluene to fuming nitric acid of sp. gr. 1·400, it dissolves, and after some time the mixture solidifies to a crystalline mass. On treating this with water and recrystallising the product from alcohol, reddish-brown needles consisting of *mononitrazotoluene* are obtained; this melts at 87° and is soluble in alcohol, ether, benzene, and chloroform. If the nitric acid is stronger (sp. gr. 1·45), dark, reddish-brown crystals are obtained which are not perfectly homogeneous; they melt at 248—253° with volatilisation, and consist chiefly of *dinitrazotoluene*. B. B.

Orthonitrophenylhydrazine. By A. BISCHLER (*Ber.*, **22**, 240—241).—Orthonitrophenylhydrazine (Michael, Abstr., 1886, 699) is readily obtained by diazotising orthonitraniline and treating the product with stannous chloride and hydrochloric acid. It forms yellow needles of a silky lustre; the salts crystallise well.

Orthamidophenylhydrazine, prepared by reducing the above compound with stannous chloride and hydrochloric acid, forms white plates which soon become brown when exposed to air. N. H. M.

Azimido-compounds. By T. ZINCKE and H. ARZBERGER (*Annalen*, **249**, 350—372; compare Abstracts, 1887, 730—731, and 1888, 159). —*Bromazimidobenzene* is prepared by acting on an alcoholic solution of bromonitracetanilide [1 : 3 : 4] with dilute acetic acid and iron powder. When the reduction is accomplished, hot water is added to the mixture, the iron is precipitated by the addition of sodium carbonate, and the mixture is filtered hot. The filtrate is at once acidified with hydrochloric acid and mixed with sodium nitrite, when acetylbromazimidobenzene is deposited as a yellowish-white precipitate. This compound is decomposed by boiling with strong hydrochloric acid, yielding crystals of bromazimidobenzene, $C_6H_3BrN_3H$. This melts at 158—159°, and is freely soluble in alcohol and in glacial acetic acid. It is also soluble in alkalis, but is reprecipitated from its alkaline solutions by carbonic anhydride. It dissolves in sodium ethoxide, forming the sodium-compound $C_6H_3BrN_3Na$. Bromazimidobenzene forms compounds with acids as well as with metals. The hydrochloride and platinochloride, $(C_6H_3BrN_3H)_2,H_2PtCl_6$, are crystalline.

The acetyl derivative, $C_6H_3BrN_3Ac$, crystallises in needles, soluble in ether, benzene, and chloroform, and melts at 117—118°. Bromazimidobenzene unites with methyl iodide, forming *dimethylbromobenzeneazammonium iodide*, $C_6H_3BrN_3Me_2I$. This compound is decomposed by distillation in a vacuum, yielding methyl iodide and *methylbromazimidobenzene*, $C_6H_3BrN_3Me$; this is a crystalline compound which is soluble in alcohol, melts at 80° and forms a crystalline platinochloride. *Dimethylbromobenzeneazammonium chloride*, prepared by the action of silver chloride on the iodide, crystallises in needles. It is freely soluble in alcohol and in water, and melts with decomposition at 204°. The platinochloride crystallises in yellow needles and melts at 229°. The *chloriodine additive* product, $C_6H_3BrN_3Me_2Cl,ICl$, melts at 186—187°, and appears to crystallise in the monoclinic system.

Dimethylbromobenzeneazammonium bromide crystallises in needles soluble in alcohol and water; it melts at 206° with decomposition. The perbromide, $C_6H_3BrN_3Me_2Br,Br_2$, melts at 167°. *Dimethylbromobenzeneazammonium iodide* melts with decomposition at 200°. The periodide melts at 142—143°. *Dimethylbromobenzeneazammonium hydroxide* is known only in aqueous solution. It has a strongly alkaline reaction, and precipitates iron and copper salts from their solutions.

Benzylbromazimidobenzene, $C_6H_3BrN_3{\cdot}C_7H_7$, and *dibenzylbromobenzeneazammonium chloride*, $C_6H_3BrN_3Cl(C_7H_7)_2$, are prepared by heating at 100° a mixture of methyl alcohol (3 parts), benzyl chloride (3 parts), and bromazimidobenzene (2 parts). The crude product is evaporated and the residue dissolved in ether. Repeated treatment with water removes the azammonium chloride from the ethereal solution. The residue which remains on evaporating the ether becomes crystalline when moistened with methyl alcohol. After treatment with ammonia, it is purified by recrystallisation from dilute hydrochloric acid and from alcohol. Benzylbromazimidobenzene crystallises in silky needles, melts at 108°, and is soluble in alcohol and benzene. The *platinochloride*, $(C_6H_3BrN_3{\cdot}C_7H_7)_2,PtCl_6$, is crystalline. Dibenzylbromobenzeneazammonium chloride also forms a crystalline platinochloride.

Methylbenzylbromobenzeneazammonium iodide, $C_6H_3BrN_3(C_7H_7)MeI$, crystallises in needles and melts at 153—154°. The *chloriodochloride* melts at 123° with decomposition, and the *periodide* melts at 99°.

Trichlorobromazimidobenzene, $C_6Cl_3BrN_3H$, prepared by boiling the crude acetyl-derivative of bromazimidobenzene with nitrohydrochloric acid, melts between 246° and 250°, and is freely soluble in alcohol, benzene, and in acetic acid. This compound unites with bases but not with acids.

Methyltrichlorobromazimidobenzene, $C_6Cl_3BrN_3Me$, melts at 196°, and is insoluble in alcohol and acetic acid.

Dimethyltrichlorobromobenzeneazammonium iodide, $C_6Cl_3BrN_3Me_2I$, melts at 185°, and forms needle-shaped crystals which are sparingly soluble in water and have an intensely bitter taste. W. C. W.

Theory of the Formation of Aniline-blue. By R. Hirsch (*Chem. Zeit.*, **12**, 1725—1726).—The author endeavoured to prepare aniline-blue by heating together rosaniline and paratoluidine, and confirms Nietzki's statement that no blue is formed unless some organic acid is present. It was thought that the acids might form anilides, and that these reacted with the rosaniline to yield the blue; however, experiments with acetanilide and rosaniline, both with and without aniline, did not support this view. In another experiment, leucaniline, aniline, and benzoic acid were heated at 180° for two hours in a current of carbonic anhydride, when, contrary to expectations, the leucaniline remained unchanged, with the exception of a small quantity which became accidentally oxidised. The author thinks that the carbinol-group in the rosaniline takes some part in the formation of the blue. D. A. L.

Aldehyde-blue. By L. Gattermann and G. Wichmann (*Ber.*, **22**, 227—236).—Aldehyde-blue can be prepared by dissolving pararosaniline (5 grams) in a mixture of concentrated hydrochloric acid (55 grams) and water (55 grams), and, after adding aldehyde (22 grams) to the solution, keeping the mixture for 24 hours at the ordinary temperature. The whole is then diluted to 1 litre, the dye precipitated with sodium chloride, dried on porous plates, dissolved in absolute alcohol, and the filtered solution evaporated at the ordinary temperature. The same compound can also be prepared from pararosaniline and paraldehyde as described above; the yield is larger by this method, 10 to 12 grams of the pure substance being obtained from 10 grams of pararosaniline. It is a dark-blue powder, which on rubbing, or when compressed, shows a bronze-coloured metallic lustre. It is very hygroscopic and very readily soluble in water and alcohol, but insoluble in ether, benzene, and light petroleum. This dye is the hydrochloride of some base, but when treated with concentrated hydrochloric acid, it combines with a further quantity of acid, forming a reddish-yellow salt. The free *base* separates in light-red flocks when alkali is added to an aqueous solution of its salts. The salt shows all the properties of a rosaniline dye, and yields a colourless, amorphous leuco-base when reduced with zinc-dust and hydrochloric acid. The leuco-base dissolves in hydrochloric acid, forming a colourless solution which soon becomes blue on exposure to the air, and is rapidly converted into the original colouring matter by oxidising agents.

Aldehyde-blue yields a colourless, amorphous base when heated at 220° with concentrated hydrochloric acid; when heated alone, water and hydrogen chloride are evolved, but on raising the temperature a strong smell of quinoline is perceptible, and a heavy oil condenses and solidifies on the cooler portions of the tube. This substance, after purifying by dissolving in dilute hydrochloric acid, boiling with animal charcoal and reprecipitating, was obtained in colourless flocks; its composition is $C_{10}H_9N$, and it is probably a polymeric quinoline, because when quinaldine hydrochloride is heated at about 220°, an amorphous substance, identical in properties with that obtained from aldehyde-blue, is formed. It is readily soluble in alcohol, and the hydrochloric acid solution gives precipitates with platinic chloride, mercuric chloride, and bromine-water.

The *picrate*, $(C_{10}H_9N)_3,2C_6H_3N_3O_7$, is precipitated on adding picric acid to an alcoholic solution. The free base melts without decomposing, but has no well-defined melting point; when heated more strongly it is decomposed, but in a partial vacuum it boils without decomposition. The relationship between this base and Claus' diquinoline is shown also by the fact that both substances dissolve in hydrochloric acid with a red coloration. As this compound is probably a triquinaldine, aldehyde-blue is probably the chloride of *triquinaldylcarbinol*, $CCl(C_{10}NH_8)_3,HCl + 3H_2O$. This formula agrees fairly well with the analyses, and is also in accordance with the fact that nitrous acid has no action on aldehyde-blue.

A blue colouring matter, probably $C_{10}NH_7Me{\cdot}CCl(C_{10}NH_8)_2,HCl + 3H_2O$, is obtained by treating rosaniline with paraldehyde under the conditions stated above: this compound resembles aldehyde-blue in all its properties, and when heated, yields a compound very similar to triquinaldine.

Many attempts were made under various conditions to convert aldehyde-blue into aldehyde-green, but all were unsuccessful: when an aqueous solution of the blue is treated at 100° with hydrogen sulphide and sulphurous anhydride, a blue precipitate only is produced. Two distinct blue compounds are formed by the action of aldehyde on rosaniline: the sodium chloride filtrate from the aldehyde-blue contains a blue dye in solution. This substance is precipitated on adding alkali to the solution; it dissolves in hydrochloric acid with a blue coloration, and gives aldehyde-green when treated with hydrogen sulphide and sulphurous anhydride, but does not yield a blue precipitate. A light-green, amorphous base is precipitated when alkali is added to an aqueous solution of aldehyde-green; when this base is heated, the odour of both quinoline bases and sulphur-compounds is perceptible.

Aldehyde-blue can be suitably employed for staining microscopic preparations which have been hardened by alcohol.

A blue dye, different from aldehyde-blue, is obtained when aldehyde or paraldehyde and pararosaniline react at about 50°. This compound contains a larger proportion of chlorine and a smaller proportion of carbon than aldehyde-blue. F. S. K.

Silico-organic Compound of a new Type. By J. E. Reynolds (*Proc. Roy. Soc.*, **45**, 39—40).—A well-defined crystalline substance, *silicotetraphenylamide*, $Si(NHPh)_4$, is obtained by the action of silicon tetrabromide on excess of aniline dissolved in benzene, aniline hydrobromide being also formed. If the aniline is not in excess, the liberated bromine forms a brominated compound with it. The crystalline substance is purified by evaporation of the benzene solution, and crystallisation of the residue from carbon bisulphide. It forms short prisms, which melt at 136—137°, and do not decompose at

210°. When distilled at 80 mm. pressure, aniline and a substance, seemingly the silicon analogue of carbodiphenylimide, are obtained. It is anticipated that compounds similar to the above will be obtained from the homologues of aniline. H. K. T.

Aromatic Boron and Silicon Compounds. By A. MICHAELIS (*Ber.*, **22**, 241—243).—A reply to Gattermann (this vol., p. 344). Phenyl boron chloride, $BPhCl_2$, reacts with chlorobenzene and sodium with formation of *boron triphenyl*, which crystallises well and burns with a green flame when ignited. (Compare Michaelis and Becker, *Ber.*, **13**, 59, and Abstr., 1882, 731; Michaelis, *Annalen*, **229**, 397.) N. H. M.

Preparation of Terephthalaldehyde. By M. HÖNIG (*Monatsh.*, **9**, 1150—1153).—Paraxylenyl bromide, $C_6H_4(CHBr_2)_2$ [= 1 : 4], is obtained by acting on dry paraxylene, contained in a retort provided with an inverted condenser, and heated first at 140°, and eventually at 170° and 200°, with six times its weight of bromine previously dried over sulphuric acid. On cooling, almost the whole product crystallises in a mass of needles, the small quantity of oil remaining is removed by pressure, the crystals are washed with cold chloroform, and finally recrystallised from warm chloroform; the solution, on cooling, deposits large prisms which melt at 169°.

On heating paraxylenyl bromide with three times its weight of sulphuric acid (sp. gr. 1·825) at 120—130°, and pouring the product into water, terephthalaldehyde crystallises out in needles, which are quite pure after one recrystallisation from water. It melts at 116°, boils at 245—248°, and its compound with phenylhydrazine crystallises from alcohol in golden scales which melt with decomposition at 250°. G. T. M.

Acetophenone-derivatives. By C. ENGLER and O. ZIELKE (*Ber.*, **22**, 203—207).—Ethyl paranitrobenzoylacetate is a solid substance melting at 54—55°.

Paranitracetophenone is best prepared by mixing ethyl nitrophenylpropiolate with concentrated sulphuric acid, and keeping the mixture at 35—40° for 10 to 12 hours; the solution is then poured into water, boiled until the evolution of carbonic anhydride ceases, and the product recrystallised from carbon bisulphide and dilute alcohol. The *hydrazone* is crystalline, and melts at 132°.

Bromoparanitracetophenone, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}CH_2Br$, is obtained by gradually mixing equivalent quantities of bromine and nitracetophenone in glacial acetic acid, then boiling, and lastly precipitating the ketone by adding water. It crystallises from a mixture of benzene and light petroleum, in needles, melts at 98°, and is soluble in acetone, glacial acetic acid, carbon bisulphide, ether, and hot alcohol. The *hydrazone* crystallises in yellow needles.

Paranitrobenzoyl carbinol, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}CH_2{\cdot}OH$, is prepared by boiling the bromide with sodium acetate, first in glacial acetic acid and then in dilute acetic acid solution; it is a crystalline compound, melts at 121°, is readily soluble in warm alkalis, and yields a reddish, crystalline *hydrazone*.

Dibromoparanitracetophenone, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}CHBr_2$, is formed when a glacial acetic acid solution of nitracetophenone is boiled with rather more than the calculated quantity of bromine. It crystallises from a mixture of benzene and light petroleum in large, quadratic plates, which melt at 67·4°, and probably contain benzene; it is readily soluble in carbon bisulphide, acetone, glacial acetic acid and ether, but only sparingly in cold alcohol, and is not decomposed when boiled with water. When boiled with sodium carbonate, it yields paranitrobenzoic acid, parazoxybenzoylformic acid, and bromoform, but when treated in the cold with the calculated quantity of very dilute potash it is partially converted into nitrobenzoic acid and paranitromandelic acid (compare this vol., p. 508).

Parazoxybenzoylformic acid, $N_2O(C_6H_4{\cdot}CO{\cdot}COOH)_2$, is formed when dibromonitracetophenone is boiled with alkalis, and can also be obtained by boiling ethyl paranitromandelate with a concentrated solution of sodium carbonate, and decomposing the resulting sodium salt with hydrochloric acid. It separates from ether in yellow, nodular crystals, melts at 190°, and explodes when heated more strongly. The *potassium* and *ammonium* salts are readily soluble, but the *sodium* salt is only sparingly soluble in water. The *methyl* salt, $C_{18}H_{14}N_2O_7$, crystallises in yellow needles, melts at 173—175°, and is moderately soluble in benzene and glacial acetic acid, but only sparingly in alcohol. The acid gives a cherry-red coloration with strong sulphuric acid and benzene containing thiophen, and on diluting with water greyish-blue flocks are precipitated. When warmed with strong sulphuric acid, a gas, probably carbon monoxide, is evolved.

F. S. K.

Derivatives of Phenylacetic Acid and Phenylglyoxylic Acid. By G. HAUSKNECHT (*Ber.*, **22**, 324—330).—*Phenylacetodiethylamide*, $CH_2Ph{\cdot}CONEt_2$, is prepared by treating phenylacetic chloride with diethylamine in very dilute ethereal solution. It crystallises in nacreous plates, melts at 86°, and boils at 295—297° (corr.). It is not changed when treated with sodium ethoxide and benzyl chloride or with sodium ethoxide and isobutyl bromide.

Phenylacetodiphenylamide, $CH_2Ph{\cdot}CONPh_2$, prepared in like manner from phenylacetic chloride and diphenylamine, crystallises in small, yellowish needles melting at 72°. The hydrogen-atom in the methylene-group is not replaceable by alkyl radicles. The hydrogen in the methylene-group in the methyl salts of ortho- and para-nitrophenylacetate is not replaceable by alkyls.

Paranitrophenylacetic acid is oxidised to paranitrobenzoic acid when treated with nitrous acid in alkaline solution.

Methyl dinitrophenylacetateazotoluene, $C_{16}H_{14}O_6N_4$, prepared by treating methyl dinitrophenylacetate with diazotoluene (compare p. 516), crystallises in bright red needles, melts at 168°, and is sparingly soluble in cold alcohol.

Methyl dinitrophenylacetateazo-xylene, $C_{17}H_{16}O_6N_4$, crystallises in dark red needles melting at 159°.

Methyldinitrophenylacetateazonaphthalene, $C_{19}H_{14}O_6N_4$, crystallises in dark brown prisms, and melts at 94°. The last three compounds are all insoluble in aqueous alkalis.

Sodium methyldinitrophenylacetateazobenzenesulphonate,

$C_{15}H_{11}O_9N_4SNa$,

crystallises in small, yellow plates, and is readily soluble in water but insoluble in alcohol.

Diazobenzene chloride has no action on the two nitrophenylacetic acids.

The *silver* salts of ortho- and para-nitrobenzyl cyanide were obtained in an impure condition in the form of brownish-black precipitates, by treating the respective cyanides with potash and silver nitrate in alcoholic solution. *Lead orthobenzyl cyanide* is yellowish-brown, the *copper* salt is green. The *lead* salt of the para-compound is brown, the *copper* salt dark green.

Paranitrobenzoylphenylhydrazine, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}N_2H_2Ph$, is formed, with evolution of hydrogen cyanide, when paranitrobenzoic cyanide or chloride (1 mol.) is treated with phenylhydrazine (2 mols.). It crystallises in small, yellowish-red needles, melts at 198°, and is readily soluble in hot alcohol. It dissolves in alcoholic potash with a dark-violet coloration, which disappears on exposure to the air or on adding acid. It dissolves in warm, concentrated sulphuric acid with a blue coloration.

Paranitrobenzoyl cyanide gives a red coloration with an aqueous solution of sodium acetate, but no evolution of hydrogen cyanide takes place.

Benzoylphenylhydrazine (m. p. 169°) is formed when benzoic cyanide is treated with phenylhydrazine. F. S. K.

Nitrohydroxycinnamic Acids. By G. LUFF (*Ber.*, **22**, 291—299).—Metamidocinnamic acid (30 grams) dissolved in sulphuric acid (5 parts) and well cooled, was gradually treated with the calculated amount of potassium nitrate; the solution was then poured into water, and an excess of sodium nitrite added. The diazotised solution was afterwards boiled and filtered hot.

Orthonitrometahydroxycinnamic acid, $[COOH : OH : NO_2 = 1 : 3 : 6]$, separates from the solution obtained as just described in yellow flakes. It melts at 216°, and dissolves very readily in alcohol, very sparingly in hot water, ether, and acetic acid.

Orthonitrocoumaric acid, $C_9H_7NO_5$ $[COOH : NO_2 : OH = 1 : 2 : 3]$, is obtained from the filtrate from the above acid by boiling with basic zinc carbonate, decomposing the zinc salt with sulphuric acid, and extracting with ether. It melts at 218°, dissolves readily in hot water, ether, and dilute alcohol, sparingly in benzene, and hardly at all in chloroform. The *zinc salt* forms very slender, pale yellow needles, very readily soluble in alcohol. The acid has an intensely sweet taste.

Symmetrical metanitrohydroxycinnamic acid, $[COOH : OH : NO_2 = 1 : 3 : 5]$, is obtained by evaporating the mother-liquor from the above zinc salt, and treating the zinc salt which separates with dilute sulphuric acid. It forms lustrous crystals rather readily soluble in hot water, alcohol, and ether.

On repeating the above operations, the acid (m. p. 216°) was not again obtained; metahydroxybenzaldehyde was found in the product. The acid (m. p. 216°) is formed if the metamidocinnamic acid is first converted into the acetyl-compound.

Metahydroxycinnamic acid was prepared by suspending the amido-acid hydrochloride in water, diazotising with an excess of sodium nitrite, boiling the product, and filtering from resin. The yield was 75 per cent. of the theoretical.

Paranitrometahydroxycinnamic acid, [COOH : OH : NO_2 = 1 : 3 : 4], is obtained by slowly treating a solution of metahydroxycinnamic acid in glacial acetic acid with a slight excess of nitric acid (sp. gr. = 1·4); after some time reddish-brown crystals separate, and are crystallised from alcohol. It crystallises in gold-coloured needles melting at 248°, is extremely sparingly soluble in water, cold alcohol, and ether, practically insoluble in benzene and chloroform. Orthonitrocinnamic and metanitrometahydroxycinnamic acids are also formed.

The constitution of all four nitrohydroxycinnamic acids, as given, was determined by conversion into the corresponding nitrohydroxybenzoic acids. N. H. M.

Action of Methyl Iodide on Ethyl Phenylamidocrotonate. By M. Conrad and F. Eckhardt (*Ber.*, **22**, 83—86).—When ethyl phenylamidocrotonate (anilacetoacetate) is heated with methyl iodide at 130—140° for seven hours, it yields a product which on treatment with dilute ammonia divides itself into an oily and an aqueous layer. The oily layer contains ethyl acetate, aniline, and a compound, possibly dimethyltoluidine, boiling at 208°. The aqueous layer contains phenyllutidonecarboxylic acid; this acid, when heated at 270° until carbonic anhydride ceases to be evolved, is converted into phenyllutidone, which crystallises from water with 1 mol. H_2O (compare Abstr., 1887, 500). W. P. W.

Preparation of Nitromandelic Acids. By C. Engler and O. Zielke (*Ber.*, **22**, 207—209).—Orthonitromandelic acid (compare Engler and Wöhrle, Abstr., 1887, 948) can be prepared as follows:—Hydrochloric acid is gradually poured into a well-cooled mixture of dry potassium cyanide and an ethereal solution of orthonitrobenzaldehyde, the whole being constantly shaken; excess of methyl alcohol is then added, and hydrogen chloride passed into the solution. The hydrochloride of the imido-ether which separates is washed with ether, dissolved in water, and the solution filtered; after a short time, methyl orthonitromandelate separates from the solution. The free acid, obtained by hydrolysing the ethereal salt with sulphuric acid, is identical with the compound previously obtained from acetophenone. The yield is 15 to 20 per cent. of the theoretical quantity. The *methyl salt* melts at 74·5°, and is readily soluble in alcohol and ether, but only sparingly in light petroleum.

Paranitromandelic acid (compare p. 506) is easily obtained from paranitrobenzaldehyde as described above; the resulting methyl salt is hydrolysed with a mixture of equal volumes of water and concentrated sulphuric acid, and the free acid is extracted with ether. It crystallises from a mixture of ether and light petroleum, melts at 126°, and is readily soluble in acetone, glacial acetic acid, alcohol, and hot water, but only sparingly in chloroform, carbon bisulphide, and benzene. When treated with cold dilute alkalis, or when boiled with sodium carbonate, it is to a large extent converted into parazoxybenzoylformic acid, and when heated with concentrated sulphuric acid, carbon monoxide is evolved. The salts of the alkalis and alkaline earths are readily soluble. The *silver* salt is very sparingly soluble and is unstable. The *ethyl* salt, prepared by decomposing the imido-ether hydrochloride, crystallises from light petroleum in colourless needles melting at 75—76°. The *methyl* salt crystallises from benzene in prisms and melts at 87°. F. S. K.

Tautomeric Compounds. By J. U. Nef (*Amer. Chem. J.*, **11**, 1—17).—*Ethyl quinonediimidotetracarboxylate*, $C_6(NH)_2(COOEt)_4$, is prepared by adding bromine to a cooled solution of ethyl diamidopyromellitate.

It is a yellow solid, crystallising from alcohol in prisms which melt at 161°. It is volatile without decomposition, and dissolves readily in chloroform, benzene, and hot alcohol, with a pure yellow colour and without fluorescence. The alcoholic solution gives no coloration with ferric chloride; with zinc-dust and acetic acid, it is readily reduced to ethyl diamidopyromellitate.

With a view to determine whether the metal or alcohol radicle in the salts of ethyl quinoltetracarboxylate is united to carbon or to oxygen, the following compounds were prepared and studied:—

Ethyl sodioquinoltetracarboxylate, $C_6O_2Na_2(COOEt)_4$, prepared by the action of sodium ethoxide on ethyl quinoltetracarboxylate, separates as a red, gelatinous precipitate from the mixture. When dry, it is perfectly stable. With solutions of barium chloride, lead acetate, and cupric sulphate it forms yellow precipitates; silver nitrate is instantly reduced; with hydroxylamine hydrochloride, the original ethyl salt is regenerated. With methyl iodide, it forms a *dimethyl*-derivative, $C_6(MeO)_2(COOEt)_4$, melting at 95°; this crystallises in colourless needles, and is volatile without decomposition; its solutions fluoresce; with ferric chloride, it gives no coloration.

The corresponding *diacetyl*-derivative, $C_6(AcO)_2(COOEt)_4$, prepared by the action of acetic chloride on the dry sodium salt, is a colourless substance, volatile without decomposition, insoluble in alkalis, and melting at 120°. Its solutions show no fluorescence, and give no coloration with ferric chloride. It does not react with bromine.

In a similar series of experiments carried out with ethyl paradiketohexamethylenetetracarboxylate, the *sodium*-derivative was obtained by the action of sodium ethoxide on the diketo-compound. It is a pale-rose-coloured substance, and reacts with metallic salts and hydroxylamine in a manner exactly corresponding with the sodium-derivative of the quinol-compound. With bromine-water, it forms no additive compound, but is converted into the quinol-derivative. The *diacetyl*-derivative, $C_6(HO)_2Ac_2(COOEt)_4$, crystallises from alcohol in colourless needles melting at 142°. It gives a blood-red coloration with ferric chloride, dissolves in soda and sodium carbonate solutions, and its salts give reactions entirely analogous to those of the phenols.

With bromine-water, a product melting at 155° and containing no bromine is formed; it is not the diacetyl salt of the quinol-derivative. It forms an acetyl-derivative with acetic chloride, and reduces silver nitrate in the cold. J. W. L.

Derivatives of Resorcinoldisulphonic Acid. By F. ULZER (*Monatsh.*, 9, 1127—1131).—The author finds that the nitrogenous compound, which Fischer (Abstr., 1881, 1147) obtained in small quantity by the action of potassium nitrite on potassium resorcinoldisulphonate, is a salt of nitrosoresorcinoldisulphonic acid. It may be readily prepared in quantity by allowing a solution of potassium nitrite (20 grams) to drop slowly into a solution of potassium resorcinoldisulphonate (100 grams) in water (400 c.c.) and acetic acid (15 c.c.), the containing vessel being frequently shaken during the addition of the nitrite, after which it is allowed to remain in a warm place for several hours, and is cooled in ice-water, when violet-coloured crystals of *potassium nitrosoresorcindisulphonate*, $NO{\cdot}C_6H_4(OH)(SO_3K)_2{\cdot}OK$, are deposited.

On oxidation of potassium nitrosoresorcinoldisulphonate with 3 per cent. hydrogen peroxide or 2 per cent. permanganate, *potassium nitroresorcinoldisulphonate*, $C_6H(SO_3K)_2(OH)_2{\cdot}NO_2$, is obtained. It crystallises in golden-yellow prisms, its aqueous solution gives a deep blood-red coloured solution with ferric chloride, and on carefully warming with fuming nitric acid it furnishes styphnic acid. The corresponding *amidoresorcinoldisulphonic acid*, $C_6H(SO_3H)_2(OH)_2{\cdot}NH_2 + 3H_2O$, is obtained on reduction of the nitro-compound with tin and hydrochloric acid. It crystallises in silky needles which decompose at 240° without previously melting. G. T. M.

Preparation of Tetramethyldiamidotriphenylmethane. By M. NENCKI (*Monatsh.*, 9, 1148—1149; compare O. Fischer, Abstr., 1880, 40).—This base may readily be prepared in quantity by the following method:—A mixture of benzaldehyde (40 grams), dimethylaniline (100 grams), and 93 per cent. alcohol (40 grams) is placed in a large flask heated in a water-bath and provided with an inverted condenser. Phosphorus oxychloride (65 grams) is added very slowly from a dropping funnel, and the mixture is then heated for about half an hour, after which the product is dissolved in warm water, the solution filtered, and, when cold, treated with excess of soda. The oil thus obtained solidifies on standing, and on recrystallisation from alcohol furnishes pure tetramethyldiamidotriphenylmethane, the yield being nearly theoretical. G. T. M.

Diphenyl Ether and Dinitrodiphenyl Ether. By R. HIRSCH (*Ber.*, 22, 335—336).—Diphenol can be easily obtained by diazotising benzidine and boiling the product with water; 50 grams of benzidine yield 40—42 grams of diphenol.

Diphenyl ethyl ether, prepared by boiling diphenol (20 grams) with ethyl iodide (35 grams) and potash (12 grams) in alcoholic solution (150 grams), crystallises from glacial acetic acid in needles, melts at

174—176°, and is moderately soluble in hot alcohol, but insoluble in water.

Dinitrodiphenyl ethyl ether, obtained by nitrating the ether in glacial acetic acid solution, crystallises from alcohol, melts at 192—193°, and is converted into dinitrodiphenol when boiled with alcoholic potash.

Dianisidine can be prepared by boiling a glacial acetic acid solution of the dinitro-compound with tin and hydrochloric acid, and treating the product with nitrous acid. It yields colouring matters with naphthol- and naphthylamine-sulphonic acid. F. S. K.

Action of Nitrous Acid on Tetramethyldiamidobenzophenone and Analogous Compounds. By E. Bischoff (*Ber.*, **22**, 337—346; compare Abstr., 1888, 1197).—*Nitrosotetramethyldiamidobenzophenone picrate*, $C_{17}H_{19}N_3O_2,C_6H_3N_3O_7$, prepared by treating the ketone with picric acid in alcoholic solution, crystallises in orange-red needles melting at 150—152°. It is readily soluble in warm alcohol, but only sparingly in hot water, and insoluble in the cold. The *hydrochloride*, $C_{17}H_{19}N_3O_2,2HCl$, is precipitated when hydrogen chloride is passed into a benzene solution of the ketone; it is decomposed by water. The *mercurochloride* is a granular, crystalline compound. The *hydrazone*, $C_{23}H_{25}N_5O_3$, crystallises from hot alcohol in red needles, melts at 148°, and is soluble in hot alcohol, benzene, and hydrochloric acid, but insoluble in water.

Nitrosodimethamidobenzophenone, $COPh\cdot C_6H_2(NMe_2):NOH$, is obtained when sodium nitrite (2·15 grams) is gradually added to a dilute and well-cooled hydrochloric acid solution of dimethamidobenzophenone (7 grams); the oily product, which is precipitated on adding dilute sodium carbonate solution, is purified by dissolving in ether and shaking the solution with animal charcoal. It is a reddish-yellow oil, gives the nitroso-reaction, and yields an unstable hydrochloride. When reduced with tin and concentrated hydrochloric acid, it is converted into dimethamidobenzophenone.

Paradimethamidobenzoic acid (compare Michler, this Journal, 1876, ii, 68) is best prepared by heating an intimate mixture of tetramethyldiamidobenzophenone (1 part) and soda-lime (2—3 parts) at 340° for two hours, or distilling the mixture until no more dimethylaniline passes. The crude product is extracted with hot water, precipitated from the concentrated solution with dilute acetic acid, and recrystallised from alcohol. The *calcium* salt crystallises in yellowish plates.

Nitrosoparadimethamidobenzoic acid, $COOH\cdot C_6H_2(NMe_2):NOH$, is obtained when the preceding compound is treated with nitrous acid as described above. It crystallises from warm alcohol in yellow plates, melts at 224°, and is readily soluble in benzene, chloroform, and light petroleum, but only sparingly in ether. The *picrate*,

$$C_9H_{10}N_2O_3,C_6H_3N_3O_7,$$

crystallises in yellow needles melting at 168°. The *hydrochloride*, $C_9H_{10}N_2O_3,HCl$, crystallises in colourless needles, and is stable in the air. The *oxalate* melts at 178—181°. It also forms salts with platinic and mercuric chlorides. The nitroso-compound is reconverted into paradimethylamidobenzoic acid when heated with stannous chloride and concentrated hydrochloric acid.

Methyl paradimethamidobenzoate, $NMe_2{\cdot}C_6H_4{\cdot}COOMe$, crystallises from hot alcohol in plates, melts at 102°, and is readily soluble in benzene, ether, and chloroform, but only moderately so in dilute alcohol, and insoluble in alkalis.

Methyl nitrosoparadimethamidobenzoate, $OH{\cdot}N{:}C_6H_4(NMe_2){\cdot}COOMe$, crystallises from alcohol in golden-yellow plates, melts at 101°, and is readily soluble in ether and hot alcohol, but insoluble in water. It gives Liebermann's nitroso-reaction, is readily converted into the corresponding acid when boiled with alcoholic potash, and yields paradimethamidobenzoic acid when warmed with stannous chloride and concentrated hydrochloric acid. The *hydrochloride*, $C_{10}H_{12}N_2O_3,HCl$, crystallises in short, colourless needles. The *picrate*,

$$C_{10}H_{12}N_2O_3,C_6H_3N_3O_7,$$

crystallises in golden-yellow needles and is readily soluble in warm alcohol, but insoluble in water. The methyl salt also forms a platinochloride. F. S. K.

Derivatives of Deoxybenzoïn. By E. BISCHOFF (*Ber.*, **22**, 346—348).—*Propyldeoxybenzoïn*, prepared from sodiodeoxybenzoïn and propyl bromide, crystallises from alcohol in moss-like needles, melts at 33° and boils at 328—331° (corr.). The *oxime*, $CHPr^{\alpha}Ph{\cdot}CPh{:}NOH$, crystallises from alcohol in needles and melts at 100°. *Isopropyldeoxybenzoïn*, melts at 48° and boils at 324—326° (corr.). The *oxime* crystallises in needles and melts at 69—70°. The *hydrazone* crystallises in needles, melts at 72°, and decomposes on exposure to the air.

Hexyldeoxybenzoïn crystallises from alcohol in needles or plates, melts at 59°, and boils at 344—346° (corr.).

The *oxime*, $C_6H_{13}{\cdot}CHPh{\cdot}CPh{:}NOH$, crystallises in needles and melts at 89°.

Octyldeoxybenzoïn melts at 61° and boils at 350—355° (corr.). The *oxime*, $C_8H_{17}{\cdot}CHPh{\cdot}CPh{:}NOH$, crystallises in long needles and melts at 101°. F. S. K.

Benziles. By R. STIERLIN (*Ber.*, **22**, 376—383).—In preparing anisoïn by Bosler's method (Abstr., 1881, 421), it is best, as soon as the mixture has been boiled sufficiently, to cool directly and at the same time shake well for 15—20 minutes; the anisoïn then separates immediately in considerable quantities.

α-Anisildioxime, $OMe{\cdot}C_6H_4{\cdot}C(NOH){\cdot}C(NOH){\cdot}C_6H_4{\cdot}OMe$, is precipitated when anisil is boiled for a long time with excess of hydroxylamine hydrochloride in methyl alcohol solution. It is a crystalline powder, melts at 217°, and resembles α-benzildioxime in properties. It is soluble in hot glacial acetic acid and in dilute soda, but almost insoluble in alcohol, ether, and benzene. The *diacetyl*-derivative, $C_{20}H_{20}N_2O_6$, crystallises in prisms, melts at 139°, and is sparingly soluble in cold alcohol and glacial acetic acid.

β-Anisildioxime is obtained, together with the monoxime and other impurities, when the filtrate from the α-compound is evaporated. The pure compound is prepared by heating the α-derivative (1 part) at 160—170° with absolute alcohol (2—3 parts), or by heating a mixture of ainsil (2 parts) and hydroxylamine hydrochloride (1·2 parts) at 170° with absolute alcohol (6 parts) and two drops of concentrated hydrochloric acid. It crystallises in slender, colourless needles, melts at 195°, and is readily soluble in alcohol, glacial acetic acid, and soda. The *diacetyl*-derivative melts at 130° and is more readily soluble in alcohol and glacial acetic acid than the corresponding derivative of the α-oxime.

Anisiloxime, $OMe\cdot C_6H_4\cdot C(NOH)\cdot CO\cdot C_6H_4\cdot OMe$, is formed when an alcoholic solution of anisil (2 parts) is boiled for 10 minutes with hydroxylamine hydrochloride (1·2 parts). It separates from alcohol in crystalline aggregates, melts at 130°, and is readily soluble in ether, benzene, chloroform, and glacial acetic acid.

Paratoluoïn (*diparadimethylbenzoïn*,) $C_6H_4Me\cdot CO\cdot CH(OH)\cdot C_6H_4Me$, is obtained by boiling paramethylbenzaldehyde (10 parts) with potassium cyanide (2 parts) and 50 per cent. alcohol (30 parts) for about two hours, and then shaking the solution until the crystalline product separates. It crystallises in yellowish prisms, melts at 88—89°, and is readily soluble in alcohol, ether, benzene, chloroform, and glacial acetic acid, but only sparingly in hot water. It turns green when treated with fuming sulphuric acid. The *acetyl*-derivative, $C_{16}H_{15}O_2Ac$, melting at 100°, and the *benzoyl*-derivative, $C_{16}H_{15}O_2Bz$, melting at 119°, are colourless, crystalline compounds readily soluble in alcohol and ether.

Paratolil, $C_6H_4Me\cdot CO\cdot CO\cdot C_6H_4Me$, prepared by boiling toluoïn (1 part) with concentrated nitric acid (2 parts), crystallises from alcohol in yellowish plates, melts at 104—105°, and is soluble in ether, benzene, and glacial acetic acid. It gives a violet coloration when boiled with potash and absolute alcohol, and when treated with hydroxylamine hydrochloride, as described above, it yields two isomeric dioximes. The *α-dioxime*, $C_6H_4Me\cdot C(NOH)\cdot C(NOH)\cdot C_6H_4Me$, crystallises in plates or needles, melts at 217°, and is only sparingly soluble in alcohol, ether, and glacial acetic acid; the *acetyl*-derivative, $C_{20}H_{20}N_2O_4$, crystallises in prisms melting at 133—134°. The *β-dioxime* crystallises in needles, melts at 225°, and is readily soluble in alcohol; the *acetyl*-derivative melts at 144°.

Deoxytoluoïn, $C_6H_4Me\cdot CH_2\cdot CO\cdot C_6H_4Me$, prepared by reducing toluoïn with zinc and hydrochloric acid in boiling alcoholic solution, crystallises in needles, melts at 102°, and is readily soluble in ether and benzene, but insoluble in water; it is turned brownish-red by sodium ethoxide. The *benzyl*-derivative, $C_{23}H_{22}O$, crystallises in needles, melts at 92—93°, and is readily soluble in alcohol, ether, and benzene.

F. S. K.

Nitration of Naphthionic Acid. By R. NIETZKI and J. ZÜBELEN (*Ber.*, **22**, 451—453).—When sodium naphthionate is heated with acetic anhydride, it is readily converted into an acetyl-derivative which, on nitration in the cold, yields acetylamidonitronaphthalenesulphonic acid; the *ammonium* salt of this acid, $NO_2\cdot C_{10}H_5(NHAc)\cdot SO_3NH_4$, crystallises in yellow needles. *Nitronaphthylaminesulphonic acid*, $NO_2\cdot C_{10}H_5(NH_2)\cdot SO_3H$, is obtained by heating the acetylated derivative with dilute aqueous potash; it crystallises in colourless needles, yields red crystalline salts with alkalis, is readily diazotised, forming a diazo-compound yielding azo-dyes on treatment with amines or phenols, and is converted by the action of alkali into nitronaphthylamine (m. p. = 119°). It follows, therefore, that the constitution of the acid is $[NH_2 : SO_3H : NO_2 = 1 : 4 : 4']$. W. P. W.

Action of Phosphorus Pentachloride on β-Hydroxynaphthoic Acid. By H. RABE (*Ber.*, **22**, 392—396).—The *chloride*, $POCl_2\cdot O\cdot C_{10}H_6\cdot COCl$, is prepared by treating β-hydroxy-α-naphthoic acid with phosphorus pentachloride; it crystallises in white, satiny needles melting at 38°. When treated with water, or, preferably, allowed to remain exposed to the air for two days, it is converted into *α-carboxylnaphthyl-β-phosphoric acid*, $PO(OH)_2\cdot O\cdot C_{10}H_6\cdot COOH$, which crystallises in tufts of white needles, melts at 156°, and is readily soluble in water, alcohol, and acetone, sparingly soluble in benzene, and almost insoluble in light petroleum. The *silver* salt, $C_{11}H_6O_6PAg_3$, was prepared; the ammonium salt, on boiling its aqueous solution, decomposes into phosphoric acid, carbonic anhydride, and β-naphthol.

The chloride, when treated with absolute alcohol, yields a *diethyl* salt, $PO(OEt)_2\cdot O\cdot C_{10}H_6\cdot COOH$, which forms colourless, rhombohedral crystals, melts at 113°, is soluble in alcohol and ether, and decomposes when boiled with water. Phosphorus pentachloride reacts with the dichloride under pressure at 180—190°, forming *β-chloronaphthoic trichloride*, $C_{10}H_6Cl\cdot CCl_3$, a dark-brown, fluorescent oil which on exposure to the air is converted into *β-chloro-α-naphthoic acid*, $C_{10}H_6Cl\cdot COOH$. This is crystalline, melts at 152—153°, is readily soluble in alcohol and ether, and dissolves in 1000 parts of water at 20°, and in 126 parts at 100°. The *sodium* salt crystallises in thin, lustrous scales; the *calcium* salt, with 2 mols. H_2O, dissolves in 75 parts of hot and 150 parts of cold water; the *methyl* salt crystallises in white, broad, brittle prisms and melts at 50°. W. P. W.

Constitution of β-Naphthylamine-α-Sulphonic Acid. By C. IMMERHEISER (*Ber.*, **22**, 412—413).—The author points out that the formation of β-pyridinephenyleneketonesulphonic acid from β-naphthylamine-α-sulphonic acid (compare p. 527) is only possible if the compound is heteronucleal. Adopting the view ascribed to Cleve (*Ber.*, **20**, 75) and Forsling (*Ber.*, **20**, 2105) that β-naphthylamine-γ-sulphonic acid (Dahl's acid) has probably the constitution $[NH_2 : SO_3H = 2 : 4']$, the author points out that the alternative formula $[NH_2 : SO_3H = 2 : 1']$ must be that of β-naphthylamine-α-sulphonic acid. W. P. W.

Note by Abstractor.—Both Cleve and Forsling (*l. c.*) adopt provisionally the formula 2 : 1′ and not 2 : 4′ for the Dahl acid, and therefore the author's conclusions, based on the assumption made by Cleve and Forsling, would point to the formula 2 : 4′ and not 2 : 1′ as that of β-naphthylamine-α-sulphonic acid. Since the publication of this paper Armstrong and Wynne (Proc., 1889, 49, 50) have proved that the former acid has the constitution 2 : 4′ and the latter 2 : 1′.

W. P. W.

Constitution of β-Naphthol-α-Sulphonic Acid and β-Naphthol-α-Disulphonic Acid (R-Acid). By W. Pfitzinger and C. Duisberg (*Ber.*, **22**, 396—399).—When Bayer's β-naphthol-α-sulphonic acid is heated with ammonia in an autoclave, it is converted into so-called β-naphthylamine-α-sulphonic acid (Badische acid) which yields naphthalene-α-sulphonic acid when its amido-group is displaced by hydrogen by the hydrazine method. It follows, therefore, that each of these acids contains its sulphonic group in the α-position.

β-Naphthol-α-disulphonic acid (R-acid) when similarly treated yields Ebert and Merz's naphthalene-α-disulphonic acid, and consequently must contain a sulphonic group in a β-position in each nucleus.

W. P. W.

Note by Abstractor.—Since the publication of this paper, the constitution of the so-called β-naphthylamine-α-sulphonic acid (Badische acid) has been shown to be [$NH_2 : SO_3H = 2 : 1'$] (Armstrong and Wynne, Proc., 1889, 50); it follows, therefore, that β-naphthol-α-sulphonic acid has the constitution [$OH : SO_3H = 2 : 1'$]. In the same paper (p. 53) it is also shown that Ebert and Merz's naphthalene-α-disulphonic acid has the constitution 2 : 2′; consequently β-naphthol-α-disulphonic acid (R-acid) must have the constitution [$OH : SO_3H : SO_3H = 2 : 3 : 3'$].

W. P. W.

β-Naphthol-α-Sulphonic Acid. By R. Nietzki and J. Zübelen (*Ber.*, **22**, 453—456).—Naphthalene-α-sulphonic acid is obtained when β-naphthylamine-α-sulphonic acid, derived from β-naphthol-α-sulphonic acid, is diazotised and boiled with alcohol (compare preceding Abstract). When warmed with dilute nitric acid, β-naphthol-α-sulphonic acid is converted into a *dinitro*-derivative (croceïn-yellow) which forms a *dipotassium* salt, $OK\cdot C_{10}H_4(NO_2)\cdot SO_3K$, crystallising in golden-yellow scales, and a *potassium* salt,

$$OH\cdot C_{10}H_4(NO_2)_2\cdot SO_3K,$$

crystallising in long, yellow needles. On reduction with stannous chloride and hydrochloric acid, the dinitro-derivative is converted into the *hydrochloride* of *diamidonaphtholsulphonic acid*,

$$OH\cdot C_{10}H_4(NH_2)_2\cdot SO_3H,HCl,$$

which crystallises in colourless needles; it forms the *diimido*-derivative, $C_{10}H_8SN_2O_4$, on oxidation with ferric chloride, and yields a *diazo-compound*, $OH\cdot C_{10}H_4(NH_2)<\substack{SO_3\\ N_2}>$, crystallising in sparingly soluble green needles.

W. P. W.

Unorganised Ferments. By N. Kravkoff (*J. Russ. Chem. Soc.*, 1888, **20**, 623—632; comp. Abstr., 1888, 862).—In order to prepare diastase, barley-malt was ground and treated for half an hour with water at 35° to 40°; the liquid was then strained and filtered, and the solution saturated with powdered ammonium sulphate. The precipitate, after being collected, was washed with alcohol, treated with absolute alcohol for some time, dried at 35° to 40° and extracted with water. The solution thus obtained, when freed from salts by dialysis, was very limpid, gave none of the reactions of albuminoïds, and had a powerful action on starch. The following results in part confirm those obtained by Chittenden and Cummins (Abstr., 1885, 999), but in some respects are not in accordance with them. The mineral acids, hydrochloric, nitric, and sulphuric of 0·0002 per cent., and the organic acids, acetic and lactic, of 0·002 per cent., destroy the diastatic action of the ferment, and this action is not restored by 0·3 per cent. solution of sodium carbonate, or by albuminoïds; this action is found to depend on the strength of the acid, duration of action, and temperature. Carbonic acid in solution, but not gaseous carbonic anhydride, has a considerable retarding action. Alkalis show a retarding action merely; even a 5 per cent. solution of sodium carbonate does not stop the process. Neutral salts also act in the same way. In the stomach, however, owing to the presence of other compounds, especially albumins, globulins, and peptones, the action of diastatic substances is not stopped even in the presence of 0·2 per cent. hydrochloric acid (Schmidt), these substances having a protecting and sometimes even a stimulating action, as shown by direct experiment. For this purpose, the albuminoïd substance must be added first and then the acid, otherwise the fermentative process is stopped at once. This shows that starch may be actually converted into sugar in the stomach. It has been assumed hitherto, that ferments are incapable of diffusion through membranes; the author, however, shows that such a diffusion can take place, but that it depends on the medium below the dialysing membrane. Thus diastase diffuses very slowly into water, although its action on starch through a membrane is tolerably rapid; the action of pepsin and trypsin is much slower. The composition of diastase seems to be less complicated than that of trypsin and pepsin.

The author has found diastatic ferments in almost all animal tissues, and it seems that ferments may be regarded as products of decomposition of living protoplasm. B. B.

Ring-formation with Elimination of a Nitro-group from the Benzene Nucleus. By V. Meyer (*Ber.*, **22**, 319—323).—The compound $C_6H_3(NO_2)_2\cdot C(COOMe){:}N\cdot NHPh$, melting at 182—183°, is obtained when methyl dinitrophenylacetate is treated with a solution of diazobenzene chloride (compare A. and V. Meyer, Abstr., 1888, 693). If the yellowish-red alcoholic solution of this substance is mixed with a little potash (or soda), a deep blue solution of the salt $C_6H_3\cdot(NO_2)_2\cdot C(COOMe){:}N\cdot NKPh$ is formed; on keeping for a few minutes at the ordinary temperature, the blue solution turns bright-yellow and considerable quantities of a mixture of potassium nitrite and the benzopyrazole-derivative,  $NO_2\cdot C_6H_4{<}\begin{array}{l}C(COOK)\\NPh - N\end{array}{\gg}$, separates in the form of light-yellow crystals.

Nitrophenylbenzopyrazolecarboxylic acid (*nitrophenylisindazolecar-*

boxylic acid), $NO_2\cdot C_6H_4<\begin{matrix}C(COOH)\\NPh\text{—}N\end{matrix}\gg$, is obtained when the potassium salt is warmed for a long time with dilute sulphuric acid. It crystallises in small, pale-yellow needles, melts at 272°, turns brown at 265°, and is sparingly soluble in alcohol. The *methyl* salt is prepared by treating the acid with methyl alcohol and hydrogen chloride, first in the cold and then at a higher temperature; it crystallises in small, bright-yellow needles, melts at 191—192°, and gives a slight pyrazole-reaction. The compounds (hydrazones) which methyl dinitrophenylacetate yields with diazotoluene, diazo-xylene, and diazobenzenesulphonic acid, behave towards alkalis in the same way as that obtained from diazobenzene.

Methyl dinitrophenylacetate yields a deep-brown salt with alkalis, but no further change occurs under the conditions described above.

F. S. K.

Compounds of Alloxan with Pyrazolic Bases. By G. Pellizzari (*Gazzetta*, **18**, 340—344).—In a former memoir (Abstr., 1888, 142), the author showed that alloxan was capable of combining with amines with formation of new compounds; he has now investigated the compounds obtained by the action of phenylmethylpyrazolone and phenyldimethylpyrazolone (antipyrin). Aqueous solutions of alloxan dissolve these bases, and on heating the liquid to boiling for a few minutes, crystalline precipitates are obtained having the composition

$$\begin{matrix}NPh\cdot CO\\ |\\ N{=}CMe\end{matrix}\!\!>CH\cdot C(OH)<\!\!\begin{matrix}CO\cdot NH\\CO\cdot NH\end{matrix}\!\!>CO$$, and

$$\begin{matrix}NPh\text{—}CO\\ |\\ NMe\cdot CMe\end{matrix}\!\!\gg C\cdot C(OH)<\!\!\begin{matrix}CO\cdot NH\\CO\cdot NH\end{matrix}\!\!>CO$$

respectively. The latter, *phenyldimethypyrazolonetartronylcarbamide*, is but slightly soluble in water, and decomposes at 261°; the former, *phenylmethylpyrazolonetartronylcarbamide*, crystallises from water in long, yellow needles containing 3 mols. H_2O, and decomposes at 170—180°. They combine both with acids and with bases. When dissolved in cold aqueous potash, ammonia is produced, and on adding acetic acid to the solution much carbonic anhydride is evolved, and white crystalline precipitates are produced consisting respectively of *phenylmethylpyrazolonetartronylimide*,

$$C_3N_2OPhMeH\cdot C(OH)<\begin{matrix}CO\\CO\end{matrix}>NH,$$

and *phenyldimethylpyrazolonetartronylimide*,

$$C_3N_2OPhMe_2\cdot C(OH)<\begin{matrix}CO\\CO\end{matrix}>NH.$$

These compounds also have both basic and acid properties. The former is easily decomposable; the latter crystallises from alcohol or water in colourless needles which melt with decomposition at 245—250°.

If instead of using cold aqueous potash, the substances just described are boiled with potash, a different reaction takes place. Under these circumstances, the antipyrin-derivative yields a substance of the composition $C_{12}H_{12}N_2O_2$; this is far more easily obtained, however, by boiling either of the antipyrin-derivatives with concentrated hydrochloric acid for some hours, and concentrating the solution. On cooling it deposits the hydrochloride, $C_{12}H_{12}N_2O_2,HCl + H_2O$, in white, lustrous needles. This hydrochloride loses acid on repeated crystallisation from water, the base, which is insoluble in water, being deposited. The base is insoluble in ether and benzene, but dissolves in hot alcohol, from which it crystallises on cooling in colourless, transparent prisms melting at 238° with decomposition. It is not acted on by acetic anhydride or by reducing agents, and it does not form compounds with phenylhydrazine or hydroxylamine.

When the phenylmethylpyrazolone-derivatives are boiled with potash, they are converted into "*phenylmethylmethoxypyrazolone*" (phenylmethylpyrazolone carbinol), $C_3N_2OPhMeH{\cdot}CH_2{\cdot}OH$, a substance crystallising in white nodules insoluble in water, ether, and benzene, but soluble in hot alcohol and in acetic acid. When heated at 180—185°, it loses a molecule of water, and is converted into *phenylmethylmethylenepyrazolone*, $C_3N_2OPhMe{:}CH_2$; this substance is more conveniently prepared, however, by merely boiling the alcoholic or acetic acid solution. It forms long, orange-yellow needles which melt at 178°. By the reducing action of zinc and acetic acid, it is converted into a compound which crystallises in slender, colourless needles melting at about 120°. It is, in all probability, a *phenyldimethylpyrazolone* of the formula  $\left.\begin{matrix}NPh{\cdot}CO\\ | \\ N{=}CMe\end{matrix}\right>CHMe$.

When treated with hydrochloric acid, the phenylmethylpyrazolone-derivatives undergo a totally different change. On boiling the tartronylcarbamide for a short time with concentrated hydrochloric acid, a new compound is precipitated in orange-red needles which decompose at 250° without melting. It is insoluble in water, and but little soluble in alcohol. As analysis showed that it was formed from the tartronylcarbamide by the elimination of H_2O, it in all probability is *phenylmethylpyrazolonemalonylcarbamide*,

$$\left.\begin{matrix}NPh{\cdot}CO\\ | \\ N{=}CMe\end{matrix}\right>C\left<\begin{matrix}CO{\cdot}NH\\ CO{\cdot}NH\end{matrix}\right>CO.$$

The oxidising action of nitric acid on these compounds completely destroys the alloxanic chain; in the case of the antipyrin-derivatives with formation of nitroantipyrin. C. E. G.

Reduction of Quinoline-derivatives. By E. BAMBERGER (*Ber.*, 22, 353—355).—Tetrahydroquinoline is not reduced by sodium and boiling amyl alcohol. When moist carbonic anhydride is passed into a solution of tetrahydroquinoline in light petroleum, a heavy, oily carbonate is precipitated, and gradually solidifies to a mass of colourless crystals.

β-Naphthaquinoline yields two isomeric octohydro-derivatives, which have probably the constitution  $C_6H_4\left<\begin{matrix}CH_2{:}CH_2\\ C_5NH_9{-}\end{matrix}\right>$ and  $C_6H_8\left<\begin{matrix}CH{:}CH\\ C_5NH_7{-}\end{matrix}\right>$. The former is produced in by far the larger quantity, and melts at 91°, the latter melting at 60°. Both compounds are easily obtained in crystals, and differ fundamentally both in chemical and physiological properties.

α-Naphthaquinoline, when treated in like manner, yields a crystalline octohydride, $C_6H_8<\genfrac{}{}{0pt}{}{CH:CH}{C_5NH_7}>$, which in its properties resembles the β-derivative melting at 60°. F. S. K.

Quinoline-derivatives from Ethyl Orthonitrobenzoylmalonate. By C. A. Bischoff (*Ber.*, **22**, 386—388).—*Ethyl α-ethoxy-γ-hydroxy-β-quinolinecarboxylate*, $OEt·C_9NH_4(OH)·COOEt$ [= 2′ : 4′ : 3′], is formed when ethyl orthonitrobenzoylmalonate dissolved in absolute alcohol is treated in the cold with zinc-foil and hydrogen chloride. It crystallises in small, colourless needles, melts at 107°, and the solutions give a violet coloration with ferric chloride.

When ethyl orthonitrobenzoylmalonate is treated with hydrochloric acid and zinc-dust at the ordinary temperature, or if it is heated with zinc-dust and glacial acetic acid, various products are obtained, amongst which seem to be the ethereal salt described above, hydrogen ethyl salts, and *dihydroxyquinolinecarboxylic acid*, [$(OH)_2$: COOH = 2′ : 4′ : 3′]. This acid, which could only be isolated in the form of the silver salt, is converted into α-γ-dihydroxyquinoline (compare Baeyer and Bloem, Abstr., 1883, 197, and Friedländer and Weinberg, *Ber.*, **15**, 2683) when boiled for a long time with concentrated hydrochloric acid.

When ethyl orthonitrobenzoylmalonate is reduced with tin and hydrochloric acid in dilute alcoholic solution, α-γ-dihydroxyquinoline, α-ethoxy-γ-hydroxyquinoline, and various blue and green compounds are formed. The yield of the dihydroxy-derivative is 80 per cent.; none of the colouring matters are true dyes.

α-Ethoxy-γ-hydroxyquinoline crystallises in colourless needles and melts at 228°.

Azodihydroxyquinoline, $N_2[C_9NH_4(OH)_2]_2$ [N_2 : $(OH)_2$ = 3′ : 2′: 4′], is obtained when nitrosodihydroxyquinoline is treated with hydrogen sulphide in ammoniacal solution It is very stable, and dyes silk, wool. and unmordanted cotton-wool a bright orange-yellow.

Nitrodihydroxypyridinecarboxylic acid, [NO_2 : $(OH)_2$: COOH = 3 : 2 : 4 : 5 or 3 : 2 : 4 : 6], is formed when dihydroxyquinoline is treated with nitric acid. Ethyl benzylorthonitrobenzoylmalonate yields on reduction a hydrogen ethyl salt of a ketone acid. This compound melts at 147°, and has the constitution

$$C_6H_4<\genfrac{}{}{0pt}{}{CO-C(C_7H_7)·COOH}{N{=}C·OEt}$$

F. S. K.

Methylquinaldone and Methyllutidone. By M. Conrad and F. Eckhardt (*Ber.*, **22**, 73—83).—*γ-Hydroxyquinaldine methiodide*, $C_{10}H_9NO,MeI + H_2O$, is obtained by heating sodium hydroxyquinaldine with methyl iodide and benzene at 140° for about three hours. It crystallises in long, satiny needles, and when anhydrous, melts at 201°. When heated in aqueous solution with silver chloride, it is converted into the corresponding *chloride*, $C_{10}H_9NO,MeCl + H_2O$, which crystallises in well-formed, prismatic crystals, melts at 217°, and yields a crystalline *platinochloride*, $(C_{11}H_{12}NO)_2PtCl_6$, melting at 240° with decomposition.

γ-Methoxyquinaldine methiodide, $C_{11}H_{11}NO,MeI$, is prepared by heating γ-methoxyquinaldine with benzene and the calculated quantity of methyl iodide at 80—100° for some hours. It crystallises in white, lustrous needles, melts when anhydrous at 201°, is sparingly soluble in cold water, and yields methyl-γ-quinaldone (Abstr., 1887, 680) on treatment with silver oxide suspended in water.

γ-Chloroquinaldine methiodide crystallises in greenish-yellow, needle-like forms.

Lutidone methiodide, C_7H_9NO,MeI, is formed by heating lutidone with methyl alcohol and an excess of methyl iodide at 140° for some hours. It is crystalline, melts when anhydrous at 242°, is readily soluble in water and methyl alcohol, and on decomposition with silver oxide is converted into methyllutidone (Abstr., 1887, 500).

Methoxylutidine is prepared by heating chlorolutidine at 150—160° with a solution of sodium methoxide in alcohol. It boils at 203°, and has a sp. gr. = 1·1011 at 24° compared with water at 15°. The *platinochloride*, $(C_8H_{12}NO)_2,H_2PtCl_6$, is a yellow, crystalline compound sparingly soluble in water; the *methiodide*, $C_9H_{14}NOI$, crystallises in long, white prisms, melts at about 204° with decomposition, and is converted into methyllutidone by treatment with silver oxide and water.

Ethoxylutidine is obtained by heating chlorolutidine with a solution of sodium ethoxide in alcohol. It is a colourless oil which boils at 215° without decomposition, and yields a crystalline *methiodide*, $C_{10}H_{16}NOI$; this melts at 196°, and on digestion with silver oxide is converted into methyllutidone. W. P. W.

Metamidoquinaldine. By GERDEISSEN (*Ber.*, 22, 244—254).—Ortho- and meta-amidoquinaldine are prepared from the corresponding nitro-derivatives. Dry quinaldine nitrate (100 grams) is gradually added to sulphuric acid (1 kilo.), and after half an hour the mixture is diluted with water (3 litres), and nearly neutralised with solid sodium carbonate. The very small amount of resin which separates on neutralising is readily removed; and on treating the acid solution with a small amount of aqueous soda (so that it still remains acid) the orthonitro-compound separates; it is then collected, treated with an excess of soda, and kept in a cool place. The yield is 37 grams of ortho- and 56 grams of meta-nitroquinaldine. The reduction to amido-derivatives is best effected by adding the nitro-compound (30 grams) to an amount of stannous chloride sufficient to reduce 40 grams, and boiling.

Methylphenanthroline, $\left.\begin{matrix}CH{=}N\\ |\\ CH{:}CH\end{matrix}\right\rangle C_9NH_4Me$ [CH : N : Me = 1 : 2 : 2′], is obtained together with an isomeride when a mixture of metamidoquinaldine (100 grams), glycerol (320 grams), and orthonitrophenol (75 grams), is gradually treated with sulphuric acid (270 grams). Amidophenol and hydroxyquinoline are also formed. The dark oily mixture of bases obtained is treated with hydrochloric acid, and the crystals covered with alcohol. The salt is then dissolved in water,

treated with ammonia, and extracted with benzene; the solution is dried with potash, distilled, and the crystalline residue extracted with ether, which dissolves only the methylphenanthroline. This is further purified by repeatedly crystallising the hydrochloride from alcohol. The free base, with 3 mols. H_2O, melts at 49—50°; it loses its water when kept over sulphuric acid, and then melts at 64—65°. It boils at above 360°, dissolves readily in cold benzene, and is soluble in boiling water, aqueous and absolute alcohol, and in ether, sparingly soluble in light petroleum. The *hydrochloride*, with 1 mol. H_2O, crystallises in needles, dissolves readily in hot water, and is soluble in hot aqueous alcohol, insoluble in ether; the *sulphate*, with 1 mol. H_2O, crystallises from alcohol in slender, silky needles; the *picrate* forms slender, sulphur-coloured needles melting at 216—217°; the *chromate* crystallises from water in very lustrous, red prisms; the *platinochloride*, with 1 mol. H_2O, the *ethiodide* (with 2 mols. H_2O), melting at 100—110°, and the *platinochloride* of the *ethochloride*,

$$C_{13}H_{10}N_2,EtCl,H_2PtCl_6,$$

are described. When methylphenanthroline is oxidised with permanganate, a *phenanthrolinecarboxylic acid*, $C_{12}H_7N_2{\cdot}COOH$, is obtained. This crystallises in pale yellow needles which melt at 208—209°, and decompose at 210° with evolution of carbonic anhydride and formation of Skraup's phenanthroline.

The *isomeric base*, $C_{13}H_{10}N_2 + 4H_2O$, crystallises from dilute alcohol in lustrous, concentrically grouped needles melting at 81—82°; the anhydrous base melts at 108—109°. It dissolves readily in hot benzene and hot dilute alcohol, and is insoluble in cold ether and cold light petroleum. It distils without decomposition. It has the constitution  $\left.\begin{matrix}CH{=}N\\ |\\ CH{:}CH\end{matrix}\right> C_9NH_4Me$ [N : CH : Me = 2 : 3 : 2′].

Methylphenanthroline,  $\left.\begin{matrix}CH{=}N\\ |\\ CH{:}CH\end{matrix}\right> C_9NH_4Me$ [N : CH : Me = 1 : 2 : 2′], prepared from orthamidoquinaldine, glycerol, orthonitrophenol, and sulphuric acid, crystallises with 2 mols. H_2O and melts at 53°; the anhydrous base melts at 75—76°. It dissolves very easily in hot benzene, readily in chloroform, rather readily in glacial acetic acid, and sparingly in ether and in light petroleum. It does not distil without decomposition. N. H. M.

Metaquinaldineacrylic Acid and Metaquinaldinealdehyde.

By F. ECKHARDT (*Ber.*, **22**, 271—285).—*Metaquinaldineacrylic acid*, $C_{13}H_{11}NO_2$, is prepared by the action of strong hydrochloric acid (300 grams) on metamidocinnamic acid hydrochloride (60 grams) and paraldehyde (45 grams) at 150°. The product is treated with water, freed from resin, and evaporated. The crystals of the crude hydrochloride (12 grams) are dissolved in water and treated with a solution of sodium acetate (12 grams), and quickly filtered from the resin which separates; after some time the free acid separates. This is repeatedly crystallised from hot alcohol and decolorised by means of animal charcoal. It forms small, slightly yellowish, monoclinic prisms, melts at 246° with decomposition, is very sparingly soluble in ether, chloroform, and light petroleum, more soluble in alcohol, benzene, and acetone. It has an acid reaction, and has at the same time basic properties, being readily soluble in dilute alkalis, less soluble in dilute acids. When heated, a small amount of a sublimate of slender needles melting at 223° is formed. The *hydrochloride*, $C_{13}H_{11}NO_2,HCl + H_2O$, crystallises in rhombic needles; it is easily dissociated; the *nitrate* (with 1 mol. H_2O) forms long, lustrous needles readily soluble in water; the *chromate* crystallises in orange-red needles; the *platinochloride* (with 2 mols. H_2O) crystallises in yellow needles; the *picrate* (with 1 mol. H_2O) separates from the alcoholic solution in groups of hair-like needles, soluble in alcohol, acetone, hot water, and acetic acid; the anhydrous salt melts at 150—152°. The *silver salt* (with 2 and 4 mols. H_2O) and the *calcium salt* (with $1\frac{1}{2}$ mol. H_2O), which crystallises in slender needles, are described. The neutral solution of the ammonium salt gives precipitates wiih various metallic salts which are described.

An *isomeric metaquinaldineacrylic acid* was obtained on one occasion from the alcoholic mother-liquor from the above acid. It crystallises in monoclinic plates (with 1 mol. H_2O) melting at 184°; it also crystallises with $\frac{1}{2}$ mol. EtOH and melts then at 204°. The *hydrochloride* crystallises in groups of very slender needles. The acid differs from that described above in the behaviour of its ammoniacal solution towards calcium and barium chlorides and magnesium sulphate: the one gives precipitates, the other does not.

Metaquinaldinealdehyde, $C_{11}H_9NO$, is obtained by dissolving the acid (10 grams) in sodium carbonate, diluting with water (500 c.c.), and adding benzene (250 grams); the whole is then cooled to 0° and gradually treated with a 6 per cent. solution of permanganate (10 grams). After 12 hours, it is filtered through calico, and the benzene separated and evaporated down; the oil thus obtained solidifies when cooled and is crystallised from light petroleum. It is purified by steam distillation. It forms white, matted hairs melting at 73°, which are readily soluble in benzene, ether, acetone, and alcohol, less so in light petroleum and hot water. The hot aqueous solution has a penetrating, unpleasant odour. The anhydrous salt melts at 61°. It reduces ammoniacal silver solutions, and yields a double compound with hydrogen sodium sulphite. The *hydrochloride* crystallises in pale-yellow needles; the *picrate* forms slender, matted needles, which blacken at 174°, and melt at 182° with decomposition; the *platinochloride*, $(C_{11}H_9NO)_2,H_2PtCl_6$, crystallises in orange-coloured, triclinic plates, melts at 211°, and is sparingly soluble in hot alcohol. When the aldehyde is heated with quinaldine and zinc chloride at 150°, a compound melting at 69° is formed. The *hydrochloride* of the phenylhydrazine-compound forms long, very thin, brick-coloured, matted hairs; the *sulphate*, $(C_{17}H_{15}N_3)_4,3H_2SO_4 + 9H_2O$, crystallises in small, brick-red needles. When metaquinaldinealdehyde (0·5 gram) is boiled with silver oxide (from 2 grams of silver nitrate), it is converted into Döbner and v. Miller's metaquinaldinecarboxylic acid (*Abstr.*, 1884, 1200).

Quinaldineacrylic acid (10 grams) was heated on a water-bath with pure chloral (35 grams), and the pulverulent hydrochloride thus formed extracted with alcohol. On evaporating the alcohol, a black, resinous substance was obtained, which was treated with hydrochloric acid; the light brown solution was precipitated with sodium carbonate, and the *trichloro-derivative*, $C_{12}NH_8O_2{\cdot}CH_2{\cdot}CH(OH){\cdot}CCl_3$, which separated, crystallised from alcohol. It forms colourless prisms melting at 201°. The *hydrochloride*, $C_{15}NH_{12}Cl_3O_3,HCl$, was repeatedly crystallised from alcohol and decolorised with animal charcoal. It crystallises in slender prisms melting above 300°. The *silver salt*, $COOAg{\cdot}CH{:}CH{\cdot}C_9NH_5{\cdot}CH_2{\cdot}CH(OH){\cdot}CCl_3$, crystallises in slender, white needles. When the resinous condensation product is treated with strong instead of with weak hydrochloric acid, the hydrochloride of a compound is obtained which only dissolves in hot caustic alkalis. This *hydrochloride* melts at 217°; the *free base*, which has the formula $C_{28}N_2H_{25}O_6Cl_5$, crystallises in needles melting at 128°.

α-Metaquinolinediacrylic acid, $C_9NH_5(CH{:}CH{\cdot}COOH)_2$, is obtained when the hydrochloride of the above trichlorinated derivative (9 grams) is heated on a water-bath with a solution of potassium carbonate (10 grams) in water (110 grains) for three hours, the product being filtered and fractionally precipitated with sodium carbonate. It melts at above 300°, is insoluble in water, sparingly soluble in hot alcohol.

N. H. M.

2′ : 3′-Dimethylquinoline. By G. Rohde (*Ber.*, **22**, 267—271). —2′ : 3′-Dimethylquinoline (Abstr., 1887, 974) crystallises in the rhombic system and boils at 261° (uncorr.) under 729 mm. pressure (not 255—260°). The platinochloride blackens at 230°; the picrate melts at 225°. The *chromate*, $(C_{11}H_{11}N)_2,H_2Cr_2O_7$, crystallises in orange-coloured spear-heads which become brown at 150° and decompose completely at 185°; the *hydrochloride*, $C_{11}H_{11}N,HCl + 2H_2O$, forms concentrically grouped needles of a vitreous lustre, very readily soluble in water and alcohol; the *sulphate*, $C_{11}H_{11}N,H_2SO_4 + H_2O$, crystallises in slender, concentrically grouped needles, extremely soluble in water, moderately soluble in alcohol, it melts at 235°; the *nitrate* crystallises in prisms very readily soluble in water and alcohol. The *methiodide*, $C_{11}H_{11}N,MeI + \frac{1}{2}H_2O$, crystallises from alcohol in groups of bright yellow, bent needles, melting at 218°. When 2′ : 3′-dimethylquinoline dissolved in sulphuric acid is treated with sufficient chromic acid to oxidise one methyl-group, an acid is obtained which is identical with Friedländer and Göhring's α-methylquinoline-β-carboxylic acid (Abstr., 1883, 1149).

The base obtained by the condensation of quinaldine with benzil (*loc. cit.*) has the formula $C_9NH_4Me{\cdot}CH{:}CPh{\cdot}COPh$; it melts at 176° (not 173°) and has a striking resemblance to acridine; the solutions of the salts show an intense green fluorescence. When heated for some hours at 180°, it is converted into a *polymeride*, which forms yellow crystals melting at 240°; this is a very feeble base and is extremely insoluble in the usual solvents. All attempts to effect a condensation between the methyl-group of the dimethylquinoline and the carbonyl-group of the benzil were unsuccessful.

N. H. M.

Action of Acetone on Ortho- and Para-amidophenol. By C. ENGLER and A. BAUER (*Ber.*, **22**, 209—215).—*Orthohydroxy-α-γ-dimethylquinoline*, $C_9NH_4Me_2{\cdot}OH$ [= 2′ : 4′ : 1], is formed together with methane when dry orthamidophenol hydrochloride (1 mol.) is heated with acetone (3 mols.) for 48 hours at 170—180°. The crude product is extracted with hydrochloric acid and acetone, and the mixed solutions distilled with steam to remove acetone and condensation products. The solution is then concentrated, partially neutralised with soda, filtered from resinous products, and the basic substances precipitated with sodium carbonate, excess being carefully avoided. The precipitate is washed with hot water, dried, dissolved in absolute alcohol, and concentrated sulphuric acid added to the solution; the precipitated crystalline sulphate, a further quantity of which can be obtained by adding ether to the alcoholic solution, is washed with alcohol and ether, dissolved in water, and, after evaporating the alcohol, potassium dichromate is added to the cold solution. The crystalline dichromate is decomposed with dilute sodium carbonate, and the base, which is precipitated in a flocculent condition, is crystallised from ether. Hydroxydimethylquinoline crystallises in prisms, melts at 65°, and boils at 281° (uncorr.). It is readily soluble in ether, benzene, alcohol, acetone, and chloroform, but only sparingly in light petroleum, and almost insoluble in water. It is slightly volatile with steam, sublimes when heated, and has an intensely bitter taste and the peculiar odour of quinoline-derivatives. It dissolves in soda, the solution giving orange or red precipitates with diazochlorides; the colouring matter obtained with β-naphthylamine dyes silk yellowish-brown. In a neutral solution of the base, ferric chloride gives a green coloration, which disappears slowly on heating but immediately on adding acids. A yellow, crystalline substance is precipitated when water is added to a hot alcoholic solution which has been previously mixed with bromine. The *sulphate*, $C_{11}H_{11}NO,H_2SO_4$, crystallises in slender needles and is soluble in water but only sparingly in hot absolute alcohol. The *hydrochloride* crystallises from hot concentrated hydrochloric acid or alcohol in yellowish, anhydrous plates, and is readily soluble in water but insoluble in ether; it sublimes without melting. The *platinochloride*, $(C_{11}H_{11}NO)_2,H_2PtCl_6 + 2H_2O$, crystallises in bright-yellow needles and loses its water at 110°. The *dichromate*, $(C_{11}H_{11}NO)_2,H_2Cr_2O_7$, crystallises in citron-yellow, microscopic needles containing water and is sparingly soluble in cold water. The *picrate*, $C_{11}H_{11}NO,C_6H_3N_3O_7$, crystallises in plates or prisms, turns brown at 200°, melts at 207°, and is completely decomposed at 210°; it is almost insoluble in water, and only sparingly in hot alcohol, benzene, chloroform, and acetone. The yield of hydroxydimethylquinoline, by the method described above, is not more than 20 per cent. of the amidophenol employed. Better results are obtained when a mixture of acetone (1 mol.) and paraldehyde (1 mol.) is saturated with hydrogen chloride, kept for two to three days, and then heated at 100° for six hours with a concentrated hydrochloric acid solution of amidophenol (⅔ mol). (Compare Beyer, Abstr., 1885, 672 and 1246.) The product is purified as described above.

Several sulphonic acids are formed when α-γ-dimethylquinoline is treated with fuming sulphuric acid; when the more sparingly soluble portion of the product is melted with soda, a mixture of substances is obtained, from which, in one experiment, a crystalline product melting above 70° was isolated. (Compare Beyer, Abstr., 1886, 629.) This substance is probably an orthohydroxyquinoline, but it is not identical with the orthohydroxy-derivative described above.

Parahydroxy-α-γ-dimethylquinoline is obtained, together with methane, when paramidophenol is heated with acetone for several days at 170—180°. The product can be purified as described in the case of the ortho-derivative or by means of the crystalline hydrochloride. The yield is only about 12 per cent. of the theoretical quantity, but better results are obtained by using a mixture of acetone and acetaldehyde as described above. It crystallises from alcohol in prisms or small plates, melts at 214° (uncorr.), and boils above 360° with partial decomposition. It is readily soluble in alcohol and acetone, but only sparingly in ether, and almost insoluble in benzene and hot water; it is readily soluble in acids and in alkalis but not in ammonia; the alkaline solutions are precipitated by carbonic anhydride and give coloured precipitates with diazochlorides. The acid alcoholic solution of the colouring matter obtained with β-naphthylamine dyes silk red. Ferric chloride produces a brown coloration in an alcoholic solution of the base, and with bromine an amorphous bromide is obtained. The *hydrochloride*, $C_{11}H_{11}NO,HCl$, crystallises from alcohol in yellowish needles, is readily soluble in water and sublimes when heated. The *platinochloride*, $(C_{11}H_{11}NO)_2,H_2PtCl_6 + 2H_2O$, crystallises in yellow needles and is sparingly soluble in water and alcohol; it loses its water at 110° and decomposes when heated more strongly. The *sulphate*, $(C_{11}H_{11}NO)_2,H_2SO_4$, crystallises from water in colourless needles and is almost insoluble in hot alcohol. The *picrate*, $C_{11}H_{11}NO,C_6H_3N_3O_7$, crystallises in large prisms, melts at 225° with decomposition, is very sparingly soluble in most ordinary solvents and almost insoluble in water. The *dichromate* is not easily obtained in crystals. F. S. K.

β-Naphthaquinaldine. By F. SEITZ (*Ber.*, **22**, 254—266).—*β-Naphthaquinaldine* crystallises in rhombic plates, melts at 82°, and distils with difficulty with steam. The *hydrochloride*, with 2 mols. H_2O, crystallises in slender, lustrous needles, sparingly soluble in cold water; the *nitrate*, with 1 mol. H_2O, forms slender needles which become pale rose-coloured when exposed to air; the *sulphate*, $C_{14}H_{11}N,H_2SO_4 + 2H_2O$ crystallises in very slender needles, very readily soluble in hot water; the *picrate* forms microscopic needles, melts at 220—221° with decomposition, dissolves very sparingly in boiling water, readily in glacial acetic acid; the *methiodide* crystallises in straw-coloured needles, melts at 241—247° with decomposition, and dissolves readily in boiling water, sparingly in alcohol.

By the action of a mixture of fuming nitric and strong sulphuric acids on β-naphthaquinaldine, four nitro-compounds are formed, two of which are soluble and two insoluble in alcohol.

Dinitro-β-naphthalquinaldine, $C_{14}H_9N(NO_2)_2$, is obtained by crystallising that portion of the product which is soluble in alcohol from glacial acetic acid, and melts at 226—227°. The other soluble compound melts at 250°; it was not further examined.

A second *dinitro-derivative* crystallising in long, yellowish needles, melting at 230°, and the *tetranitro-compound*, $C_{14}H_7N(NO_2)_4$, which crystallises in yellowish-brown, lustrous plates melting at 277°, are insoluble in alcohol, and are separated by crytallisation from glacial acetic acid.

A third *dinitro-derivative* is formed when dry β-naphthaquinaldine nitrate is added to strong sulphuric acid. It crystallises in colourless needles, melts at 205—212°, dissolves readily in benzene and is insoluble in light petroleum.

Carboxyphenylpicolinecarboxylic acid, $COOH{\cdot}C_6H_4{\cdot}C_5NHMe.COOH$ [$C_5N : COOH = 1 : 2$; $C_6H_4 : Me : COOH = 3 : 6 : 2$], is obtained by treating β-naphthaquinaldine (10 grams) suspended in water ($1\frac{1}{2}$ litre) with sulphuric acid (10 grams), and adding to the cold solution potassium permanganate (30 grams), dissolved in water (500 c.c.). Orthophthalic and naphthaquinolinecarboxylic acids are also formed. It crystallises in needles (anhydrous) or in prisms (with 1 mol. H_2O), melts at 201° with violent evolution of carbonic anhydride, and is very sparingly soluble in cold water. *Sodium carboxyphenylpicolinecarboxylate*, $C_{14}H_9Na_2NO_4 + 2H_2O$, forms slender needles, sparingly soluble in boiling alcohol, readily in water; the *potassium salt* is more readily soluble; the *zinc salt* (with $1\frac{1}{2}$ mol. H_2O) is almost insoluble in water; the *copper salt* (with $1\frac{1}{2}$ mol. H_2O) crystallises in microscopic, bluish-green plates. The formation of the acid from β-naphthaquinaldine is analogous to that of β-phenylpyridinedicarboxylic acid from β-naphthaquinoline (Skraup and Cobenzl, Abstr., 1883, 1011). Assuming the acid to have the constitution given above, β-naphthaquinaldine would have the constitution  $C_{10}H_6\!<\!\begin{matrix}N=CMe\\ CH:CH\end{matrix}$ [$CH : N = 1 : 2$].

β-Naphthaquinolinecarboxylic acid,  $C_{10}H_6\!<\!\begin{matrix}N=C{\cdot}COOH\\ CH:CH\end{matrix}$ [$CH : N = 1 : 2$], is obtained as sodium salt by extracting the manganese dioxide formed in the above oxidation experiment with dilute aqueous soda. The acid crystallises from alcohol in very slender, matted needles, which melt with decomposition at 187°; when heated on platinum foil, it evolves irritating vapours. It is almost insoluble in water, sparingly soluble in alcohol and boiling glacial acetic acid. The *sodium salt*, $C_{14}H_8NaNO_2 + 2\frac{1}{2}H_2O$, crystallises in very lustrous scales or needles, sparingly soluble in cold water. The *barium salt* (with 4 mols. H_2O) separates as a flaky precipitate, which becomes crystalline by prolonged boiling; the *copper salt* (with $1\frac{1}{2}$ mol. H_2O) is insoluble in water. The *hydrochloride*, $C_{14}H_9NO_2,HCl$, crystallises in yellow, hair-like needles, and is readily decomposed by water and alcohol; the *platinochloride*, $(C_{14}H_9NO_2)_2,H_2PtCl_6 + 2H_2O$, forms yellow, matted needles, very sparingly soluble in hot dilute hydrochloric acid; water decomposes it readily. The production of the carboxylic acid in the oxidation of β-naphthaquinaldine corresponds with the formation of quinaldic acid from quinaldine (Döbner and v. Miller, Abstr., 1884, 185).

When β-naphthaquinolinecarboxylic acid is heated at 190—200°, β-naphthaquinoline is formed. The platinochloride crystallises with 2 mols. H_2O (not 1 mol. Compare Skraup and Cobenzl, *loc. cit.*, and Lellmann and Schmidt, *Ber.*, **20**, 3156).

Trichlorhydroxyethylidene-β-naphthaquinaldine, $C_{16}H_{10}NCl_3 + H_2O$, is prepared by v. Miller and Spady's method (Abstr., 1886, 264), by the action of chloral on β-naphthaquinaldine (equal mols.). The reaction takes place with rise of temperature. The whole is then heated for five hours on a water-bath. It crystallises in rhombs, melts at 185°, is insoluble in water, almost insoluble in ether; the best solvent is boiling benzene. N. H. M.

Oxidation of β-Naphthaquinolinesulphonic Acid. By C. Immerheiser (*Ber.*, **22**, 402—411).—The β-naphthaquinolinesulphonic acid was prepared by Skraup's method from pure β-naphthylamine-α-sulphonic acid (Abstr., 1885, 561).

β-Phenylpyridinesulphodicarboxylic acid,

$$SO_3H{\cdot}C_6H_3(COOH){\cdot}C_5NH_3{\cdot}COOH$$

[$C_5N : COOH : SO_3H = 1 : 2 : 6$; $C_6 : COOH = 3 : 2$], is formed by oxidising a 1 per cent. solution of potassium β-naphthaquinolinesulphonate with the calculated quantity of potassium permanganate in ½ per cent. solution. It crystallises from water in transparent, colourless, hard crystals, has an unpleasant, sour taste, and is readily soluble in hot, sparingly soluble in cold water, and almost insoluble in alcohol, ether, benzene, &c. The *potassium*, *barium*, *silver*, and *lead* salts were prepared, but could not be obtained in crystalline form.

β-Pyridinephenyleneketonesulphonic acid,  $SO_3H{\cdot}C_6H_3{<}\genfrac{}{}{0pt}{}{CO\text{—}}{C_5NH_3}{>}$, is prepared by oxidising a solution of potassium β-naphthaquinolinesulphonate in 50 times its weight of 20 per cent. aqueous potash with the calculated quantity of potassium permanganate in ½ per cent. solution. It crystallises from water in scales with 1 mol. H_2O, is readily soluble in hot, and sparingly soluble in cold water, and is almost insoluble in alcohol and ether. The *potassium* salt with 1 mol. H_2O crystallises in long, yellow needles, or in yellow, transparent, monoclinic prisms; the *barium* salt with 2 mols. H_2O crystallises in tufts of yellow needles; the *silver* salt with 1 mol. H_2O crystallises in slender, yellow, hair-like forms; the *lead* salt with 3 mols. H_2O crystallises in lustrous, yellow needles. The *phenylhydrazone*,

$$C_{13}H_7NSO_3{\cdot}N_2HPh,$$

crystallises from acetic acid in small, red needles, decomposes at 295° without melting, and is insoluble in almost all solvents; the *oxime*, $C_{13}H_7NSO_3{:}NOH$, forms yellowish, crystalline flocks, decomposes at 290° without melting, and is sparingly soluble in cold water.

W. P. W.

Condensation of Paranitrobenzaldehyde with Quinaldine. By W. Bulach (*Ber.*, **22**, 285—290).—When a dry ethereal solution of paranitrobenzylidenequinaldine (Abstr., 1887, 976) is treated with bromine, the compound $C_{17}H_{12}N_2O_2Br_2$ is formed; this crystallises from alcohol in lustrous, gold-coloured, matted needles which become brown at 230° and melt at 276°.

Amidobenzylidenequinaldine, $C_{17}H_{14}N_2$, prepared by reducing the nitro-compound with tin and hydrochloric acid, crystallises from weak alcohol in long, gold-coloured needles melting at 172—173°. It is also formed when the base $C_{17}H_{14}N_2O_2$ (*loc. cit.*) is reduced with tin and hydrochloric acid. The *acetyl-derivative*, $C_{19}H_{16}N_2O$, prepared by heating the amido-base with acetic anhydride in a reflux apparatus, crystallises from alcohol in large, tabular, monoclinic crystals which melt at 194° and dissolve readily in alcohol and light petroleum.

Parahydroxybenzylidenequinaldine, $C_9NH_6{\cdot}CH{:}CH{\cdot}C_6H_4{\cdot}OH$, is obtained by diazotising the amido-base and boiling the product with water; it forms brown crystals melting at 255° with decomposition. With β-naphtholdisulphonic acid, the *diazo-compound* yields a dye which colours silk copper-red.

Diquinolylethylene (*ethylenediquinoline*), $C_2H_2(C_9NH_6)_2$, [$CH = 2'$; $CH = 3$], is prepared by heating paramidobenzylidenequinaldine (20 grams) with glycerol (70 grams), sulphuric acid (30 grams), and orthonitrophenol (14 grams) in a reflux apparatus; the heating is discontinued as soon as gas is evolved, as the reaction becomes very violent; it is then heated for one or two hours. The product is diluted with water, saturated with potash and boiled; the resin is dissolved in benzene and boiled with animal charcoal. It crystallises in groups of needles, melts at 146—147°, is sparingly soluble in alcohol and benzene, readily in glacial acetic acid. The *hydriodide* crystallises in brick-red prisms; the *sulphate* in needles. The *dibromide*, $C_2H_2Br_2(C_9NH_6)_2$, crystallises in needles, becomes brown at 280°, and does not melt at 300°; it is readily soluble in hot alcohol. When ethylenediquinoline is heated with hydriodic acid and amorphous phosphorus at 150°, the compound $C_{20}H_{16}N_2$ is formed; this crystallises in lustrous prisms melting at 106·5°.

Ethylenequinolinequinaldine, $C_9NH_6{\cdot}CH{:}CH{\cdot}C_9NH_5Me$ [$CH = 2'$; $CH : Me = 3 : 2'$], is prepared by adding a slight excess of paraldehyde to paramidobenzylidenequinaldine (20 grams) and hydrochloric acid (70 grams) heated at 150°; the reaction soon becomes violent. It is heated for five hours, diluted with water, filtered, and treated with aqueous soda; the resin is dried and repeatedly extracted with alcohol. It is purified by means of the picrate, and the free base crystallised from petroleum (b. p. 100—130°). It crystallises in lustrous, reddish plates, melts at 157·5°, and dissolves very easily in alcohol, ether, and chloroform, less readily in benzene. The salts are mostly sparingly soluble, gelatinous substances. N. H. M.

The Sulphur of Proteïds. By A. Krüger (*Pflüger's Archiv*, **43**, 244—264).—Mulder (*Annalen*, **61**, 121) was the earliest to investigate the condition of the sulphur contained in proteïds, and the fruit of his work was his "Proteïn Theory." He observed that the sulphur is readily separated from the remainder of the proteïd, and the sulphur-free radicle proteïn was supposed to be combined with different amounts of sulphur, so producing different proteïds.

Liebig and others, who showed the inaccuracy of Mulder's work and conclusions, pointed out that warming a proteïd with potash not only removed sulphur but ammonia; and even though the residue gives no further colour with lead salts, it still retains some sulphur.

It is thus possible to speak of two forms of sulphur in proteïd: that which is loosely and that which is firmly combined; and Danilewsky (*Zeit. physiol. Chem.*, **7**, 440) further differentiated the loosely combined sulphur into four varieties according as to whether it was removable with a ½, 2, 5, or 10 per cent. solution respectively of sodium hydroxide. The slowness of the alkali in removing all removable sulphur is analogous to what occurs in cystin (Goldmann and Baumann, Abstr., 1888, 519). The total sulphur (S) and the loosely bound sulphur (L) were estimated in white of egg and fibrin. The results were as follows:—

	S.	L.	S : L.
White of egg	1·66	0·44	4 : 1·06
Fibrin	1·20	0·38	3 : 0·95

There appear to be certain native proteïds which give no blackening with lead and alkali: these contain about 0·8 per cent. or less of sulphur, and seemingly all is in the firmly combined condition. Legumin (sulphur 0·4 per cent., Ritthausen), and caseïn (sulphur 0·8 per cent., Hammarsten) are examples of these.

The proteïd which had been treated with potassium hydroxide for the removal of the loosely combined sulphur was then examined: it was found to be an amorphous peptone-like substance which by saturation with ammonium sulphate was separated into two substances: one precipitable by the salt gave the reactions of an albumose, the other left in solution was a peptone (in Kühne's sense of the word). The percentage composition of these substances was as follows:—

	C.	H.	N.	S.	O.	Ash.
Egg albumin ...	52·98	7·09	15·70	1·6—1·8	22·41	—
Propeptone.....	55·76	6·93	14·46	1·28	21·57	(0·31)
Peptone	48·06	6·73	11·70	0·47	33·04	(2·88)

	C.	H.	N.	S.	O.	Ash.
Fibrin	52·50	6·95	16·57	1·22	22·76	—
Propeptone	55·26	6·75	15·46	0·79	21·74	(0·21)
Peptone	52·58	6·60	14·43	0·47	25·92	(0·85)

In the propeptone in both cases there is a fall in the percentage of nitrogen and sulphur, which is still more marked in the peptone. The sulphur in the propeptone is approximately equal to that in the mother substance which was in the firmly combined condition; and the composition of the two propeptones is nearly the same: thus a substance appears to be formed from different proteïds which has the same composition and which contains all the firmly combined sulphur. The composition of the two peptones is, however, very different, and they are probably produced from the propeptones by further hydrating action; the loss of sulphur is probably due to the formation of another sulphur-containing organic compound that escaped detection; sulphates are not formed.

The concluding portion of the paper is devoted to a theoretical consideration of the probable way in which the sulphur is actually present in the proteïd. Tables are given of the chief sulphur-containing substances known, and as to whether or not they are blackened by lead and alkali. The number of those that are not blackened is much smaller than those that are. The firmly bound sulphur is compared to that in mercaptan, thioether, and sulphinic compounds, and the loosely combined sulphur to that in thio-acids, cystin, and compounds in which either the group ⁝C⁚S or ⁝C·S·S·C⁚ is present.

W. D. H.

Myosin. By R. H. Chittenden and G. W. Cummins (*Studies from Lab. Physiol. Chem., Yale Univ.*, **3**, 115—138).—Ammonium chloride solutions were found the most efficacious in extracting myosin from flesh. The salt was removed by dialysis, and the myosin obtained in a jelly-like condition. This appears to be, as pointed out by Halliburton, a genuine recoagulation rather than a simple precipitation (Abstr., 1887, 984). A large number of preparations were made from different animals, and the results of elementary analysis show a very close agreement. With regard to the temperature of heat-coagulation of this proteïd, the results differ slightly in different animals, and also differ, to a slight extent, from those obtained by Halliburton: this is, no doubt, to be explained by the character of the saline solution used, Halliburton having used a magnesium or sodium sulphate solution. The general results justify the assumption that myosin as it occurs throughout the animal kingdom is a single chemical compound formed, as suggested by Halliburton, by the interaction of one or more myosinogens and a ferment.

W. D. H.

Caseoses, Caseïn Dyspeptone, and Caseïn-Peptone. By R. H. Chittenden and others (*Studies from Lab. Physiol. Chem., Yale Univ.*, **3**, 66—105).—This paper gives fuller and further details than were before published (Abstr., 1888, 76) of the properties and elementary composition of the peptone formed from caseïn, of the intermediate products (caseoses), and of an insoluble bye-product formed during the earlier stages of the digestive process (caseïn-dyspeptone).

W. D. H.

Reduced Hæmoglobin. By L. Hermann (*Pflüger's Archiv*, **43**, 235).—The spectrum of reduced hæmoglobin is generally described as showing only one absorption-band. But if this band be examined carefully (whether the reduction has been produced by Stokes' reagent, ammonium sulphide, or a stream of hydrogen), it will be seen to consist of two: a wide dominant band, and, separated from it by a less brightly illuminated narrow space, a narrow band almost coincident with the D line. W. D. H.

Reducing Action of Indigo-white on Oxyhæmoglobin. By E. Lambling (*Compt. rend. Soc. Biol.*, [2], 5, 394—396).—Schützenberger (*Bull. Soc. Chim.*, 1873, 150) used indigo-white to remove the oxygen from oxyhæmoglobin, and obtained by that method a result higher by 4—5 c.c. of oxygen per 100 c.c. of blood than by the method of extracting the gas by the mercurial air-pump. This difference increases with the length of time employed in the extraction of the gas by the air-pump, and it is easily explicable on the theory that the loss of the oxygen is due to its combination with the still living tissue elements in the blood, especially as the temperature at which the operation is performed is 40—50°, and, perhaps, also to the formation of methæmoglobin. Hoppe-Seyler (*Physiol. Chem.*, 451), however, considers that the reduction of oxyhæmoglobin does not stop at hæmoglobin, but goes on to hæmochromogen when indigo-white is employed: the experiments on which this opinion is based are, however, not stated. In the present research, spectroscopic observations were made on the effect of the prolonged action of a stream of hydrogen and of indigo-white respectively on solutions of oxyhæmoglobin obtained by diluting blood with water. In neither case did the bands of hæmochromogen appear, but the reduction always stopped when hæmoglobin was formed. W. D. H.

Pigments of the Urine. By C. A. MACMUNN (*J. Physiol.*, **10**, 71—121).—A full account, with plates of absorption-spectra and measurement of bands, of experiments of which an account has already appeared (Abstr., 1888, 614). W. D. H.

Physiological Chemistry.

Gases of Peptone Blood. By LAHOUSSE (*Archiv f. Anat. u. Physiol., Physiol. Abth.*, 1889, 77—82).—As compared with normal blood, the amount of carbonic anhydride in "peptone-blood" is greatly diminished, approximately to about half the normal; on the other hand, the amount of oxygen is slightly increased, namely, from 15—16 to 16—17 per cent. The experiments were performed on dogs. "Peptone blood" does not clot, and in connection with the diminution of carbonic anhydride it is interesting to note the well-known fact, that passing a stream of that gas through the blood or through "peptone plasma" will cause it to coagulate. The temperature of the body first rises slightly during "peptone narcosis," and then returns to the normal, or rather below it. W. D. H.

Amount of Hæmoglobin in the Blood during Inanition. By S. GROLL and L. HERMANN (*Pflüger's Archiv*, **43**, 239—244).—The question investigated was the relation of hæmoglobin to the total solids of the blood during starvation: the experiments were carried out on rabbits, cats, and a dog:—

If p = total solids of the blood per cent.,
h = amount of hæmoglobin, as measured by the graduations on Fleischl's hæmometer;

then $q = h/p$ is the colour quotient, which was the object of investigation. The results, which are given in tabular form in 16 experiments, show that during a state of hunger, hæmoglobin is less quickly used up than the other solid constituents of the blood. W. D. H.

Production of the Proteïds of the Blood. By S. Torup (*Compt. rend. Soc. Biol.* [2], 5, 413—416).—It is well known that peptone is absent from the blood even during the periods of most active digestion. During or immediately after absorption, the peptones are transformed either into the proteïds of the blood (fibrinogen, serum-globulin, serum-albumin), or into certain nitrogenous non-proteïd substances. The former hypothesis is that most generally held by physiologists. The present experiments bearing on this point are merely preliminary to a more detailed investigation not yet completed. They were three in number, all made on dogs. Blood was removed from the animal at three different periods extending over a week, during which time the animal received no food. The blood was analysed, and in order to prevent any alteration in the volume and pressure of the blood, a solution of sodium chloride (0·7 per cent.) was injected in amount equal to that of the blood removed.

In all three experiments, the results were perfectly concordant: one may therefore serve as an example of the whole.

	Dates.		
	2nd Feb.	4th Feb.	8th Feb.
Weight of dog	11·5 kilos.	10·85 kilos.	10·5 kilos.
Percentage of proteïds in blood	13·7	14 9	15·5
Percentage of globulin in serum	1·4	1·8	2·0
Percentage of albumin in serum	2·7	2·9	3 1
Percentage of fibrin in blood	0·18	0·22	0·41
Red corpuscles per cubic millimeter of blood	3450000	3750000	4540000
Quantity of blood in c.c.	897	—	863

The conclusions drawn are as follow:—

1. If a certain quantity of the blood is removed, and the animal is left in a state of inanition, an increase of the proteïd constituents of the blood takes place. This increase is not only relative, but absolute.

2. The increase is chiefly due to the increase in the number of the red corpuscles.

3. The increase of the proteïds of the serum is less marked, but is sufficiently manifest.

4. The increase of fibrin is considerable when the small quantity existing in normal blood is taken into account.

5. In these experiments, the increase in these constituents could not have been due to peptones absorbed from the alimentary canal.

Influence of Saline Materials on Gaseous Metabolism in Man. By A. LOEWY (*Pflüger's Archiv*, **43**, 515—532).—v. Mering and Zuntz (*Pflüger's Archiv*, **15**, 634; **32**, 173) found that when nutritive materials, either nitrogenous or non-nitrogenous, were introduced into the circulation, the oxygen taken in remained unaltered; the carbonic anhydride exhaled was increased owing to the burning off of the substance given. When the material was introduced into the stomach, the rise of oxygen used would be quite well explained by the increased work of the digestion apparatus. Voit (*Zeit. Biol.*, **14**) and Rubner (*ibid.*, **19**), on the contrary, did not find any increase in the oxygen used through activity of the alimentary tract. The work of other observers in the same direction is also quoted, and the subject is of some practical interest, as therapeutically the cures of Carlsbad, Marienbad, &c., consist in increasing the activity of the intestinal tract by the administration of saline purges. These experiments were therefore undertaken. The rabbit was the animal, and Glauber's salts the saline purge selected. Further experiments were performed on men. Such a salt can itself produce no alteration in gaseous interchange due to its own combustion.

The details of the method employed are given, and the results show in tabular form, the volume of air breathed, oxygen used, carbonic anhydride given out per minute and per cent., and, lastly, the respiratory quotient. This is given first for the normal state, then for the same person under the influence of sodium sulphate. The result constantly obtained was an increase of the gaseous exchanges in the lungs during the latter period: not only is the carbonic anhydride exhaled increased, but the oxygen taken in is increased also. Thus the results are in accord with those of v. Mering and Zuntz.

The increased metabolism appears to be due to the activity both of the muscular tissue of the intestine and of the glands, but probably the former is the more important factor concerned. W. D. H.

Digestion in Mules. By A. SANSON (*Compt. rend. Soc. Biol.* [2], **5**, 316—318).—From experiments on a horse, mule, and ass, the conclusion is drawn that the power of digesting proteïds is greater in the mule than in the horse, and that this power is inherited in the mule from the ass. W. D. H.

Influence of certain Therapeutic Agents on Amylolytic and Proteolytic Digestion. By R. H. CHITTENDEN and C. W. STEWART (*Studies from Lab. Physiol. Chem., Yale Univ.*, **3**, 60—65).—The methods employed were similar to those used in previous experiments of the kind (Abstr., 1888, 78).

Antipyrin in large doses has a slight inhibitory influence on amylolytic digestion; antifebrin or acetanilide is comparatively insoluble in water, and so large percentages could not be employed; such as were used, however, had little or no influence on amylolytic digestion. Ethylurethane slightly stimulates amylolytic action. Paraldehyde showed a very strong inhibitory power on the same kind of digestion, and this was even more marked in the case of thallin sulphate. Caffeïne and theïne in large doses produce a slight diminution in the amount of starch converted.

The action of the same drugs on gastric digestion was then investigated. Antipyrin has a decided inhibitory influence, and when present to the extent of 3 per cent. practically stops all digestive action. Antifebrin, caffeïne, and theïne have a similar inhibitory action. The retarding action of urethane is very slight, and paraldehyde and thallin sulphate have a decided stimulating action on the pepsin ferment.

On the proteolytic action of trypsin two substances only were tested, namely, antifebrin and paraldehyde; both showed a marked inhibitory action. W. D. H.

Influence of Urethane, Paraldehyde, Antipyrin, and Antifebrin on Proteïd Metabolism. By R. H. Chittenden and others (*Studies from Lab. Physiol. Chem., Yale Univ.*, 3, 39—59; and *Zeit. Biol.*, 25, 496—512).—The experiments with ethylurethane were conducted wholly upon the person of a healthy man. The experiment extended over six weeks, during which time a fixed diet was taken. Body equilibrium being established, the urine was analysed daily, first for a period without, and then for a second period with, the administration of the drug. The experiment was repeated, and the results, of which full details are given, were as follows: the drug has a decided diuretic action, most noticeable on the second day after the drug is taken; the excretion of nitrogen is decidedly below the normal, even after a dose of 5—10 grains. The phosphorus excreted seems to be slightly increased with small doses, diminished with large doses. The excretion of sulphur runs parallel with that of nitrogen. No hypnotic action was produced with the doses taken.

The experiments with paraldehyde were similarly conducted, not, however, on a man, but on a dog; the animal remained perfectly well during the experiment, exhibiting neither nausea nor sleepiness. The drug was found to produce practically no influence on proteïd metabolism.

The action of antipyrin was investigated by means of experiments on a healthy man. Urea and uric acid were estimated separately, and were found to be diminished in amount by the administration of the drug. Antifebrin (also investigated by experiments on man) slightly increases the excretion of urea, but hinders that of uric acid.

W. D. H.

Gastric Juice of Crayfish. By Stamati (*Compt. rend. Soc. Biol.* [2], 5, 16—17).—By means of a gastric fistula, the gastric juice can be easily collected from the crayfish. This secretion is yellowish, somewhat opalescent, and always alkaline. It digests fibrin rapidly, forming peptones, which give the ordinary reactions; it also transforms starch into sugar. It appears also that fats are emulsified and fatty acids liberated. W. D. H.

Secretion of Saliva. By J. N. Langley and H. M. Fletcher (*Proc. Roy. Soc.*, 45, 16—18).—The author's confirm Heidenhain's law that the precentage of salt in saliva increases with the rate of secretion. The following facts were also observed:—Stimulating the sympathetic gives saliva containing a larger percentage of salt than that obtained by stimulating the chorda. Dyspnœa increases the percentage of salts and of organic substances, as do bleeding and clamping the carotid. Injection of sodium chloride, 0·2—0·6 per cent., increases the secretion of saliva but decreases the percentage of salts. Sodium carbonate also increases the secretion. Injection of strong salt solution increases the percentage of salts and of organic substances; this being probably due to a decrease in the blood flow through the gland. The general results of the investigation are that the secretion of water, salts, and organic substances is determined by the strength of the stimulus, the character of the blood, and the amount supplied to the gland, and is not due to the stimulation of any particular nerve.

H. K. T.

Aqueous Humor. By A. GRUENHAGEN (*Pflüger's Archiv*, **43**, 377—384).—The substance in the aqueous humor that reduces Fehling's solution, and which was described by Kühn (this vol., p. 177) as sugar, cannot be sugar, as it does not ferment with yeast. The dextrorotatory action of the humor is apparently due to sarcolactic acid, together with a "still unknown dextrorotatory substance" with which it is mixed. The substance which causes the reduction of alkaline solutions of copper hydroxide is precipitable by lead acetate and ammonia; it is not precipitated by potassic-mercuric iodide, it is optically inactive, and seems not to be a carbohydrate.

W. D. H.

Reducing Substances in Urine. By HAGEMANN (*Pflüger's Archiv*, **43**, 501—514).—It has long been known that sugar is not the only substance occurring in urine which reduces alkaline solutions of cupric hydroxide. Uric acid and creatinine act similarly; but more important still are the compounds of glycuronic acid that have been more recently described. This substance occurs in normal and in certain pathological conditions, and is much increased by the administration of camphor, chloral hydrate, phenol, benzoic acid, and other drugs. The existence of this acid in urine and its reducing action similar to that of sugar, renders a very careful examination of the urine necessary in suspected cases of diabetes.

Various practical difficulties in the use of Fehling's solution are pointed out; the most important of these appears to be the difficulty of finding a trustworthy end reaction; it was, however, found that the small addition of calcium chloride prevents the mechanical suspension of cuprous oxide in the solution, and that a filtrate free from copper can be obtained when all the cupric oxide has been reduced (Flückiger, *Zeit. physiol. Chem.*, **9**, 335). It is, however, necessary in urine to test the first two drops of the filtrate; by the time the third drop comes through, oxidation of the cuprous oxide has taken place, and cupric oxide is in solution. Such rapid reoxidation does not occur in solutions of pure dextrose. But by quick filtration, and testing the two first drops as just stated, approximately equal results are obtained by titration as by Allihn's method of weighing. Using always the same amount of calcium chloride solution, it was found necessary to make a certain small addition to the amount of sugar as obtained.

In horse's urine (the animal being fed on an average diet, of which the details are given) no sugar was found, but on the average 0·004886 per cent. of reducing substances, or about 14 grams per diem. There were merely traces of uric acid and creatinine: the greater amount of the reducing substance is probably glycuronic acid. It is considered probable that glycuronic acid is derived from certain changes in proteïds, especially those occurring in the intestine of the nature of putrefaction. In animals that take large quantities of proteïd food, the amount of glycuronic acid in the urine is greater than is the case in the horse. W. D. H.

Rennet in Human Urine. By F. HELWES (*Pflüger's Archiv*, **43**, 384—396).—Rennet ferment is pretty regularly present in normal human urine, but often the amount present is exceedingly small. The small amount is what one would expect, when the fact is remembered that alkalis destroy the ferment more easily than they destroy pepsin (Hammarsten). W. D. H.

Nitrogenous Constituents of Urine. By K. BOHLAND (*Pflüger's Archiv*, **43**, 30—70).—Pflüger and Bohland found that 13·4 per cent. of the nitrogen of the urine was not combined as urea. The present research relates to this point, the amount of ammonia and ammonium salts being also determined. The total nitrogen was first estimated. Urea was then estimated by Bunsen's method after the removal of the extractives precipitable by phosphotungstic acid. The amount of nitrogen in this precipitate was estimated, and also the ammonia by Schlösing's method, both in the fresh urine and in the urine rendered alkaline after treatment with phosphotungstic acid. These processes were carried out in 13 series of urines, many of them from patients suffering from fever. The results and details of each analysis are given in full and in tabular form. The mean result was as follows:—15·54 per cent. of the nitrogen is not combined as urea: of this 0·065 exists as preformed ammonia; the nitrogen in the precipitate produced by phosphotungstic acid was 6·51 per cent. of the whole; 4·4 per cent. of nitrogen from unknown substances was found in the urine from which the precipitate produced by phosphotungstic acid had been filtered off. W. D. H.

Chemical Composition of a Kidney which had undergone Waxy Degeneration. By E. LAMBLING (*Compt. rend. Soc. Biol.* [2], **5**, 51—52).—The method of analysis employed was Hoppe-Seyler's (Gottwalt, *Zeit. physiol. Chem.*, **4**, 437). The blood was first removed by a stream of saline solution: the kidney was then reduced to a fine state of subdivision: the substances soluble in water, and in solutions of sodium carbonate, and sodium chloride removed successively. The residue was heated with water in a sealed tube at 120° to convert the collagen of the connective tissue into gelatin. The albuminoïd (amyloïd) substance was isolated in another portion of the renal tissue by the method of Friedreich and Kekulé

(*Virchow's Archiv*, **16**, 58), and then purified by Kühne's method (*Maly's Jahresber.*, **3**, 31) by artificial digestion with gastric juice and subsequent treatment with baryta-water. The percentage results compared with those of Gottwalt in healthy kidneys are as follows :—

	Healthy kidney.	Waxy kidney.
Albumin	1·116—1·394	0·792
Globulin	8·633—9·225	5·553
Other proteïds......	1·436—1·598	0·485
Gelatin............	0·996—1·849	2·685
Albuminoïd substance	—	0·992

There is thus a diminution in the proteïds present, as compared with healthy kidneys; but the percentage of albuminoïd material appears very low, considering the very advanced state of degeneration revealed by the microscope. It is considered possible that the transparent, swollen appearance of the organ may be in part due to the formation of a substance of the nature of the hyalins described by Krukenberg (Abstr., 1886, 481). W. D. H.

Influence of Arsenic and Antimony on the Glycogenic Function and Fatty Degeneration of the Liver. By R. H. CHITTENDEN and J. A. BLAKE (*Studies from Lab. Physiol. Chem., Yale Univ.*, **3**, 106—114).—From a few experiments on rabbits and fowls, it would appear that small doses of antimonious oxide long continued tend to increase the body-weight, and particularly the weight of the liver. Further, the increase in liver-weight is accompanied by an increased percentage of fat and a slight increase of glycogen in the liver. With corresponding doses of arsenious oxide, on the other hand, the results would indicate a diminution in body-weight, also a diminution in the weight of the liver and amount of liver glycogen. In some cases there is, however, pronounced fatty degeneration of the liver.

W. D. H.

Physiological Action of Uranium Salts. By R. H. CHITTENDEN and A. LAMBERT (*Studies from Lab. Physiol. Chem., Yale Univ.*, **3**, 1—18, and *Zeit. Biol.*, **25**, 513—532).—Previous experiments (Abstr., 1888, 78) have shown that uranium salts have a marked inhibitory influence on the activity of the digestive ferments; the present investigation relates to (1) the influence of uranium salts on proteïd metabolism; (2) their toxic action; and (3) the influence of uranium in the production of glycosuria.

The experiments on proteïd metabolism were conducted on dogs and rabbits; the animal under investigation was confined in a suitable cage, and fed during an experiment on a constant diet of known composition. When nitrogenous equilibrium was established, the 24 hours' urine was analysed for a number of consecutive days; uranyl nitrate was then administered with the food in gradually increasing quantities for a number of days, and the urine again examined. The points noted in the urine were reaction, volume, specific gravity, amounts of nitrogen, sulphur, and phosphorus.

In these and other cases, the presence or absence of albumin or sugar in the urine was also noted, and if present, the amount was estimated: albumin by boiling with acetic acid, and weighing the coagulum thus produced, sugar by Allihn's gravimetric method.

Experiments on the toxic action of uranium salts were confined wholly to the action of pure uranyl nitrate on rabbits.

The results obtained may be thus summarised:—Uranium is an irritant poison, and like other metallic irritants produces gastro-intestinal irritation of more or less intensity. But it is not in any sense a rapid poison, and the injection of a fatal dose is not followed by any noticeable effects for some time. The action of a small amount (0·15 gram) seems to be as rapid and pronounced as that of a larger quantity (1 gram). The first noticeable symptom is muscular weakness; the salt checks digestion, but apparently increases to a slight extent proteïd metabolism: it increases the output of carbonic anhydride, raises the body temperature, and finally leads to emaciation.

In the kidney, a condition of acute nephritis and destruction of the renal tissue is found like that produced in poisoning by arsenic, mercury, and phosphorus. Albuminuria is severe and constant. With small doses, the volume of urine is increased, but when toxic action is pronounced there may be partial or even complete suppression of that secretion. The production of glycosuria generally occurs after that of albuminuria, but it is a very constant and characteristic symptom. Salkowski has shown that mercury, and H. C. Wood (*Therapeutics*, p. 110) that phosphorus, will occasionally produce diabetes when given in toxic doses. The urine, in cases of uranium poisoning, invariably contains a large amount of crystallised calcium oxalate. In chronic poisoning by uranium, the nervous symptoms (loss of sight and of co-ordinating power) sometimes predominate.
W. D. H.

Relative Absorption of Nickel and Cobalt Salts. By R. H. CHITTENDEN and C. NORRIS (*Studies from Lab. Physiol. Chem., Yale Univ.*, 3, 148—157).—Doses of these salts were given to rabbits, the symptoms observed, and after death the relative quantities of the metal in different organs estimated. The soluble nickel and cobalt salts are possessed of decidedly toxic properties, but their poisonous action is slow and manifested only when large doses are administered. The two salts act very much alike. Both cause death by stopping the heart, and also produce enteritis and interference with digestive processes. Unlike uranium, the metals have no action on the liver or kidney. Both salts, but especially those of cobalt, produce paralysis of the extremities. The salts form in great measure insoluble compounds with the proteïds of the food, and are excreted with the fæces; part enters the circulation, and is rapidly distributed to all parts of the body, and is eliminated ultimately in the urine. The body temperature is raised, and the peripheral cutaneous vessels are constricted.

Among the organs, the spinal cord and brain stand first in their power of picking up and storing the metal; this is also the case with arsenic. As in the case of arsenic also, the muscular tissues retain a larger percentage of the metals than the liver or kidneys; the muscular tissue of the back acts in this way to a greater extent than that of the leg; this fact is not explicable on the ground of difference in vascularity. The lungs and heart also contain high percentages of the metal. W. D. H.

Physiological Action of Antharobin and Chrysarobin. By T. WEYL (*Pflüger's Archiv*, **43**, 367—377; compare Liebermann, Abstr., 1888, 518).—From experiments on man and on healthy animals, the following conclusions are drawn:—

Chrysarobin acts poisonously in very small doses, producing vomiting, diarrhœa, and albuminuria; antharobin, on the other hand, applied by inunction, subcutaneous injection, or by the stomach, is free from poisonous action. It is therefore preferable, when practicable, to use antharobin instead of chrysarobin therapeutically.

Antharobin appears in the urine for the most part unchanged; a small portion is oxidised to form alizarin. The amount of alizarin increases when the urine is left for a time. Any certain proof that chrysarobin passes into the condition of chrysophanic acid in the organism is not yet forthcoming. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Disengagement of Carbonic Anhydride with Anaerobic Yeast. By GRÉHANT and QUINQUAUD (*Compt. rend. Soc. Biol.* [2], **5**, 400).—Yeast suspended in distilled water, and placed in the vacuum of a mercurial air-pump, gives off carbonic anhydride in large quantities, but no oxygen. It thus contains carbon and oxygen in its own substance. The disengagement of gas occurs most readily at a temperature of 40°. After the action is allowed to go on for more than 24 hours, small quantities of hydrogen, and even of nitrogen, are also formed, doubtless from the occurrence of putrefaction in the proteid substances contained in the yeast cells. When this decomposition has occurred, the yeast loses its property of making sugar ferment. W. D. H.

Chemical Composition of the Bacillus from Erythema Nodosum. By V. BOVET (*Monatsh.*, **9**, 1154—1157).—Seven litres of recently sterilised beef extract, containing 5 per cent. of glycerol and 1 per cent. of peptone, were impregnated with Demme's pure culture (*Fortschritt. Med.*, April, 1888), and allowed to remain at 37—38° for eight days, when the fluid commenced to clear, and a thick layer of bacteria collected at the bottom of the containing vessel. The air-dried bacteria weighed 4·148 grams, and lost 2·9532 grams on drying at 110°, the residue having the following composition:—

Extracted by alcohol	8·97 per cent.
Extracted by ether	1·99 „
Ash (PO_4, Cl, K, Ca, and Mg)	7·5 „
Albuminoïds	64·2 „
Cellulose and other non-nitrogenous substances	17·34 „

The alcoholic extract produced no toxicological action when injected under the skin of a guinea-pig. G. T. M.

Reserve Materials, especially Tannin, contained in Evergreen Leaves. By E. SCHULTZ (? SCHULZE) (*Ann. Agronom.*, **14**, 525—526).—The author's microchemical observations support the view of Sachs and Haberlandt that the persistent leaves of evergreens serve as storehouses of reserve material in winter; at any rate, that is true as regards the Gymnosperms and the majority of Dicotyledons. The leaves of conifers contain tannin, sometimes alone, sometimes associated with starch and oil; when oil is present, it is generally in cells free from starch. The author regards tannin as a reserve material. J. M. H. M.

The Reserve Substances in Evergreen Leaves, with Special Reference to Tannin. By E. SCHULZE (*Bied. Centr.*, **18**, 137).—Evergreen leaves contain starch, fatty oil, and tannin as reserve substances. The leaves either contain two reserve substances simultaneously at the period of rest or growth, in which case they are present as starch and tannin or fatty oil and tannin, or else there is only one substance, tannin, present. When starch and tannin occur together, the latter is generally more in the elements of the assimilation tissue, and in the parenchyma sheaths of the fibrovascular bundles in the lamina, whilst the starch is more in the midrib and its immediate vicinity. Tannin and starch only rarely occur simultaneously in the same cells. When the cells are rich in starch, they contain a smaller amount of tannin, and *vice versâ.* In the case of leaves containing fatty oil and tannin, the cells which contain the oil are free from tannin. In most evergreen leaves in which tannin alone is present as reserve substance, it is equally distributed over the elements of the leaf sheath and the midrib. N. H. M.

Transformation of Force and of Material in Plant Respiration. By H. RODEWALD (*Ann. Agronom.*, **14**, 526; compare the author's previous researches, Abstr., 1878, 979).—Experiments with the thickened horny stem of the kohl rabi, arranged in such a manner as to allow simultaneous determinations of the heat evolved, the carbonic anhydride emitted, and the oxygen absorbed, show the ratio CO_2/O to be 1·061. The greater part of the combustible substance is therefore carbohydrate, and must be glucose, since starch and the dextrins are not found in this vegetable. Glucose furnishes 4·95 cal. by combustion for each c.c. of carbonic anhydride formed; in the experiments each c.c. of carbonic anhydride found corresponded to 4·57 cal., or each c.c. of oxygen absorbed to 4·46 cal. Perhaps a small quantity of a more oxygenised substance was burned with the glucose in the plant. J. M. H. M.

Absence of Nitric Acid in Wine-must. By E. POLLAK (*Chem. Zeit.*, **12**, 1623—1624).—In a previous communication, the author stated that he had detected nitric acid in certain musts, he now finds this must have been due to impurities derived from the butts, inasmuch as nitric acid was not detected in the following year either in musts of similar origin, or in the grape-juice. D. A. L.

Absence of Nitrates in Forest Trees. By E. EBERMAYER (*Ann. Agronom.*, **14**, 571).—The soil of forests, and the drainage water of such soil, contain no nitrates, hence their absence from the trees. If trees are grown in a well-manured field, or in garden soil, their organs always give the nitrate reaction with diphenylamine and sulphuric acid. J. M. H. M.

Laurel-nut Oil. By D. HOOPER (*Pharm. J. Trans.* [3], **19**, 525).—The oil examined was derived from *Calophyllum inophyllum*, which occurs throughout India and Malaya. It is thick, greenish-yellow, of fragrant odour, and of bitter taste. It congeals at 19°, and is quite solid at 16°, at which temperature its sp. gr. is 0·9315. The free acid corresponds with 1·89 parts of potash per 100 of oil; its saponification requires 19·6 per cent. of potash. It yields to alcohol 7 per cent. of a peculiar green extract, and the general results place it in close relationship with cotton-seed oil, and in an intermediate position between drying and non-drying oils. R. R.

Quince and Salep Mucus. By R. GANS and B. TOLLENS (*Annalen*, **249**, 245—257).—The syrup from the quince yields furfuraldehyde on distillation with dilute sulphuric acid, indicating the presence of arabinose or xylose, but no crystalline carbohydrate was isolated. The syrup contains neither dextrose nor galactose, as neither saccharic nor mucic acids were formed on oxidation. No furfuraldehyde is obtained by distilling salep syrup with dilute acids. On oxidation, salep yields saccharic acid but no mucic acid. With phenylhydrazine and sodium acetate, the syrup forms a precipitate which can be separated by repeated recrystallisation into the phenylhydrazine compounds of dextrose and mannose. These results show that the syrup contains dextrose and mannose, but neither galactose nor arabinose. W. C. W.

Tannic Acid in Caucasian Wild Sumach. By A. LIDOFF (*J. Russ. Chem. Soc.*, 1888, **20**, 607—608).—Tannic acid was determined by Fleck's method. The leaves and stalks of *Rhus cotinus* were found to contain 13·26 per cent. of tannic acid, the leaves of *Rhus coriaria* 15·31 per cent., and the stalks 3·40 per cent. of tannic and 11 per cent. of gallic acid. B. B.

Field Experiments at Grignon in 1888. By P. P. DEHÉRAIN (*Ann. Agronom.*, **14**, 529—554).—*Wheat.*—The experiments relate to attempts to introduce the "Square-head" wheat into cultivation in France to replace the Bordeaux wheat, the former having been found by the author to bear much heavier manuring without liability to become laid, and to give in consequence much heavier crops than the latter. The experiments of 1887 and 1888 have brought out a difference between the two stocks of Square-head seed in the author's possession, leading him to suppose that one strain may be found better adapted than another to support the greater heat of central and southern France, and may be still further acclimatised by cultivation. If Square-head, or other good yielding wheat, is grown after clover on light land, an application of manure is found beneficial; with Bordeaux wheat, on the contrary, this practice would result in the crop being laid. The summers of 1887 and 1888 were opposite in character: the former hot and dry, the latter cold and wet. The result was that in 1887 the starch in the grain increased rapidly in the week or two preceding harvest, owing to the physiological activity of the leaves; in 1888 the starch remained stationary during the same period, but there was a rapid increase in the albuminoïd and ash, the roots being able to find and carry up into the plant abundance of nitrogen compounds and minerals.

Oats.—Grown after sugar-beet in the four-course rotation, the two most prolific varieties hitherto tried by the author ("l'avoine des salines," commonly grown in the north, and Vilmorin's new variety, "l'avoine géante à grappes,") gave in 1888 mean yields of 34·6 and 33·6 metric quintals of grain, and 67·0 and 55·7 metric quintals of straw per hectare.

Forage Crops.—In certain cases, especially where there is a great demand for green stuff to be consumed on the farm, as in dairying, it may be advantageous, in climates which admit of it, to substitute for the clover which usually follows the oat crop, *T. incarnatum* and forage maize, the latter being sown at the end of June, after removal of the trifolium and a good dunging.

Sugar-beet.—The results of the previous year's experiments are confirmed. Farmers having once purchased an improved strain of seed will find it economical to grow their own seed from well-shaped, medium sized roots of 300—400 grams weight. On light lands, farmyard manure is indispensable. J. M. H. M.

Calcium in Soils. By P. DE MONDESIR (*Compt. rend.*, **108**, 185—187).—Almost all soils, and even those of the most acid character, contain a notable quantity of calcium which does not exist in the form of calcium carbonate as is usually assumed, but is present in combination with other constituents of the soil. Calcium carbonate, as a matter of fact, is absent from a large number of soils, and the sulphate, phosphate, and nitrate are present in very minute quantity, if at all. It follows, therefore, that this compound of calcium with the humoid matter is the most important form in which calcium is present in soils.

The author insists on the importance of carefully distinguishing the different forms in which calcium occurs in any soil, and of not making the usual but erroneous assumption that it occurs mainly in the form of carbonate. C. H. B.

Humous Compounds in Soil. By C. G. EGGERTZ (*Bied. Centr.*, 1889, 75—80).—The author considers that humic and ulmic acids, as generally produced from carbohydrates, are not natural, but laboratory products, whilst crenic and apocrenic acids are genuine compounds, whose properties are but little known. The real ammonium humates are completely soluble in water, whereas the artificially prepared substances are insoluble after drying. If ammonium humate is heated at 110°, or if dry humic acid is exposed to ammonia, a highly nitrogenous compound is produced, in which the nitrogen is intimately combined with the complex organic molecule. Repeated solution in alkali and precipitation by acid results in a partial decomposition, but the whole of the nitrogen is not separated. Sulphur and iron, which appear in natural humous compounds, are not present as sulphates or salt of iron, but are to be considered as combined with the organic compounds.

Humous soils owe their absorptive capacity for phosphates to the phosphorus which is combined in them, for if this phosphorus is removed by acids, &c., the humous compounds can no longer absorb phosphates. The decomposition which humic acids appear to suffer by repeated solution and precipitation, results in the formation of new compounds, which are more soluble in acids than the original substance. Silicic acid appears to be present in peaty soils in the form of ammonium silicate. The amount of matter dissolved out by 4 per cent. acid from a soil, more than represents the potential plant nutriment, as the natural acid which renders this nutriment soluble is much feebler than the acids usually employed in analysis. Ammonia acts on a soil by decomposing the humous compounds; lime acts beneficially by setting free ammonia, which again reacts on humates. E. W. P.

Analysis of Tobacco "Screenings." By L. P. BROWN (*Amer. Chem. J.*, **11**, 37—38).—This material consists of small fragments of stems and leaves, which, with the dust, are sifted from the tobacco during manufacture. It is not unfrequently applied as a top dressing to grass, &c.

Analytical Chemistry.

Kaolin Balls for Gas Analysis by Bunsen's Method. By N. A. Bunge (*J. Russ. Chem. Soc.*, 1888, **20**, 694—701).—In gas analysis, instead of using balls made of papier-maché or coke soaked with various liquids such as alkaline pyrogallol solution, sulphuric acid, &c., for the absoption of certain gases, the author recommends a mixture of kaolin and soot; this is made into a paste and formed into balls of about 10 mm. in diameter; the ball is then fastened at the end of a hooked, thick platinum wire, and compressed in an ordinary bullet mould (or as the author recommends, in a mould made of plaster of Paris). After taking the ball out of the mould, it is cleaned, smoothed, dried, and heated to redness by a Bunsen burner. In this way, a coherent, porous ball is obtained, which breaks with difficulty and may be used over and over again. The best proportions are 3 parts of kaolin to 1 part of soot. [A thick solution of honey may be added with advantage.—B. B.] In order to saturate the ball with pyrogallol solution, a thick test-tube is nearly filled with mercury, and the remaining space with a solution of 1 gram of pyrogallol in 2 c.c. of water. After adding 1·3 grams of solid potash, the test-tube is inverted over mercury. To use it, the ball is brought up from below into the solution, and as soon as no more bubbles of gas are observed to escape, it is brought into the gas to be analysed, keeping it under the mercury all the time, and not allowing it to come even for one moment into contact with air. In order to avoid the tedious process of transferring gases, described by Bunsen*, the author uses Doyère's trough and Salet's pipette, the last so modified as to admit of the explosion of gases in it. Instead of determining as steam, the volume of water formed in the combustion of hydrocarbons and gaseous mixtures, the author proposes to determine by absorption the amount of oxygen remaining after the explosion and absorption of carbonic anhydride; the oxygen added must in this case be absolutely pure.

B. B.

---

* It is to be regretted that Bunsen has not yet described his simple apparatus for transferring gases after the absorption of carbonic anhydride by a solution of caustic soda. This, with many other undescribed pieces of apparatus, has been in use in his laboratory since 1878.—B. B.

Quantitative Estimations by Measurement of Electric Conductivity. By E. REICHERT (*Zeit. anal. Chem.*, **28**, 1—25).—The electric conductivity of a solution is a function of its strength, so that when only a single electrolyte is present, its amount can be ascertained from the conductivity of the solution. The author proposes to call this the *rheometric* method. It can be used with especial advantage for solutions which are too dilute for the densimetric method.

The apparatus consists of a galvanic element, a simple induction coil with alternate currents, packed up so as to be inaudible, a bridge with appropriate means of introducing resistance, a telephone, and the cells for the solutions. These are in the form of pyknometer bottles, with delicate thermometers ground into the necks, and are somewhat varied in construction according to the degree of conductivity to be measured. The conductivity of electrolytes is largely influenced by temperature, the cells are therefore so arranged that contact can be instantaneously made by pushing them into a spring clip at the right moment. The electrodes consist of thin platinum foil fused into the walls of the bottles. To avoid polarisation they are platinised. It is necessary that the cells should stand on a perfectly level surface, otherwise the resistance will be different when measured in opposite directions. The mercury resistance values of the cells is ascertained by filling one of them with a solution of known conductivity—such as a 23·7 per cent. solution of zinc sulphate absolutely free from acid, which according to Kohlrausch has a conductivity of 4·52 Siemens' units (taking mercury as 10^6). The other cells can be compared with the first, using solutions of appropriate conductivity.

The author has employed this method for the determination of the amount of mineral matter in sugar, molasses, &c. The sugar and accompanying organic matters are practically non-conductors. The conductivity is proportional to the amount of ash, and the results for widely varying percentages of ash agree closely with those obtained by chemical methods. Dilute solutions (13 or 26 grams per litre) give the best results, when a correction is made for the conductivity of distilled water. The resistance does not increase with dilution in the same ratio as in pure salt solutions, in consequence of the simultaneous diminution in viscosity. Denoting as the viscosity (z) of a solution the value $\frac{p}{k} = \frac{\text{ash in 100 c.c.}}{\text{conductivity}}$, and plotting the values of p as abscissæ and z as ordinates on a system of rectangular co-ordinates, the curve obtained is in all cases sensibly a straight line. Denoting by b the intercept on the axis of ordinates, and by a the increase of z for 1 per cent. of ash in the usual equation $z = ap + b$, the value of b is almost exactly the same, viz., 0·845, for all the specimens of sugar, molasses, &c., examined, whilst the value of a diminishes with the increase in the percentage of ash in the solid sugar, being roughly proportional to the percentage of sugar divided by the percentage of ash.

The method appears also to have some value for the examination of natural waters. The specific conductivity multiplied by 72·28 gives approximately the number of milligrams of solid residue per litre. It is pointed out that variations in the purity of a water stream could be observed at a distant station by means of the telephone.

M. J. S.

Use of Hydrogen Peroxide in Analysis. By F. P. DUNNINGTON (*Chem. News*, **59**, 76).—The presence of hydrogen peroxide assists the solution of lead peroxide in nitric acid. Precipitated or ignited manganic oxide or ignited ceric oxide also dissolves readily in dilute acids if mixed with hydrogen peroxide. D. A. L.

Estimation of Water in Silicates, such as Tourmalin, Vesuvian, &c. By P. JANNASCH (*Ber.*, **22**, 221—223).—To estimate the water in tourmalin and other minerals, the finely divided substance is dried over calcium chloride for an hour and intimately mixed with a large quantity of very finely divided, dry lead chromate. The mixture is placed in the hinder part of an ordinary bayonet-shaped combustion tube, 46—47 cm. in length, between two layers of finely powdered, dry lead chromate. A rather longer layer of coarsely powdered, dry lead chromate is then placed on each side and lastly a copper spiral. A weighed calcium chloride tube and a weighed soda-lime tube, guarded by a small soda-lime tube, are attached, and the process is then carried out just as in an ordinary elementary analysis. A stream of dry air is passed through the apparatus during the whole operation, and the mixture of mineral and lead chromate should be heated as strongly as possible for about half an hour. The quantity of carbonic anhydride can be estimated at the same time from the increase in weight of the soda-lime tube.

F. S. K.

Source of Error in the Determination of Nitrogen in Substances containing Halogens. By R. ZSIGMONDY (*Zeit. anal. Chem.*, **28**, 58—60).—In determining nitrogen by Dumas' method, and employing cupric oxide containing chloride, the results are apt to come out too high. This is due to the absorption of oxygen by the cuprous chloride (which takes place at 100—300°), when, for the purpose of oxidising the copper reduced in a previous analysis, the contents of the combustion tube are ignited and cooled in a current of that gas. This oxygen is given up again on strong ignition, and may in part be carried over with the nitrogen. It may be arrested by sufficiently increasing the length of the plug of metallic copper in the front part of the tube, but sharper results are obtained by substituting a stream of carbonic anhydride for the oxygen during the cooling after oxidation. With this modification, the use of cupric oxide for the combustion of substances containing halogens is perfectly admissible, and yields highly satisfactory results.

M. J. S.

Estimation of Nitrogen by Kjeldahl's Method. By C. VIOLLETTE (*Compt. rend.*, **108**, 181—183).—The nitrogen in a sample of cake prepared from the residues from the fermentation of maize was estimated by soda-lime, by Dumas' method, and by Kjeldahl's method; these gave respectively the following results: 4·17, 4·29, 4·29 per cent.

Nordhausen sulphuric acid was used instead of the ordinary concentrated acid. Like L'Hote (this vol., p. 438), the author finds that the use of mercury accelerates the operation, but also that in some cases it tends to give low results, probably owing to the formation of some mercury ammonia-derivative which is not decomposed by boiling with sodium sulphide and hydroxide. C. H. B.

Estimation of Nitrogen in Nitrates by Kjeldahl's Method. By O. FOERSTER (*Chem. Zeit.*, **12**, 1555).—0·5 gram of potassium nitrate is dissolved in 15 c.c. of phenolsulphonic acid (5 per cent. phenol), and mixed with 1 to 2 grams of crystalline sodium thiosulphate, being kept cool during both operations; the estimation is then continued in the usual manner. The author's results are 0·09—0·18 per cent. too low, this is attributed to small quantities of ammonia escaping absorption by the acid. (Compare Scovell, this vol., p. 308.) D. A. L.

Detection of Nitrates in Soils. By KREUSLER (*Bied. Centr.*, 1889, 74—75).—The diphenylamine reaction which is employed for the detection of nitrates in soils is not infallible, as salts of ferric and manganese oxide also produce a blue coloration. The brucine reaction is likewise produced by the higher oxides of manganese, although not by iron compounds. E. W. P.

Estimation of Nitrogen and Phosphoric Acid in Organic Substances. By O. LANGE (*Chem. Zeit.*, **12**, 1587—1588).—The following plan allows the estimation of phosphoric acid by the citrate method, and of nitrogen by Kjeldahl's method to be made in the same portion of substance, and gives results which compare well with those obtained in the usual way.

10 grams of the substance is heated with 50 c.c. of concentrated sulphuric acid and 0·5 to 1 gram of copper sulphate in a half-litre flask; when the reaction is complete, the flask is filled to the mark, 50 c.c. of the solution is mixed with 100 c.c. of Märcker's citrate solution and 25 c.c. of magnesia mixture for the estimation of phosphoric acid; whilst the nitrogen is determined in another 50 c.c. by distillation with soda. D. A. L.

Estimation of Phosphoric Acid in Sweet Wines. By W. FRESENIUS (*Zeit. anal. Chem.*, **28**, 67—71).—In wines containing much sugar, a loss of phosphoric acid takes place during the incineration of the residue. A higher result is obtained when the residue is deflagrated with alkaline carbonate and nitrate. Destruction of the sugar by fermentation before incinerating leads to the same result. When time allows, this should be effected by adding only a trace of yeast, since then no correction for the phosphoric acid in the yeast is required, and the amount of organic matter to be burnt is kept as low as possible.

Attention is called to the possibility of manufacturing sweet wines without either the addition of sugar or concentration of the must, by arresting the fermentation at an early stage by the addition of alcohol.

The determination of the glycerol affords the best indication whether this has been the case or not, since with normal fermentation the glycerol should be from 7 to 10 per cent. of the alcohol present.

M. J. S.

Estimation of Phosphoric Acid in the Presence of Ammonium Citrate. By F. SEYFERT (*Chem. Zeit.*, **12**, 1390).—The complete precipitation of ammonium magnesium phosphate (compare Stutzer, this vol., p. 186) or barium sulphate, or calcium oxalate, may be considerably accelerated by stirring 20—30 times with a feather with the barbs cut short, at the same time rubbing it vigorously against the sides of the beaker; as soon as the precipitate has settled to some extent, it may be filtered without pressure, and the whole analysis finished in a fraction of the time usually required.

D. A. L.

The Molybdate Test for Hypophosphites. By E. J. MILLARD (*Pharm. J. Trans.* [3], **19**, 585).—Although it has been stated by Winkler (*Ann. Phys. Chem.* **111**, 443) and others that hypophosphorous acid and hypophosphites give a blue colour or precipitate with ammonium molybdate, the author has never been able to obtain such a reaction with acid, neutral, or alkaline solutions of the molybdate, or he has obtained at most only a faint coloration after a considerable time. On the other hand, he finds that the addition of a small quantity of sulphurous acid renders the test a most delicate one, and one with which the ordinary nitric acid solution of ammonium molybdate answers well. Phosphates, pyrophosphates, and phosphites do not give the reaction when similarly treated. In pure solutions it is possible to detect 1 part of hypophosphorous acid in 2000.

R. R.

Arsenic in Bone Phosphate used for Cattle Feeding. By H. FRESENIUS (*Zeit. anal. Chem.*, **28**, 64—57).—It has long been the practice to mix with cattle fodder a certain quantity of precipitated calcium phosphate, manufactured by treating bones or bone-ash with hydrochloric acid and precipitating with milk of lime. If the hydrochloric acid used contains arsenic this passes into the precipitate, and, according to its proportion, may act either beneficially as a tonic, or injuriously as a poison. To determine it, the method of R. Fresenius and Hintz was found the most advantageous. 10 grams of substance is mixed in a retort with 100 c.c. of hydrochloric acid (1·19) and 5 c.c. of a saturated solution of ferrous chloride, and the acid is distilled off down to a small residue. The whole of the arsenic is obtained in the distillate, which is free from all but traces of organic matter, so that it is in a very suitable condition for precipitation as trisulphide. In 25 samples examined during the past year, the arsenic varied from 0·028 to 0·17 per cent. No data exist for fixing the admissible maximum in a cattle food.

M. J. S.

Apparatus for the Electrolytic Estimation of Metals. By L. C. LEVOIR (*Zeit. anal. Chem.*, **28**, 63).—The solution to be electrolysed is contained in a large platinum basin resting upon three metallic knobs connected with the positive pole of the battery. The cathode consists of a smaller platinum basin suspended concentrically within the former at a distance of about 30 mm., by means of three wires and a hook which dips into a pool of mercury in the wooden arm of the stand. The evolution of oxygen which takes place at the surface of the larger basin keeps the liquid well mixed and facilitates the rapid and regular deposition of the metal on the outside of the inner basin. M. J. S.

Estimation of Zinc in presence of Manganese. By G. NEUMANN (*Zeit. anal. Chem.*, **28**, 57—58).—The author had studied the precipitation of zinc from a formic acid solution before the publication of the method by Bragard (Abstr., 1888, 689). The process affords a simple, rapid, and accurate separation of zinc from manganese, iron, and nickel. M. J. S.

Volumetric Estimation of Lead in presence of Tin. By YVON (*J. Pharm.* [5], **19**, 18—21).—Having had occasion to make a number of determinations of lead in presence of tin, the author devised a method which requires neither the separation of the tin nor the washing of precipitates. The lead-tin alloy is treated with nitric acid, by which the lead is dissolved and the tin converted into insoluble stannic acid. The excess of nitric acid is neutralised by the addition of a very slight excess of sodium hydroxide, and a few drops of acetic acid in excess are added. The solution is then diluted so as to contain not less than ½ per cent. of lead, and titrated with normal potassium ferrocyanide solution (10·201 grams per litre) which has been standardised against a normal lead nitrate solution (15·987 grams per litre), using drops of dilute ferric chloride solution on a porcelain slab as indicator. The process is very rapid and sufficiently exact for many purposes. J. T.

Testing Glass by Colour Reactions. By F. MYLIUS (*Ber.*, **22**, 310—314).—An aqueous solution of iodine kept in sealed tubes for a few weeks is completely decolorised owing to the action of the alkalis contained in the glass; on adding dilute sulphuric acid, the solution again becomes coloured. When a trace of a very dilute solution of silver acetate or nitrate is added to an aqueous solution of starch and pure iodine the latter becomes yellowish or colourless, owing to the combination of the free hydriodic acid; if, now, a little powdered glass is added the solution is at once coloured blue owing to the formation of an alkaline iodide. (Compare Abstr., 1887, 568.) Experiments showed that the depth of colour produced in such solutions in a quarter of an hour by lead crystal glass, Thüringer glass, thermometer glass from Zena, and Bohemian glass, was greatest in the case of the lead glass and gradually decreased in the order given.

The following method can be employed for testing the quality of glass:—The surface to be tested is first carefully washed with water, alcohol, and ether consecutively, and then covered with, or in the case of tubes filled with, a solution of iodoeosine (0·1 gram) in ether (100 c.c.) which has been previously saturated with water at the ordinary temperature; after keeping for 24 hours, the glass is washed with ether. The surface will then be covered with a red layer, purple in transmitted light, the intensity of the colour varying with the degree to which the surface has been attacked. The coloured layer is generally homogeneous and transparent, but in very bad samples it is dull and crystalline; bad glass, moreover, cannot be freed from alkali by washing with water, so that the red colour is formed immediately, whilst with samples of good glass the colour is only produced after several hours.

The principle of the method is that the free alkali produced by the action of the water in the ether, and the slight additional action of the "eosine acid," combines with the iodoeosine, forming a salt which, being insoluble in ether, is deposited on the glass.

Experiments show that this method leads to the same conclusions as Weber's hydrochloric acid method (*Dingl. polyt. J.*, **171**, 129). Glass containing lead is strongly attacked, and the mixture of lead and alkaline salts deposited on the surface can be separated by washing with water, the former remaining undissolved. Very slight variations in the surface can be detected; the difference in the intensity of the coloured layers produced with samples of the same glass, one of which has been kept in contact with cold water or dilute acids for 24 hours, or heated with water for five minutes, is distinctly noticeable.

If a glass tube, which has been submitted to electrolysis by Warburg's method, is tested, it is seen that the surface which was in connection with the anode does not become coated as it is free from alkali, the other surface, however, becomes covered with a deep-red layer, showing that the proportion of alkali has been increased by electrolysis.

The worst glass can be made capable of permanently resisting the action of water by first leaving it in contact with cold water for several days and then heating to 300—400°. After this treatment, no coloration is produced with the iodoeosine solution even after several months' time, whereas the original material and some which had been heated only to 100° give a deep-red coloration in a few hours. When the better kinds of glass are treated with water, the difference caused by the subsequent heating is not so marked.

In testing glass tubes, a colourless zone is frequently observed a little above the sealed end. This phenomenon is due to the primary formation of a layer of moist silica which, on heating at 300—400°, becomes impervious to water; at the end of the tube this layer merges into the melted glass which again becomes hygroscopic on solidifying. The inverse phenomenon occurs when tubes are sealed without having been previously cleaned. The alkaline compounds fuse on the surface of the glass, and even after washing with water, alcohol, and ether, the iodoeosine test shows a region rich in alkali; at the end of the tube, however, the alkalis have dissolved in the melted glass.

Freshly broken surfaces even of the best glass, immediately become covered with a thin red layer when thus tested. F. S. K.

Separation of Aluminium and Zirconium. By I. T. Davis, Junr. (*Amer. Chem. J.*, **11**, 26—29). — Quantitative experiments proved that zirconium is almost completely precipitated from neutral or feebly acid solutions by sodium iodate, the error amounting to

1 per cent. of the zirconium employed. The precipitate is probably an oxyiodate; when heated, it is readily and completely converted into the dioxide. As aluminium iodate is readily soluble in water, the author has experimented with the following method, which gives, as the analyses show, very good results. The hydrochloric acid solution of the two metals is neutralised with an excess of sodium carbonate until a permanent precipitate is formed. The precipitate is redissolved in the smallest quantity of hydrochloric acid, and sodium iodate added in excess. The solution is heated for about 15 minutes, allowed to remain about 12 hours, filtered, the precipitate washed with boiling water, dissolved in hydrochloric acid, precipitated with ammonia, ignited, and weighed. All iron salts must be previously separated. A convenient amount of zirconium to work with is 0·1 gram ZrO_2 in 100 c.c. J. W. L.

Direct Estimation of Oxygen and Nitrogen in Natural Waters. By A. Lalieu (*J. Pharm.* [5], **19**, 147—150).—The mixed gases are boiled off, collected in a eudiometer and measured; the oxygen is then absorbed by means of an alkaline pyrogallol solution. and the residual gas is measured again. A very small, wide-necked flask of 8 to 10 c.c. capacity has an internal diameter of 18 to 20 mm., to this is fitted a perforated stopper carrying a small cylindrical funnel with a narrow tube about 4 cm. long, stiffly held by the stopper. Supposing the gases to be in the eudiometer, and this being plunged in the water of the pneumatic trough, the small flask is charged with 4 c.c. of normal alkali solution; then 0·10 gram of pyrogallol is added, and the flask is filled completely with water, the stopper is inserted so that the liquid is forced into the head of the funnel tube: this is covered with the finger, and the liquid is agitated. The flask is now plunged into the water of the trough, the funnel filled with water, and the flask turned upwards so that the gas can be easily transferred from the eudiometer to the flask. The gas at first stays in the funnel, but by gently drawing out the stopper it can be passed bubble by bubble into the flask. After about an hour the oxygen is completely absorbed, and the residual gas can be directly transferred to the burette, after withdrawing the funnel and stopper. J. T.

Loss on Ignition in Water Analysis. By T. M. Drown (*Chem. News*, 59, 82—83).—The following plan for the estimation of organic matter in waters, by the ignition of the total solid residue left after evaporation, gives lower, and more constant and trustworthy results than the method of direct ignition generally employed. The platinum dish containing the residue is supported on a platinum wire coil or triangle in a larger platinum dish, which is kept at a moderate red heat and serves as a radiator; a platinum plate suspended about an inch above the inner dish expedites the ignition. When examining subsoil waters, they are first treated with a measured quantity of sodium carbonate, by which means the inconvenience of hygroscopic residues and the volatilisation of the chlorine or nitric acid are avoided, and the loss on ignition, after due allowance has been made for the sodium carbonate added, represents approximately the organic matter. D. A. L.

Detection of Nitrobenzene in Presence of Oil of Bitter Almonds. By K. LIST (*Chem. Zeit.*, **12**, 1727).—The substance is warmed with soda and a few drops of ferrous sulphate to remove any hydrocyanic acid; plenty of permanganate is then added to destroy the oil of bitter almonds, after which any nitrobenzene present can be recognised by its odour. D. A. L.

Examination of Commercial Alcohol. By H. BORNTRÄGER (*Zeit. anal. Chem.*, **28**, 60—62).—The chief impurities to be sought for are aldehyde, acetal, and amyl alcohol. A sample is mixed with much water. If oily drops separate on the surface, these are tested by adding an equal volume of strong sulphuric acid and then strong potash, when acetal gives an odour of acraldehyde, whilst amyl alcohol yields an agreeable odour; further, by adding 3 drops of concentrated hydrochloric acid and 10 of colourless aniline, amyl alcohol then gives a rich raspberry-red coloration, whilst acetal produces no colour. Aldehyde gives a deep-brown colour with a strong solution of potassium iodide. With a colourless mixture of rosaniline and sodium hydrogen sulphite, it yields a strong violet colour, becoming blue on addition of concentrated hydrochloric acid. Acetal and amyl alcohol give no colour with either of these reagents. A specimen of the alcohol is mixed with 2 parts of water and shaken with chloroform, which is then separated and allowed to evaporate at a moderate temperature. The residue is tested for acetal and amyl alcohol as above. A spirit which gives no coloration with an equal volume of concentrated sulphuric acid or of strong potash (1 : 3) is practically free from the above impurities. M. J. S.

Detection of Sugar in Urine. By L. CRISMER (*Arch. Pharm.* [3], **26**, 1134, from *Ann. soc. méd. chir. de Liège*, October, 1888).—1 c.c. of urine is heated to boiling with 5 c.c. of a 0·1 per cent. aqueous solution of safranine and 2 c.c. of a 10 per cent. sodium hydroxide solution. If it is decolorised, sugar is present, as even 0·001 gram of glucose in 1 c.c. of urine is sufficient to produce this effect. It may happen that a urine failing to react with Fehling's solution decolorises safranine solution, but the converse never happens. The foreign Abstractor remarks that Fehling's solution sometimes reacts when no sugar is present, in which cases safranine would have the same fault; but where Fehling's solution is not reduced, although sugar is present, then probably the safranine test would have the advantage (compare, however, Crismer, this vol., p. 446). J. T.

Estimation of Sorbite. By C. VINCENT and DELACHANAL (*Compt. rend.*, **108**, 147—148).—See p. 478.

General and Physical Chemistry.

Absorption-spectra of Epidote. By H. BECQUEREL (*Compt. rend.*, **108**, 282—284; compare *Ann. Chim. Phys.* [6], **14**, 170).—When the luminous vibrations traverse a crystal of green epidote in a direction parallel with the axis of symmetry, almost all the visible spectrum is absorbed, but if the direction of the vibrations is parallel with the plane of symmetry *g*, several absorption-bands are visible, and these disappear one by one as the orientation of the crystal is varied. The bands observed are a somewhat weak band, γ, in the orange, which has a mean wave-length of 603, and extends to D; a group, β, composed of three broad and intense bands with the same principal directions and mean wave-lengths of 473·5, 456·7, and 429 to 425; a narrow and very intense band, α, with a mean wave-length of 453·4, which is only visible when the absorption of the group β is at a minimum. When the absorption of the group β is at its maximum, the three bands coalesce, and the absorption extends through the whole of the green region up to G. Measurements of the azimuths of these bands with respect to the two optical axes, are given in a table. The anomalous principal directions of the bands α, β, γ show that they are due to three different substances, and their relative intensities vary considerably in different samples of epidote. It is not yet possible to attribute the bands to any particular elements, but γ is similar to a band seen in cobalt glass, β may be due to iron, and α resembles a band which is visible in the ordinary, but not in the extraordinary spectrum of idocrase. C. H. B.

Change of Fluorescence with Concentration. By B. WALTER (*Ann. Phys. Chem.* [2], **36**, 502—518).—In a recent paper (Abstr., 1888, 881), the author describes some investigations from which he had come to the conclusion that the fluorescence of a liquid increases without limit as the dilution increases. He has since found that Lommel (*Ann. Phys. Chem.*, **160**, 70) had come to the same conclusion. The author has recently carried out a further series of researches on the ammonium salt of fluoresceïn, obtained by saturating a concentrated aqueous solution of ammonia with fluoresceïn. By the aid of the mathematical investigation given by Lommel in the paper referred to, the author has succeeded in elucidating the phenomena more completely, and he finds that the law first stated by Lommel, and obtained independently by himself, required some modification. The result of the present investigation is that the fluorescence of a concentrated solution of the salt is zero, or, at any rate, too small to be observed. When water was gradually added, the fluorescence first attained a measurable value for a concentration of 1/25, and rapidly increased with further dilution until the concentration was reduced to 1/3200, after which it remained constant as far as the observations extended, namely, to a concentration of 1/6553600. Similar results were obtained with an alcoholic solution of Magdala-red, except that it was impossible to obtain very concentrated solutions of this substance, so that it was impossible to observe the beginning of the fluorescence.

G. W. T.

Evidence afforded by Fluorescence and Absorption of the Decomposition of Molecular Groups in Solutions. By B. Walter (*Ann. Phys. Chem.* [2], **36**, 518—532).—The fact that fluorescent liquids lose the power of fluorescence when they become sufficiently concentrated, suggested to the author that possibly the groups of molecules existing in the solid salt were only partially dissociated in the concentrated solution, but became more and more so with increasing dilution, until when the fluorescence was no longer affected by further dilution, the dissociation was complete. Assuming this to be the case, the author calls a solution "complete" when the dissociation is perfect, and "partial" when it is imperfect.

Now, according to Beer's law of absorption, a given quantity of substance in solution will absorb the same quantity of light whatever be the strength of the solution, but in the case of fluoresceïn he finds that this only holds good when the dilution has gone beyond the critical point for which the fluorescence ceases to increase with further dilution, and for the more concentrated solutions, the absorption depends on the concentration: for example, in the case of solutions of concentration 1/800, 1/400, 1/200, 1/100 respectively, the coefficients of transmission for light corresponding with the line D in the spectrum, were for a thickness of 1 mm. of the solution, 0·965, 0·878, 0·602, and 0·230, whilst according to Beer's law they should be 0·965, 0·931, 0·867, and 0·752; the deviations therefore increase with the distance from the critical point. Similar results were obtained in the case of partial and complete solutions of several other substances, some fluorescent and some not. Beer's law, therefore, requires correction, and may be re-stated as follows: The absorptive or fluorescent power of a single molecule in a solution remains constant so long as the molecule is not joined into a group with others. The author observed in the course of his previous investigations (Abstr., 1888, 883), but without understanding the reason, that when a vessel containing a fluorescent substance is illuminated by light from a bright line spectrum, if the concentration of the liquid is gradually increased, the fluorescent light which at first corresponds exactly with the absorption ceases to do so after a certain concentration has been reached, and whilst the fluorescence extends only up to a certain portion of the spectrum, starting from the ultra-violet end, the absorption extends ultimately over the whole of the spectrum when the concentration becomes sufficiently great. Experiments of this kind made with fluoresceïn, Magdala-red, and æsculin, show definitely that the solutions in which the fluorescent light corresponded with the absorption, were all complete solutions, and that the concentration at which fluorescence ceased to correspond with the absorption, was the critical one at which the solution passed from a complete to a partial one. The results of these observations led the author to the following conclusions:—(1.) In the partial solutions of the substances experimented on, single molecules and molecular groups exist together, and as concentration increases the number of the latter increases at the expense of the former. (2.) Only single molecules have the power of fluorescing. (3.) The single molecule has its known definite sphere of absorption in the spectrum, whilst the absorption of the molecular groups extends also to the neighbouring portions of the spectrum. There are, therefore, three reasons in virtue of which the fluorescence of a partial solution should diminish with increasing concentration; (1), because the number of single molecules is diminished; (2), because the molecular groups which are formed absorb ever-increasing portions of the incident light; (3), because these groups also absorb an increasing portion of the fluorescent light emitted by the single molecules. The third law, therefore, as stated by the author, affords a means of determining by optical means whether a non-fluorescent colouring matter does or does not exist in solution in more than one state of molecular aggregation, and if it can exist in more than one state, an estimate of the degree of aggregation may be formed by measuring the breadth of the partial shadow existing on each side of the dark lines of the absorption-spectrum produced on passing white light through a moderate thickness, say 50 mm. or upwards, of the solution. The author gives several examples of actual measurements made in this way in the case of solutions of the fluorescent substances, fluoresceïn and Magdala-red, and also the non-fluorescent substances, iron chloride and copper chloride. In the case of the last two there was evidence from other sources of their existing in solution in different states of molecular aggregation. In all these cases it was found that the breadth of the absorption-bands increased largely with the concentration of the solution. Another interesting observation made by the author was, that solutions of fluoresceïn and eosin in water had their fluorescent power increased by heat, the effect of which would be to increase their solubility, whilst, on the other hand, an alcoholic solution of Magdala-red, which is less soluble in hot water than in cold, had its fluorescent power diminished by being heated. This also explains the well-known fact that an aqueous solution of Magdala-red, which is more soluble in hot water than in cold, acquires fluorescent properties when it is heated, although it does not possess them when cold. G. W. T.

Electromotive Force of Selenium. By A. Righi (*Ann. Phys. Chem.* [2], **36**, 464—465).—This is a reply to some strictures made by Kalischer (this vol., p. 3) on some previous investigations of the author, according to which a current can be obtained from a selenium cell in the dark as well as under the influence of light; although the effect of light is to increase the current, not only by diminishing the resistance of the selenium but by increasing the E.M.F. of the cell. He had also found that the effect of pressure on the selenium was to diminish the E.M.F. of the cell. Kalischer maintained that these results were really residual effects, due to the previous exposure of the cell to the action of light. The author has now repeated his experiments with cells which were prepared in the dark and connected by means of insulated wires passing through one of the walls of the room, with testing instruments in another room, so that the cells were not exposed for a single moment to the action of light after the selenium had been obtained in the sensitive condition. The author finds that these cells give exactly the same results as those which had been exposed to light during and subsequent to the process of manufacture. G. W. T.

Production of the Current in the Galvanic Circuit. By L. SOHNCKE (*Zeit. physikal. Chem.*, 3, 1—10).—The author makes use of the contact and dissociation hypotheses, together with the fundamental idea that the attraction of substances for one another is by no means capable of explaining the formation of the current in the galvanic circuit. The method of reasoning is instanced in the case of the polarisation current of an ordinary water voltameter. The positively charged hydrogen attracts the negatively charged free ions, O and SO_4, present in the solution, which therefore combine with the hydrogen, giving up their charges at the one platinum plate, while at the other the negative oxygen attracts the positive hydrogen, which combines with it and gives up its charge. As the source of the energy of the current, the author regards the force originally required to separate the active substance into its ions. H. C.

Electrical Conductivity and Electrolysis of Concentrated Solutions of Sulphuric Acid. By E. BOUTY (*Compt. rend.*, **108**, 393—395).—Kohlrausch showed that sulphuric acid of the composition H_2SO_4 and H_2SO_4,H_2O have lower conductivities than any other mixtures or compounds of the acid with water. The author has determined the conductivity of acid varying from sp. gr. 1·833 to 1·032, and of acid containing 221, 555, and 1110 mols. of water respectively for each molecule of sulphuric anhydride. The specific conductivity shows a first maximum when the composition of the acid is $2H_2SO_4 + H_2O$, a minimum when the composition is $H_2SO_4 + H_2O$, and a second maximum at $H_2SO_4 + 15H_2O$. These maxima and minima are not displaced when the temperature varies from 0° to 18°. The molecular conductivity is at a minimum with the composition H_2SO_4,H_2O, and increases continually for all degrees of greater dilution, the limit being reached when one molecule of dissolved H_2SO_4 has a conductivity 200 times greater than that of the same molecule in the form of the hydrate H_2SO_4,H_2O. The only crystallisable hydrate, H_2SO_4,H_2O, is characterised by its physical properties even when in the liquid state. Its refractive index is the maximum for all rays, its absolute and molecular conductivity is the minimum at all temperatures, and it seems that this is true also of its mobility (*Ann. Phys. Chem.*, **151**, 378). No hydrate containing more water has yet been isolated, but Mendeleeff's results point to the existence of a hydrate, $H_2SO_4 + 5H_2O$ or $+ 6H_2O$, and a second, $H_2SO_4 + 15H_2O$.

The electromotive force of polarisation of platinum electrodes is 1·2 to 1·3 volts with the strongest acid, but gradually diminishes with dilution until it is only 0·7 to 0·8 volt when the composition is H_2SO_4,H_2O. It retains this value until the composition of the liquid becomes $H_2SO_4 + 5H_2O$ or $6H_2O$, and at this point it rises suddenly to 1·4 volts, but afterwards gradually although very slowly diminishes.

A molecule of the type H_2SO_4,H_2O should split up into hydrogen, sulphuric anhydride, and hydrogen peroxide. As a matter of fact hydrogen peroxide is a normal product of the electrolysis of acid of this strength. According to Richarz (*Ann. Phys. Chem.*, [2], **24**, 183), the maximum amount of hydrogen peroxide is obtained when the acid has the composition $H_2SO_4 + 1{\cdot}347H_2O$. With acid below 60 per cent., very little hydrogen peroxide is formed, but persulphuric acid and ozone are produced in considerable quantities. It may be assumed that the apparent limit at $H_2SO_4 + 5H_2O$ or $6H_2O$ really corresponds with the complete disappearance of hydrogen peroxide from the products of electrolysis, or in other words, with the complete destruction of molecules of the type H_2SO_4,H_2O, whilst the limit at $H_2SO_4 + 15H_2O$ corresponds with the complete disappearance of persulphuric acid from the products, or with the destruction of the unknown hydrate intermediate between the monohydrate and that which exists in very dilute solutions. C. H. B.

Electrical Conductivity of Solid Mercury. By C. L. WEBER (*Ann. Phys. Chem.* [2], **36**, 587—591).—This is a reply to L. Grunmach (this vol., p. 201), who criticised the results obtained by the author in a former investigation (Abstr., 1885, 1028), and by Cailletet and Bouty (Abstr., 1885, 855). The author states that his observations had been made with comparatively simple apparatus, and he considers it probable that there may be slight deviations from accuracy, but he does not admit that the corrections required can be anything like sufficient to account for the difference between his results and those of Grunmach. He further points out that his results and those of the two French physicists mentioned are in close accordance, and he traverses in detail some of Grunmach's objections to his methods of experimenting. G. W. T.

Electrochemical Measurement of Currents. By A. POTIER (*Compt. rend.*, **108**, 396—398).—When solutions of silver nitrate and mercurous nitrate contained in similar voltameters are enclosed in the same circuit, the quantities of metal deposited are not in the exact ratio of their atomic weights, and the difference may amount to 2 per cent. If mercurous nitrate is electrolysed with platinum electrodes, there is at first an evolution of hydrogen at the cathode, and this does not cease until the whole surface of the cathode is covered with mercury. A second cathode immersed in the liquid shows the same phenomenon, and it is therefore not due to the presence, at the commencement, of a small quantity of free acid which is destroyed as electrolysis proceeds. Cathodes of silver and copper give similar results, but it is somewhat longer before the evolution of gas ceases. With a cathode of metallic mercury, no hydrogen is evolved, but the metal is strongly polarised. It would seem that in all cases hydrogen is liberated at the cathode and is occluded, but is removed by diffusion or some other cause.

From these results it follows that the use of a cathode consisting of the metal which is to be deposited does not in every case prevent polarisation. C. H. B.

Free Ions. By W. OSTWALD and W. NERNST (*Zeit. physikal. Chem.*, 3, 120—130).—The authors advance further theoretical and experimental evidence in favour of the view that electrolytes contain free ions. Among others the following experiment is described:—A glass tube provided with a tap is drawn out at one end to a capillary, and filled with mercury. The capillary is then immersed in dilute sulphuric acid, and the apparatus so adjusted that the acid fills one half of the capillary. By means of a damp thread, the acid solution is then connected with a similar solution contained in a flask, the outside of which is coated with tinfoil; this is placed on an insulated stand. The tinfoil receives a positive charge from an electrical machine, and on then connecting the mercury to earth, bubbles of hydrogen appear at the junction of the mercury with the acid. The explanation given is that the positive charge of the foil attracts the negatively charged ions, whilst the positively charged ions are repelled and accumulate at the mercury. On connecting to earth, the ions give up their charges, and are therefore set free.

Other similar experiments are described, and it is likewise shown that in accordance with thermodynamical principles the ions must be already present in the solution in a free state, and that no part of the charge is used up in their liberation. H. C.

Electrolysis. By VIOLLE and CHASSAGNY (*Compt. rend.*, **108**, 284—287).—If a positive electrode consisting of a platinum wire 4·5 mm. in diameter is plunged to a considerable depth in water containing 10 per cent. of sulphuric acid, and a negative electrode consisting of a platinum wire 1·5 mm. in diameter is gradually immersed in the liquid, then, if the difference of potential between the two electrodes is not less that 32 volts, there is seen round the negative electrode a luminous sheath which separates it from the liquid and in which alone the evolution of hydrogen takes place. This sheath offers a very high resistance, which gradually diminishes as the length of wire immersed increases, and falls very suddenly at the moment when the luminous sheath disappears and gives place to a train of bubbles of hydrogen. The length of the luminous sheath increases with the electromotive force, and the quantity of energy used up in the electrolytic cell is proportional to the length of the luminous sheath which the particular current can produce. The luminosity is not continuous, and at first it consists only of points of orange light at the extremity of the electrode, but these become violet in colour and extend over the whole of the submerged wire. The electrodes become very hot, and if the circuit is broken the luminosity does not disappear immediately, and there is a hissing sound when the water comes in contact with the hot wire. The displacement of the luminous sheath by a train of bubbles of gas, which takes place when the electrode is immersed to a certain depth, is accompanied by a kind of explosion. The connection between the luminous effect and temperature is shown by the fact that even with a difference of potential somewhat below 32 volts, which is not sufficient to produce the sheath, it appears for a short time if the electrode is heated. With a sheath of any given length, an increased difference of potential produces increased intensity of the calorific and luminous effects, the sheath enlarges, evolution of gas is accelerated, and large bubbles of gas escape with a hissing noise. With a sufficiently high electromotive force, the electrodes may become red hot and may even fuse. Under such conditions it becomes very difficult to produce and maintain the luminous effect, since the sheath so readily gives place to a rapid train of bubbles of gas, which rise to the surface with a series of small explosions. This audible electrolysis is accompanied by disintegration of the electrodes, and a heavy black powder separates, which has the composition Pt_2H and decomposes in a vacuum above 400°.

Similar effects are observed when the smaller wire is made the positive electrode. A difference of potential of not less than 50 volts is required, but on the other hand the effects are more persistent. The luminous sheath may indeed be made to appear at either of the electrodes according to their relative temperatures. C. H. B.

Electrolysis of Solutions of Hydrogen Fluoride and of Potassium Antimonate with Carbon Electrodes. By A. BARTOLI and G. PAPASOGLI (*Chem. Centr.*, 1889, 177, from *L'Orosi*, **11**, 397—400).—If in the electrolysis of concentrated hydrofluoric acid a carbon positive electrode is employed, it disintegrates and falls to pieces, and yields, after purification, an impalpable powder, which is partly soluble in concentrated sulphuric acid. When treated with sodium hypochlorite, this substance yields considerable quantities of sodium fluoride and mellitic acid. In the case of a solution of potassium antimonate, the carbon pole is also rapidly attacked, and a black substance is precipitated, somewhat soluble in water, and containing antimony. It is soluble in alkalis, and is oxidised by sodium hypochlorite to mellitic and other acids of the benzene series. The authors name this substance *stibiomellogen.* J. W. L.

Conductivity of Mercury Vapour for Heat. By L. SCHLEIERMACHER (*Ann. Phys. Chem.* [2], **36**, 346—357).—In a former investigation (*ibid.* [2], **34**, 623) on the heat conductivity of air, hydrogen, and carbonic anhydride, the author obtained values for the conductivity differing from those calculated from theory. Either of the theories can, however, be brought into agreement with the observations by making certain assumptions as to the distribution of the intramolecular energy in the conduction of heat in diatomic and polyatomic gases. The simplest assumption would be that the intramolecular energy is propagated with the same velocity as the molecular energy. Boltzmann's theory would then, however, lead to values greater than those given by observation, whilst O. E. Meyer's theory would lead to values smaller than those observed. Now it appears extremely improbable that the intramolecular energy can be propagated with a greater velocity than the molecular energy, and therefore the author was inclined to believe that Meyer's theory does not correctly represent the facts. In order to decide definitely between these two theories, it was necessary to determine the conductivity for heat of a monatomic gas, for which the assumptions made would be indifferent. With this object in view, he undertook the investigation of the heat conductivity of mercury vapour described in the present paper. The method adopted for the determination was the same as that which he had previously employed, but owing to the difficulty introduced by the fact that the temperature had to be above 180°, the results obtained are not equally trustworthy. The author finds as the mean value of the conductivity k, at the temperature 203°, the value 0·00001846 C.G.S. water units. The temperature coefficient of the conductivity determined from the means of the observed values at 182·5° and 215° respectively was 0·0074. On account of the various errors of observation incidental to the experiment, this result cannot be regarded as extremely trustworthy, but as far as it goes it does not differ greatly from what would be expected from theory, for in the case of monatomic gases at constant specific heat the conductivity should depend on the temperature in exactly the same way as the coefficient of viscosity. Now, according to Koch (*Ann. Phys. Chem.* [2], **19**, 870) the relation between this coefficient and the temperature is given by the formula $\mu = \mu_0(1 + \alpha t)^{1·6}$, where $\alpha =$ 0·003665 and μ is the coefficient of viscosity. If the relation between the conductivity and the temperature is expressed by means of a similar formula, the value of the exponent is found to be 1·4. According to all existing theories, the conductivity k of a monatomic gas is proportional to the product of the viscosity coefficient η and the specific heat at constant volume c_v, so that $k/\eta c_v$ has the same value for all monatomic gases. There is little doubt that this is correct, and it agrees with the fact of observation that the conductivities of gases and also their coefficients of viscosity are independent of the pressure. The numerical value of this expression, however, is different according to the different theories, being 2·5 according to Boltzmann's hypothesis that the molecules exert a repulsive force on one another varying inversely as the 5th power of the distance, whilst according to O. E. Meyer its value should be 1·53. Taking Koch's value for the viscosity coefficient of mercury vapour, the value is found to be 3·15, which is more than double the value according to Meyer, and about 25 per cent. too great according to Boltzmann. This result shows conclusively that Meyer's theory does not represent the facts. The deviation from Boltzmann's value might possibly be attributed to the comparatively large errors of observation inseparable from the method of experiment. The following consideration, however, led the author to believe that the value 3·15 is rather too small than too great, and that therefore Boltzmann's theory must also be rejected. In order to explain conduction in polyatomic gases, according to the latter theory, it is necessary to make some assumption as to the part played in the conduction by the intramolecular energy. One of the assumptions which may be made is that the internal or progressive energy is distributed in exactly the same manner when heat conduction is going on as when there is a uniform temperature throughout. This assumption (a) leads to the conclusion that the conductivity of any gas is given by an expression of the form $k = C_a \eta c_v$, where C_a is a constant. Another possible assumption (b) is that the transference of heat is entirely due to the progressive energy of the molecules, in which case $k = \frac{5}{2}C_b(K - 1)\eta c_v$, where K is the ratio of the specific heat at constant pressure to that at constant volume and C_b is a constant. If, then, observation shows that for all gases $C_a = K/\eta c_v$ has the same value as in the case of mercury vapour, the assumption (*a*) may be assumed to be correct. If, however, $C_b = K/(\frac{3}{2}(K - 2)\eta c_v)$ is constant for all gases, assumption (*b*) is confirmed. It may be, however, that neither of these represents the state of things, and that the internal energy plays a part in the conductivity but to a lesser extent than is assumed by (*a*). In this case, the value of the first expression will be smaller and that of the second greater than for mercury vapour. Taking the values of η determined by O. E. Meyer (*Wien. Ber.*, **73**, 433) for mercury vapour, air, hydrogen, and carbonic anhydride, and the values of K determined for the same gases by A. Wüllner (*Ann. Phys. Chem.* [2], **4**, 321), the author finds that the values of C_a and C_b are as given below:—

	k.	C_a.	C_b.
Mercury	0·0000185	3·15	3·15
Air	0·0000562	1·98	3 26
Hydrogen..........	0·0004100	1·94	3·35
Carbonic anhydride .	0·0000327	1·59	3·40

This table shows that the hypothesis (*a*) must be rejected. The hypothesis (*b*) appears to agree well with experiment for the three polyatomic gases, and the values obtained for these do not differ from that obtained for mercury by more than 6 per cent. This difference may be due to errors of observation, but it may on the other hand be caused by intramolecular energy in the case of the polyatomic gas playing a part in the conductivity, but to a very much smaller extent than assumed by (*a*). In either case, the conclusion to be drawn is that in the above-mentioned gases the conduction of heat is mainly due to the transference of progressive energy only. The author then calculates the values of C_a and C_b from the results of Winkelmann's observations on carbonic oxide, nitrous oxide, and ethylene, and the results are given below:—

	k.	C_a	C_b.
Carbonic oxide	0·0000499	1·94	3·20
Nitrous oxide	0·0000350	1·84	3·94
Ethylene	0·0000395	1·71	4·66

These numbers show that neither (*a*) nor (*b*) exactly represents the truth, but that this lies, as previously suggested, between the two. The conclusions arrived at in this paper of course depend on the assumption that the conduction of heat in a gas is entirely effected by the motion of its molecules, and that there is no internal radiation from molecule to molecule. If such internal radiation took place to any extent the values of *k* for air, hydrogen, carbonic oxide, and carbonic anhydride could not agree so well together, as the absorptive power of carbonic anhydride is very high compared with that of the other three gases. Internal radiation could not therefore take place to a sufficient extent to explain the deviations from Meyer's theory, but the author considers that it may possibly occur to a certain extent, and as nothing is known about the absorptive power of mercury vapour, he does not feel justified in concluding that the great difference between the values of k for these gases, and that obtained for mercury vapour, conclusively disproves Boltzmann's theory. G. W. T.

Heat of Formation of Aniline Dichromate. By C. GIRARD and L. L'HOTE (*Compt. rend.*, **108**, 238—240).—When a dilute solution of aniline hydrochloride is mixed with an equivalent quantity of aniline or of hydrochloric acid there is no sensible thermal disturbance, and hence it follows that aniline hydrochloride is a stable salt even in dilute solutions. If potassium dichromate is added to an equivalent quantity of aniline hydrochloride solution there is a very slight reduction of temperature, and when this is corrected for the heat absorbed by the dilution of the aniline solution it is found that the reaction absorbs 0·1 Cal. The heats of neutralisation of hydrochloric acid and chromic acid by potassium are 16·7 Cals. and 13·5 Cals. respectively. Direct combination of aniline with chromic acid in the proportion to form aniline dichromate liberates + 7·2 Cals. or + 0·2 Cals. less than the combination with hydrochloric acid. This difference is exactly the same as in the case of the same two acids and potassium. C. H. B.

Alcoholates of Monosodium Glycol. By DE FORCRAND (*Compt. rend.*, **108**, 240—242).—The compounds of monosodium glycol with one molecule of methyl, ethyl, or propyl alcohol are readily obtained by dissolving sodium in three or four equivalents of the particular alcohol and then, after cooling, adding the equivalent of glycol, and evaporating at 120—140° in a current of hydrogen until crystallisation commences in the hot liquid. No glycol is given off in this operation, and hence it has completely expelled the monohydric alcohol from its combination with the sodium. The alcoholates separate in colourless needles or lamellæ, and can be dried on porous plates. The first column gives the heats of dissolution, the second the heats of formation in solution, and the third the heats of formation of the solid alcoholate from the solid glycol-derivative and the liquid alcohol :—

Methyl alcoholate....	+1·97	+0·11	+6·14
Ethyl "	+3·51	−0·03	+5·01
Propyl "	+2·67	−0·03	+6·42

These results were confirmed by measuring the heat developed, on addition of an equivalent quantity of sulphuric acid. The alcohols can be expelled at 130—150° in a current of dry hydrogen, but are not given off over sulphuric acid at 13°. Similar compounds seem to be formed by butyl and amyl alcohols, but they are not readily isolated.

Glycol displaces monhydric alcohols from their metallic derivatives, and the heats of combination of the alcohols with monosodium glycol are higher than their heats of combination with monosodium glyceroxide. Moreover, the heat of combination of monosodium glycol with glycol is higher than its heat of combination with ethyl alcohol.

C. H. B.

Compressibility of Hydrogen. By S. v. WROBLEWSKI (*Monatsh.*, 9, 1067—1125).—The present paper contains the results which had been obtained by the late author up to the time of his death, in his work on the compressibility of hydrogen. It is taken from manuscripts which he had already prepared for publication.

The behaviour of gases at the ordinary temperature on compression is such, according to the experiments of Regnault and Amagat, that the product of pressure into volume, *pv*, at first decreases with rising pressure, until a minimum is reached, and then with every further increase of pressure continually increases. All gases behave in this manner with the exception of hydrogen. Hydrogen shows no decrease and no minimum of *pv* with rising pressure, but the product continually increases with the pressure. This holds for all pressures from one atmosphere upwards, and therefore if the minimum *pv* does occur at all in the case of hydrogen, it must take place at a pressure below one atmosphere. But an objection to this deduction is that the pressure of the minimum points of *pv* for other gases is higher than the critical, and if this were the case also for hydrogen, the critical pressure would have to be extremely low and very much beneath one atmosphere.

To examine the behaviour of hydrogen under as widely different conditions as possible, the author selected four different temperatures at which to work: the boiling point of water, 100°, the melting point of ice, 0°, the boiling point of liquid ethylene, —103·5°, and the boiling point of liquid oxygen, —182·4°. The pressures employed varied from 1 to 70 atmospheres. The apparatus, of which a sketch is given, was of very simple construction. The hydrogen was compressed in a bulb of known capacity having a capillary neck, and immersed in a bath kept at a fixed temperature. The volume was measured directly by transference to a eudiometer. Liquid oxygen used in cooling the gas was prepared by cooling down oxygen under pressure to the temperature of boiling ethylene (liquefied by means of ether and carbonic anhydride), and then suddenly releasing the pressure and allowing the cold produced by expansion to liquefy the gas.

For the three first of the above four fixed temperatures, the behaviour of hydrogen on compression is that already recorded: there is a constant increase of *pv*, with pressures rising from 1 to 70 atmospheres. The curves expressing the relation between *p* and *pv*, all three have their concave sides turned towards the axis of *p*. The following three empirical equations are found to express the behaviour of hydrogen under these conditions:—

$$\begin{array}{llrl}
(1) & \text{At} & 99{\cdot}14^\circ & pv = 1{\cdot}361299 + 0{\cdot}001360051p - 0{\cdot}000004099p^2. \\
(2) & ,, & 0^\circ & pv = 0{\cdot}997393 + 0{\cdot}001308924p - 0{\cdot}000004257p^2. \\
(3) & ,, & -103{\cdot}5^\circ & pv = 0{\cdot}6187044 + 0{\cdot}00087512p - 0{\cdot}0000026916p^2.
\end{array}$$

At the fourth temperature, however, that of boiling oxygen, —182·4°, a very important change is found to have taken place. For here, for pressures up to 14 atmospheres, *pv decreases* with rising pressure; at about 14 atmospheres a minimum occurs and from this point *pv* again begins to rise and to increase continually with the pressure. The observations in this case from 16 to 70 atmospheres may be expressed by—

$$(4)\ pv = 0{\cdot}3322739 + 0{\cdot}0002599317p + 0{\cdot}0000003091856p^2.$$

It therefore appears from the above that the behaviour of hydrogen at the boiling point of oxygen is perfectly similar to that of other gases at the ordinary temperature, pv first decreasing to a minimum and afterwards increasing with rising pressure.

The results expressed in the above four equations may also be represented by the following general empirical equation:—

$$p = \frac{\mathrm{RT}}{v - \alpha} - \frac{\mathrm{K}}{\epsilon^{\mathrm{T}} v^2},$$

where T is the absolute temperature, $\mathrm{R} = 1/273$, $\alpha = 0{\cdot}00111665$, $\mathrm{K} = 0{\cdot}00051017$, and $\epsilon = 1{\cdot}003892$. From this equation, the values for T, p, and v in the critical state can be obtained by differentiating p with regard to v, and equating to zero. We get in this way in the critical state $\mathrm{T}\epsilon^{\mathrm{T}} = 8\mathrm{K}/27\mathrm{R}\alpha$; $\mathrm{P} = \mathrm{RT}/8\alpha$ and $\mathrm{V} = 3\alpha$. This gives—

	Critical temperature........	32·6 or −240·4°.
	„ pressure...........	13·3 atmospheres.
	„ volume............	0·00335.
whence	„ density...........	0·327.

Hence it appears that the critical temperature of hydrogen is excessively low, very much beneath that of any other gas, and also that hydrogen has a very low critical pressure.

It is this very low critical temperature, combined with a low critical pressure, that serves to explain the apparent exception of hydrogen at the ordinary temperature from the behaviour of other gases on compression. According to Van der Waals all gases in the critical state behave exactly alike, and are in strictly comparable conditions. These comparable conditions may be retained for states other than the critical, if, instead of expressing temperature, pressure, and volume in terms of the ordinary units, the critical temperature, pressure, and volume be each taken as unity, and gases then compared under conditions which are similar in terms of these units. All gases are then found to behave alike, and the curve expressing the relation between any two properties will be one and the same for all gases.

The author constructs the curve representing the relation between the temperature and pressure (in units of the critical) of the minimum points of pv as observed for different gases. This curve is of course one and the same for all gases, and, as the author has already shown, is the continuation of the curve for the vapour-tensions of the liquefied gases. The observations used for constructing it are chiefly those of Amagat, and are for the gases carbonic anhydride, ethylene, methane, oxygen, and nitrogen. It is found that from the point where critical temperature and pressure are each unity, the curve rapidly rises until when the pressure is about 3·1 and the temperature 1·4, a maximum is reached. From this point the curve again falls, and when the temperature is about 2·7, the pressure of the minimum points of *pv* has fallen again to the critical pressure, and is still rapidly falling.

To apply this to hydrogen, the critical temperature of which is 32·6 and the critical pressure 13·3 atmospheres. The pressure of the minimum point of *pv* for a temperature of 1·4 times the critical temperature, is about 3·1 times the critical pressure, but from this point the pressure of the minimum of *pv* continues to fall. Thus when the temperature is 2·7 times the critical, or about −185°, the pressure of the minimum point of *pv* is only equal to the critical pressure or 13·3 atmospheres, and by observation at −184·4° the pressure of this point was found to be about 14 atmospheres, a very close approximation. From this point the pressure of the minimum of *pv* continues to fall rapidly, and at length, becoming a small fraction of the critical, falls in the case of hydrogen below one atmosphere, and at temperatures still comparatively low no longer comes under observation. It will be seen that this process is really brought about by hydrogen having a very low critical temperature. combined with a very low critical pressure.

The exception observed in the behaviour of hydrogen on compression is, then, only an apparent one, hydrogen as a matter of fact behaving as all other gases.

In a note at the end Zakrzewski, who communicates this paper, gives brief details of attempts which the author had made towards liquefying hydrogen. The gas, compressed to 110 atmospheres, was cooled by means of liquid nitrogen to −213·8°. By suddenly releasing the pressure as low a temperature as −223° was obtained, but without any signs of liquefaction. H. C.

Simple Diffusion Experiment. By M. W. BEYERINCK (*Zeit. physikal. Chem.*, **3**, 110—112).—When a drop of acid is let fall on a surface of gelatin, a visible depression is formed on the surface at the edge of the drop, and this depression moves outwards as the acid diffuses. Hence it is possible to determine the rate of diffusion of an acid on a gelatin plate by measuring the rate of motion of this depression. H. C.

Raoult's Law of Freezing. By R. FABINYI (*Zeit. physikal. Chem.*, **3**, 38—45).—It is a well-known fact that the presence of impurity or admixture of foreign material lowers the melting point of any solid substance. The author has examined this lowering of the melting point in the case of naphthalene, and finds that it follows exactly similar laws to those discovered by Raoult for the reduction of the freezing point of solutions. Thus by mixing various substances in different proportions with naphthalene, and determining the melting points of the mixtures, it is found that the reduction of the melting point is proportional to the amount of foreign substance present, and is constant for equimolecular proportions.

A description of the apparatus used is given, as also the results of a number of determinations. From these latter, it appears that compounds of the most different constitution which do not contain a carboxyl-group, and themselves melt at from 37° to 273°, when mixed in the proportion of 1 mol. to 100 mols. $C_{10}H_8$, cause a reduction of the melting point of 0·60° to 0·65°. If 2 mols. per 100 be taken, double, if 3 mols., treble the above reduction is obtained. Acids, on the other hand, containing a carboxyl-group give only half the above depression in each case, so that 4 mols. of an acid become equal to only 2 mols. of a compound containing no carboxyl in this respect. H. C.

Raoult's Law of the Reduction of the Freezing Point. By J. F. Eykman (*Zeit. physikal. Chem.*, 3, 113—114).—The molecular reduction of the freezing point of phenol was found by the author to be about 76, a number agreeing with that calculated by the Van't Hoff formula (Abstr., 1888, 780), but differing from that found by Raoult, 58·3, in his experiments. As the number given by Raoult for the molecular reduction of the freezing point of naphthalene is 82, whereas according to the Van't Hoff formula it should be 69·4, the author has also made a series of determinations, using naphthalene as a solvent. The number obtained for the molecular reduction is in very fair agreement with that calculated by Van't Hoff. H. C.

Molecular Depression of the Freezing Point of Benzene by Iodoform. By E. Paternò (*Ber.*, 22, 465—466).—Raoult (*Ann. Chim. Phys.* [6], 2, 88) found that the lowering of the freezing point of benzene produced by iodoform indicated that the latter had a molecular weight double that which is generally accepted. The author gives in tabular form the results of seven experiments on the lowering of the freezing point of benzene by quantities of iodoform varying from 1·2161 to 10·5385 parts in 100 parts of benzene. The maximum molecular depression was found to be 61·46 with 1·2161 parts of iodoform, the minimum 54·76 in the two experiments with 3·5919 and 3·6561 parts of iodoform respectively. The freshly prepared solutions are light-yellow, but almost immediately become brown, an indication of partial decomposition. It was found, however, by two experiments that the freezing point of the solutions underwent no perceptible alteration after 6, or even after 24, hours.

The depression produced by iodoform must therefore be looked on as normal, and although the values found actually differ from the normal, this fact simply proves that partial decomposition takes place.

F. S. K.

Molecular Volumes of Liquids. By H. Kopp (*Annalen*, **250**, 1—117).—This lengthy communication contains a *résumé* of much of the work that has been done up to the present on the molecular volumes of liquids. It is chiefly devoted to a comparison of the molecular volumes at the boiling points, and at any fixed temperature, say, 0°, and to showing that the first alone bring out definitely those relations which exist between the molecular volume and chemical composition.

H. C.

Action of Ferments. By G. Tamman (*Zeit. physikal. Chem.*, 3, 25—37).—The action of emulsin on amygdalin, salicin, and urea, and also the action of invertin on cane-sugar, were studied. At 0° and at the boiling point of water the action of the ferment is in each case at a minimum, but between these temperatures there is a point of maximum action. At no temperature, however, is the action a complete one, although the author shows that the changes do not belong to the class of reversible reactions, and therefore do not lead to any conditions of equilibrium.

The end of the reaction is conditioned by temperature and the concentration of the solution. Thus, at temperatures as under, the following percentage amounts of amygdalin are decomposed in a 30 c.c. solution containing 0·51 gram of amygdalin and 50 milligrams of emulsin.

t	10°	15°	32°	46°	65°	72°
p	15	16	24	32	20	5

Increasing the amount of the ferment increases also the amount of decomposition up to a certain point, but beyond this has no further action, or may even decrease the amount decomposed. By adding the products of decomposition to the solution, the action of the ferment is weakened, and in a solution, the composition of which already corresponds with the end condition for the given temperature, the ferment refuses to act at all.

The actions of ferments are also studied as time reactions, and the results plotted in curves. These show that they do not follow the course of other catalytic actions, which can generally be represented by logarithmic curves, but obey more complicated laws. In this respect the action of invertin on cane-sugar and of yeast on grape-sugar, which were studied, appear to be very similar. No general rules are deduced.

H. C.

Numerical Relations of the Atomic Weights. By S. STRANSKY (*Monatsh.*, **10**, 19—25).—A number of numerical relations among the atomic weights, more particularly of allied elements, are pointed out. Among others, the following two relations are given:—(1.) The atomic weights of elements of any natural group are rational multiples of that of the first member of the series, minus a constant or some number regularly increasing in arithmetical progression. (2.) The atomic weights of elements of any natural group are rational multiples also of the second member of the series, minus a constant or some number regularly increasing in arithmetical progression. A number of tables illustrating these and other relations are given. H. C.

Lecture Experiments. By A. ALESSI (*Ber.*, **22**, 485—486).—The composition and the most important reactions of hydrogen chloride and other gases can be demonstrated as follows:—One or more small, thin, sealed bulbs, containing mercuric oxide, are placed in a strong glass flask, which is then filled with dry hydrogen chloride, closed with the thumb, and shaken until the bulbs are broken. The oxide is converted into chloride, and on opening the flask under mercury the latter completely fills the vessel. The reaction between sodium and hydrogen chloride can be shown in like manner by using sealed bulbs filled with sodium amalgam; on opening the flask under water the liquid rises and occupies half the volume, and the residual gas can be shown to consist of hydrogen. To demonstrate that hydrogen chloride contains chlorine, lead dioxide is employed; on breaking the bulbs, the brown oxide is converted into chloride, which appears moist, owing to formation of water. The flask is then opened under water, and the residual chlorine, occupying one quarter of the original volume, can be readily recognised.

To show that nitrogen and a halogen acid are formed by the action of chlorine or bromine on ammonia, the bulbs are filled with very concentrated aqueous ammonia, and, after the experiment, the flask is opened under water or dilute acid, when the liquid rises and occupies two-thirds of the volume of the vessel. The action of ammonia on hydrogen chloride and of hydrogen sulphide on metallic salts can be shown in like manner.

F. S. K.

Inorganic Chemistry.

Absorption of Hydrogen by Metals. By M. THOMA (*Zeit. physikal. Chem.*, **3**, 69—102).—Palladium charged with hydrogen electrolytically, expands and increases in volume equally in all directions. A contraction takes place on removing the hydrogen, which is greater than the previous expansion, but if the palladium is successively charged and discharged the contraction lessens in amount, not, however, with any definite regularity. Only a certain amount of hydrogen can be permanently retained, for palladium charged with hydrogen beyond a certain limit parts with the gas spontaneously. Below this limit of saturation, the expansion is proportional to the amount of hydrogen absorbed, but on passing the limit the expansion increases more rapidly than the absorption. The hydrogen retained above the limit of saturation is therefore less dense than that retained below. All hydrogen retained above the saturation point is given off when the palladium is left to itself again, and a contraction takes place equal to the expansion due to supersaturation. The supersaturation is dependent in amount very largely on the strength of the current employed. The hydrogen was found to have diffused in the palladium in one half hour to a distance of 4 to 5 mm. from the surface of attack.

Iron is also readily supersaturated with hydrogen. This takes place whenever iron comes in contact with dissociated hydrogen, either in the voltameter or that which is being generated on its own surface by the action of an acid. From the surface of the supersaturated iron, hydrogen is again spontaneously liberated, and the amount obtained is proportional to the extent of surface.

H. C.

Action of Sulphurous Acid on Sodium Thiosulphate. By A. VILLIERS (*Compt. rend.*, **108**, 402—403).—The salt to which the author attributed the composition $Na_2S_4O_8$ really contains four atoms of hydrogen, and is hydrated sodium tetrathionate, $Na_2S_4O_6 + 2H_2O$. The percentage amounts of sodium and sulphur corresponding with the two formulæ are almost identical. It follows that the only products of the interaction of sodium thiosulphate and sulphurous acid are sodium trithionate and tetrathionate.

The reaction is precisely similar with the potassium salt, but in this case the trithionate is the less soluble of the two products, and if the first crop of crystals is dissolved in hot water and the hot liquid mixed with alcohol, the trithionate separates in the anhydrous condition on cooling. C. H. B.

Preparation of Nitrous Oxide. By G. CAMPARI (*Chem. Centr.*, 1888, 1569, from *Ann. Chim. Farm.*, **8**, 253—255).—5 parts of stannous chloride, 10 parts of hydrochloric acid, sp. gr. 1·21, and 0·9 part of nitric acid, sp. gr. 1·38, are heated to boiling, when the evolution of nitrous oxide commences, and it continues to be evolved quite regularly and in a pure state. The above proportions of the ingredients should be adhered to, as otherwise the gas is evolved irregularly, and even with violent explosions. J. W. L.

Sodium Phosphite. By L. AMAT (*Compt. rend.*, **108**, 403—405).—By dissolving phosphorous acid in a large excess of sodium hydroxide and treating the product with alcohol, Zimmermann obtained an oily liquid, which he regarded as containing trisodium phosphite, Na_3PO_3, but from which he obtained no crystals. The author finds that if phosphorous acid is dissolved in sodium hydroxide in such proportion that the liquid contains the two compounds in the proportion $Na_2HPO_3 + 27NaOH$, and this solution is evaporated slowly in a vacuum, crystals separate which have the composition $Na_2HPO_3 + 5H_2O$. If a similar solution is treated with alcohol until the latter removes no more sodium hydroxide, the product is the same salt. When absolute alcohol is used, water is removed as well as sodium hydroxide, and the final product is a supersaturated solution of the disodium phosphite, which readily crystallises. The same salt is obtained by adding 4 vols. of alcohol to the mother-liquor from the crystals obtained by evaporation.

From these results it follows that trisodium phosphite does not exist, and that phosphorous acid is bibasic, as Würtz contended. C. H. B.

The Acid Character of the Salts of the Heavy Metals. By B. LACHOWICZ (*J. pr. Chem.* [2], **39**, 99—106).—Several organic bases give precipitates when shaken with aqueous solutions of salts of the heavy metals (Lachowicz and Bandrowski, Abstr., 1888, 1281); in the table (p. 570) the sign + denotes that such a precipitate is formed between the corresponding base and salt.

When the heats of formation (Thomsen's) of the salts in this table are compared, it is found that for salts of the same acid the lower the heat of formation the greater is the capability of combining with organic bases, and for salts of the same metal, the greater the heat of formation the greater is the capability of combining with organic bases.

The author explains this by supposing that when a metal forms a salt with an acid, the "energy" of the acid radicle will be more or less neutralised according as the heat of formation is greater or

	Amines of the paraffins.	Piperidine, pyridine, quinoline.	Aniline.	Toluidine.	Methylaniline.	Dimethylaniline.	β-Naphthylamine.	α-Naphthylamine.	Diphenylamine.

$CuCl_2$	+	+	+	+	+	trace	+	trace	
$AgNO_3$	+	+	+	+	+	+	+	+	

less; thus in potassium chloride (K_2,Cl_2 = 211220 cal.) the residual "energy" of the Cl is much less than in cupric chloride (Cu,Cl_2 = 51640 cal.), and still less than in hydrochloric acid (H,Cl = 44002 cal.); so that potassium chloride shows less tendency to combine with organic bases than cupric chloride, and this last less than hydrochloric acid.

The physiological action of the salts of the heavy metals may also be referred to the residual "energy" of their acid radicles, and thus depends on the heats of formation of the salts. A. G. B.

Properties of the Mercurammonium Chlorides. By G. André (*Compt. rend.*, **108**, 233—236 and 290—293).—The solutions employed contained 33·875 grams of mercuric chloride and 4·25 grams of ammonia respectively per litre, and the compounds were obtained by precipitation in the cold.

When equal volumes of the two solutions are mixed, and the precipitate is collected after several hours or days, washed with a small quantity of water, and dried at 110°, it has not exactly the composition of mercurammonium chloride, NH_2HgCl. This result is due to the decomposing action of the water, which at once becomes evident in dilute solutions, and which, as Kane has shown, results ultimately in the formation of Millon's dimercurammonium chloride, $NH_2{\cdot}Hg{\cdot}O{\cdot}HgCl$. If, however, mercuric chloride is added to an excess of ammonia and the precipitate is washed rapidly with a small quantity of water, the compound NH_2HgCl is obtained in a pure condition. The presence of Millon's compound in the precipitates formed in dilute solutions is readily detected by the fact that after these precipitates have been dried at 110°, they evolve water, if heated at a higher temperature.

With solutions of the strengths given above, the precipitate after one hour contained 0·11 mol., after 12 days 0·25 mol. of Millon's compound for each molecule of mercurammonium chloride. With 6 mols. of ammonia to each molecule of mercuric chloride, decomposition proceeds further, and the precipitate contains the two compounds in equal molecular proportions. With an increasing amount of ammonia, the precipitate eventually consists solely of the compound $NH_2{\cdot}Hg{\cdot}O{\cdot}HgCl$. Variations in the proportion of mercuric chloride have no influence on the composition of the precipitate.

If the two solutions are mixed in equal proportions, allowed to remain 24 hours, the liquid decanted off, the precipitate treated with 8 vols. of the ammonia solution, and this treatment repeated after a second 24 hours, the final product consists entirely of Millon's compound, whereas the original precipitate contained only 25 per cent. of it. If the solutions are mixed in equal proportions, allowed to remain 24 hours, the liquid decanted off, 4 vols. of water added to the precipitate, and this treatment repeated twice at intervals of 48 hours, the product has the composition $NH_2HgCl,3NH_2{\cdot}Hg{\cdot}O{\cdot}HgCl$. Direct experiments with equal volumes of the solutions, and using equal volumes of water for washing, showed that the decomposing action of the water diminishes as the concentration of the ammonia increases. Ammonium chloride acts in exactly the opposite way to water. The addition of 1 vol. of the mercuric chloride solution to 5 vols. of the ammonia solution gives a precipitate which consists almost entirely of Millon's compound; but if after 24 hours the liquid is decanted off and the precipitate is treated with 2 vols. of a solution of ammonium chloride of similar strength, and allowed to remain for two days with occasional agitation, the precipitate is completely converted into the compound NH_2HgCl. The proportion of ammonium chloride required to produce this result is smaller the smaller the quantity of dilute ammonia used in the precipitation. The addition of ammonium chloride without previously decanting the liquid from the precipitate has very little effect upon the latter. C. H. B.

Valency of Aluminium. By A. COMBES (*Compt. rend.*, **108**, 405—408).—Aluminium acetonylacetonate, $nAl(C_5H_7O_2)_3$, is a white solid which melts at 193—194°, and boils without decomposition at 314—315°. Its vapour-density as determined by V. Meyer's method at the boiling point of mercury is 11·25, which corresponds with a molecular weight of 324·8. The calculated molecular weight of the compound $Al(C_5H_7O_2)_3$ is 324·5. The evolution of gas was regular, and there was no evidence of any decomposition. It follows that at a temperature only 45° above the boiling point of the compound, molecules of the type $Al_2(C_5H_7O_2)_6$ have no existence. Whilst accepting the evidence of the existence of molecules of the formula Al_2Cl_6 at comparatively low temperatures, the author considers that the great mass of the evidence at present accumulated shows that aluminium is really trivalent. C. H. B.

Hydrogen Peroxide and Chromic Acid. By BERTHELOT (*Compt. rend.*, **108**, 477—479).—When hydrogen peroxide is mixed with potassium dichromate, and an excess of dilute ammonia is added immediately, a chamois-yellow precipitate is formed, which contains hydrogen peroxide, chromic oxide, and chromic anhydride. If the liquid is decanted off, and the precipitate is washed with water, the first washings are colourless, but succeeding washings are yellow and contain chromic acid. A certain quantity of free oxygen is also evolved, and it is evident that the precipitate is unstable, and gradually decomposes with reoxidation of the chromic oxide. It probably has the composition $n\mathrm{CrO_3,Cr_2O_3,3H_2O_2}$. A similar and probably identical precipitate is obtained when hydrogen peroxide is added to potassium hydroxide containing freshly precipitated chromic hydroxide in suspension. The same precipitate is formed if hydrogen peroxide is added to potassium dichromate containing chromic hydroxide in suspension; the green precipitate becomes yellow, and dissolves completely on addition of potassium hydroxide. The solution at first has the greenish tint observed when hydrogen peroxide is added to normal potassium chromate, but this gradually disappears.

This precipitate is the intermediate compound to which reference has been made in the author's previous papers (this vol., pp. 350 and 468). C. H. B.

Titanium Peroxide. By L. Lévy (*Compt. rend.*, **108**, 294—296). —The composition of the product of the action of hydrogen peroxide on titanic oxide has been variously stated by different authors. The want of agreement between their results is due to the fact that the action of the hydrogen peroxide is very slow, and the precipitate decomposes while being dried. As no known method of solution or precipitation permits of the separation of the peroxide from an excess of either constituent, the author endeavoured to determine the composition of the product by a method of approximation. A solution of hydrogen peroxide of known strength was mixed with definite quantities of a solution of titanic oxide in sulphuric acid. After a long time, the mixtures were examined in order to ascertain which of them still contained hydrogen peroxide. A first approximation pointed to a formula between $\mathrm{TiO_3}$ and $\mathrm{Ti_2O_7}$, a second to a formula between $\mathrm{TiO_3}$ and $\mathrm{Ti_5O_{16}}$, and a third to a formula between $\mathrm{TiO_{2\cdot98}}$ and $\mathrm{TiO_{3\cdot04}}$. In all probability the formula is $\mathrm{TiO_3}$, but these experiments only show that titanic oxide forms a peroxide at the expense of the hydrogen peroxide, and any one of the three formulæ, $\mathrm{TiO_2}$; $\mathrm{TiO_2,H_2O_2}$; $\mathrm{Ti_2O_5,H_2O_2}$, agrees with the result. The composition of the higher chloride, and the existence of additive compounds of the oxyfluoride $\mathrm{TiO_2F_2}$ and alkaline fluorides, afford additional evidence in favour of the formula $\mathrm{TiO_3}$.

Hydrogen peroxide or the titanium peroxide decolorises phenolphthaleïn, and hence if the acid solution of titanic oxide is titrated after addition of hydrogen peroxide its acidity seems to be increased. C. H. B.

Amorphous Bismuth. By F. Hérard (*Compt. rend.*, **108**, 293).—Amorphous bismuth can be obtained in the same way as amorphous antimony (Abstr., 1888, 1256) by heating ordinary bismuth to bright redness in a current of nitrogen. Hydrogen and carbonic oxide will not give the same result. The product contains 99·6 per cent. of bismuth and 0·4 per cent. of oxygen. The presence of bismuth oxide explains the high melting point 410°, but not the low sp. gr. 9·483. The amorphous bismuth is more readily attacked by reagents than the crystallised metal; in nitric acid it dissolves almost instantly. C. H. B.

Non-magnetisable Alloys of Palladium suitable for the Manufacture of Watches. By C. A. Paillard (*Dingl. polyt. J.*, **270**, 143).—The use of alloys of the following composition is recommended:—

	Pd.	Cu.	Fe.	Ag.	Au.	Pt.	Ni.
I.	60—75	15—25	1—5	—	—	—	—
II.	50—75	20—30	5—20	—	—	—	—
III.	65—75	15—25	1—5	3—10	1—2·5	0·05—2	1—5
IV.	45—50	15—25	2—5	20—25	2—5	2—5	2—5

Alloy I is obtained by mixing half the palladium with the remaining metals, fusing the mixture with borax and powdered charcoal, adding the remainder of the palladium, again fusing and pouring the mass into suitable moulds. II is a cheaper alloy and useful for common watches and certain parts of the works. Alloy III is not affected by atmospheric changes, its elasticity is not influenced by temperature, while its astatic properties are even greater than those of alloys I and II. Alloy IV, besides exhibiting all the properties of the former, is characterised by its great hardness. D. B.

Mineralogical Chemistry.

Palæopicrite from Stoppenberg, near Thale, in the Harz. By K. A. Lossen (*Chem. Centr.*, 1889, 58, from *Zeit. deut. geol. Gesell.*, **40**, 372—373).—Palæopicrite occurs in a palæozoic slate of the diabase family with much serpentinised olivine, and some plagioclase, hornblende, diabase-augite, and ilmenite. An analysis gave the following result:—

Monazite as an Accessory Constituent of Rocks. By O. A. Derby (*Amer. J. Sci.*, **37**, 109—113).—Some years ago the author's attention was called to a peculiar, heavy, yellow sand, from the province of Bahia, Brazil, which proved to consist of monazite containing 28·7 per cent. of phosphoric anhydride, 31·3 per cent. of cerium oxide, and 39·9 per cent. of didymium and lanthanum oxides. The sand occurs in considerable batches on the sea shore near Alcobaça, where it seems to have been concentrated by wave action. Monazite has since been found to be widely distributed in the sea- and river-sands of Brazil. As gneiss is the only rock that is at all abundant in the vicinity of Rio de Janeiro, it was thought that the monazite might come from that rock. All the tests made on gneiss, granite, and syenite have given, in addition to zircon, microscopic crystals of a heavy, yellow mineral which is undoubtedly monazite. The basic eruptive rocks examined have afforded no trace of this mineral. In all these tests, care was taken to select samples representing the principal mass of the rock free from veins and mineral aggregates. The rock, found to be richest in monazite, was a fine-grained granitite exposed near Rio de Janeiro. This rock contains 0·07 per cent. of monazite in fine grains. This percentage includes a small amount of zircon that could not be completely separated.

Organic Chemistry.

The Hydrocarbon $C_{60}H_{122}$. By C. Hell and C. Hägele (*Ber.*, **22**, 502—505).—The hydrocarbon $C_{60}H_{122}$ is obtained when myricyl iodide, prepared from the alcohol by Pieverling's method (this Journal, 1877, i, 586), is carefully heated at 130—140° with about one-tenth of its weight of finely divided potassium or sodium; the crude product is boiled with water, alcohol, light petroleum, and glacial acetic acid consecutively, and then repeatedly recrystallised from benzene, and boiled with light petroleum. It is a colourless powder, melting at 101—102°, very sparingly soluble in hot alcohol and ether, rather more easily in light petroleum and glacial acetic acid, but most readily in chloroform and benzene. It is partially decomposed when distilled under diminished pressure, yielding a hydrocarbon which melts at 69—70°, and is readily soluble in light petroleum.

F. S. K.

Propyl and Isopropyl Fluorides. By M. Meslans (*Compt. rend.*, **108**, 352—354).—These compounds were obtained by the action of the alkyl iodides on silver fluoride. The reaction takes place at the ordinary temperature, but more readily at about 50°, and is more energetic in the case of the isopropyl-derivative.

Propyl fluoride is a colourless gas with an ethereal odour and sweet burning taste. It burns with a luminous flame, with formation of hydrofluoric acid; when dry it has no action on glass or mercury. At +2°, under atmospheric pressure, it forms a very mobile, colourless liquid which has no action on glass. The gas is very soluble in alcohols, benzene, ether, and the alkyl iodides, and dissolves in its own volume of water at 16°. Its vapour-density at 20° is 2·161 (calc. 2·175).

Isopropyl fluoride is very similar to the preceding compound, but has a more pungent smell. It is very soluble in benzene, ether, and the alkyl iodides. Water at 15° dissolves 1·5 vols. of the gas; isopropyl iodide dissolves 70 vols.; ethyl alcohol at 16°, 27 to 30 vols. It liquefies at −5° under ordinary pressure; at 10° under a pressure of 2·5 atmos., and at 18° under a pressure of 3 atmos. It is very stable, and is not affected when heated for some time with a dilute solution of potassium hydroxide in a sealed tube at 100°.

Iodine has very little action on isopropyl fluoride, but if the gas is passed into bromine at 30°, a colourless liquid is obtained which has a pleasant, piquant odour, and boils without decomposition at 143°. Isopropyl fluoride combines readily with chlorine at 10°, and yields a liquid which readily dissolves both gases. If an excess of the fluoride is used, and the excess is expelled by gently heating, the product is a colourless liquid which boils without decomposition at 105°, has a pleasant odour, and burns with a flame with a green edge, hydrogen fluoride being formed. C. H. B.

Brominated Derivatives of Pseudobutylene. By O. Hölz (*Annalen*, **250**, 230—240).—Pseudobutylene dibromide, prepared by passing pure pseudobutylene into bromine, boils at 156—158°, and is decomposed by an alcoholic solution of potassium hydroxide, yielding *monobromopseudobutylene*, $CH_3\cdot CBr{:}CH\cdot CH_3$. This liquid boils at 87—88°, and is slowly converted into crotonylene by treatment with an alcoholic solution of sodium ethoxide at 130°. The hydrocarbon is a mobile liquid boiling at 17—18°. If it is rapidly shaken with three times its volume of concentrated hydrobromic acid, and the mixture left at 0° for an hour, then diluted with water, and the oily product purified by distillation, *crotonylene hydrobromide*, the geometrical isomeride of monobromopseudobutylene, is obtained as a colourless liquid boiling at 83—84°. By using a larger proportion of hydrobromic acid, ethylmethylcarbin dibromide, $CEtMeBr_2$, is formed. It boils at 144—145°, and is decomposed by water at 160°, yielding ethyl methyl ketone.

As crotonylene hydrobromide is much more readily attacked by an alcoholic solution of sodium ethoxide than monobromopseudobutylene, these compounds have respectively the formulæ  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\; \| \\ CH_3\cdot C\cdot Br\end{array}$ and  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\; \| \\ Br\cdot C\cdot CH_3\end{array}$.

Crotonylene dibromide, $CMeBr{:}CMeBr$, is formed by adding bromine very slowly to well-cooled crotonylene. It boils at 146—147° with slight decomposition.

Isocrotonylene dibromide is prepared by treating the product of the action of bromine on monobromopseudobutylene with alcoholic sodium ethoxide. It boils at 149—150°.

As crotonylene dibromide is more readily attacked by zinc-dust than isocrotonylene dibromide, the constitution of these compounds may be represented by the formulæ  $\begin{array}{l}CH_3\cdot C\cdot Br\\ \quad\;\; \| \\ CH_3\cdot C\cdot Br\end{array}$ and  $\begin{array}{l}CH_3\cdot C\cdot Br\\ \quad\;\; \| \\ Br\cdot C\cdot CH_3\end{array}$ respectively. Crotonylene dibromide unites with bromine, forming a crystalline tetrabromide which is converted into isodibromopseudobutylene by the action of zinc-dust. W. C. W.

Conversion of Crotonylene Hydrobromide into Bromopseudobutylene. By M. PÜCKERT (*Annalen*, **250**, 250—251).—Crotonylene dibromide, from angelic dibromide, unites with bromine in carbon bisulphide solution, forming tribromobutane. Zinc-dust acts energetically on the alcoholic solution of trichlorobutane, yielding isobromopseudobutylene boiling at 86—88°. This compound is less readily attacked by an alcoholic solution of sodium ethoxide than crotonylene hydrobromide. W. C. W.

Arrangement of Atoms in Space. Part IV. By J. WISLICENUS (*Annalen*, **250**, 224—230, and 251—254).—The results of the experiments of Hölz and Pückert confirm the accuracy of the author's speculations on the constitution of tiglic and angelic acids.

Pseudobutylene boiling at 1—3° is represented by the formula  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\; \| \\ CH_3\cdot C\cdot H\end{array}$. Pseudobutylene forms a dibromide, from which isobromopseudobutylene,  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\, \|\\ Br\cdot C\cdot CH_3\end{array}$, is easily prepared. Crotonylene hydrobromide or monobromopseudobutylene,  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\;\, \|\\ CH_3\cdot C\cdot Br\end{array}$, is the geometrical isomeride of the preceding compound. Both substances unite with bromine to form $\beta\gamma_2$-tribromobutane, $CH_3\cdot CHBr\cdot CBr_2\cdot CH_3$, and with hydrogen bromide, forming ethylmethylcarbin dibromide,

$$CH_3\cdot CH_2\cdot CBr_2\cdot CH_3.$$

Crotonylene unites with bromine to form $\beta\gamma$-dibromopseudobutylene,  $\begin{array}{l}CH_3\cdot C\cdot Br\\ \quad\;\;\, \|\\ CH\cdot{}_3C\cdot Br\end{array}$ (b. p. 147°), and $\beta\gamma_2$-tribromobutane yields isodibromopseudobutylene,  $\begin{array}{l}CH_3\cdot C\cdot Br\\ \quad\;\;\, \|\\ Br\cdot C\cdot CH_3\end{array}$ (b. p. 150°). Both compounds unite with bromine, forming the crystalline crotonylene tetrabromide. As treatment with a solution of sodium carbonate converts tiglic dibromide into crotonylene hydrobromide, and angelic dibromide into isobromopseudobutylene, the author hopes to eliminate HBr and CO_2 from the hydrobromides of tiglic and angelic acids, and in this way obtain pseudobutylene,  $\begin{array}{l}CH_3\cdot C\cdot H\\ \quad\;\;\, \|\\ CH_3\cdot C\cdot H\end{array}$, and isopseudobutylene,  $\begin{array}{l}\;\;\, H\cdot C\cdot CH_3\\ \quad\;\;\, \|\\ CH_3\cdot C\cdot H\end{array}$, respectively.
W. C. W.

Constitution of Cyanethine and its Analogues. By E. v. Meyer (*J. pr. Chem.* [2], **39**, 156).—Cyanethine and its analogues are probably diazines. The hydroxy-base of cyanethine can be obtained by the condensation of equal mols. of propionamidine and ethyl α-propiopropionate; it is therefore *hydroxymethyldiethylmetadiazine*,  $CEt\!\begin{array}{l}\diagup N{\equiv}CEt\diagdown\\ \diagdown N\cdot C(OH)\diagup\end{array}\!CMe$, and cyanethine is *amidomethyldiethylmetadiazine*,  $CEt\!\begin{array}{l}\diagup N{\equiv\!\equiv}CEt\diagdown\\ \diagdown N\cdot C(NH_2)\diagup\end{array}\!C\cdot Me$.

Pinner's dimethylhydroxypyrimidine (Abstr., 1886, 46) is identical with the hydroxy-base of cyanmethine (Abstr., 1883, 653; 1884, 1292).
A. G. B.

Polymerides of the Nitriles: Dimolecular and Trimolecular Nitriles. By E. v. Meyer (*J. pr. Chem.* [2], **39**, 188—198; compare this vol., p. 114).—Dimolecular ethyl cyanide is imidopropionylethyl cyanide (this vol., p. 114); cyanethine is amidomethyldiethylmetadiazine (preceding Abstract).

Imidobenzoylethyl cyanide, NH:CPh·CHMe·CN, is obtained when benzonitrile and ethyl cyanide (equal mols.) react with sodium in ether; a red mass is formed which, when treated with water, yields sodium hydroxide and the imido-compound, which is dissolved in ethyl acetate and precipitated by petroleum in the form of oblique, truncated prisms, melting at 97°.

α-Benzoylethyl cyanide, COPh·CHMe·CN, is formed when the above imido-compound is warmed with dilute hydrochloric acid. An oil is

the first product; this is dissolved in ether and dried over lime, when a liquid is left which has an unpleasant, aromatic odour, and gradually solidifies.

By the action of phosphorus pentachloride on α-propionylethyl cyanide (this vol., p. 114), a yellowish oil, boiling between 172° and 177°, is obtained. This has the formula C_6H_8ClN, and is probably $CEtCl\!:\!CMe{\cdot}CN$; potassium hydroxide decomposes it, evolving ammonia; hydrochloric acid at 150° acts on it, producing chiefly carbonic anhydride and diethyl ketone.

The author here replies to Hanriot and Bouveault (*Bull. Soc. Chim.*, **51**, 176), who have criticised his views on the constitution of dimolecular ethyl cyanide.

Amidomethyldiphenylmetadiazine,  $CPh\lessdot\genfrac{}{}{0pt}{}{N{=\!=}CPh}{N{\cdot}C(NH_2)}\gtrdot CMe$ (*cyandiphenylethine*), is obtained when the product of the action of sodium on ethyl cyanide is heated at 150° with an equal weight of benzonitrile in a sealed tube for three hours; the resulting mass is treated with ether and then with water, and the residue crystallised from alcohol; it melts at 172—173°, softening at 170°, and is sparingly soluble. The *sulphate* forms slender needles, and the *hydrochloride*, $C_{17}H_{15}N_3,HCl$, crystallises in prisms melting with decomposition at 238°. When the base is heated with strong hydrochloric acid, and water is added, *hydroxymethyldiphenylmetadiazine* is obtained (compare this vol., p. 114). This crystallises from hot alcohol in tufts of needles, sparingly soluble, and melting at 256°. Its *methyl*-derivative, $C_{17}H_{13}N(NMe)O$, forms prisms which melt at 121—122°.

Amidomethylethylisopropylmetadiazine, $C_{10}H_{17}N_3$, crystallises from weak alcohol in lustrous, seemingly rhombic laminæ melting at 153—154°. It is being further investigated. A. G. B.

Physical Properties of Methyl Alcohol. By W. DITTMAR and C. A. FAWSITT (*Trans. Roy. Soc. Edin.*, **33**, 509—534).—To purify crude methyl alcohol, 100 c.c. of the spirit is digested with 150 grams of powdered sodium hydroxide, after which it is distilled on a water-bath; 500 grams of oxalic acid crystals are mixed with 200 c.c. of sulphuric acid, and then 400 c.c. of the alcohol, purified as above, is added, and the whole cautiously heated on a water-bath. The methyl oxalate thus obtained is thoroughly dried by pressure, and the alcohol regenerated by digestion with water at 70°. To dehydrate the alcohol thus obtained, digestion with baryta, lime, and dried copper sulphate is necessary. A very full account of the processes, successful and unsuccessful, is given, and of many operations performed and results obtained, which, although not finally employed, led the authors to adopt fresh measures and warned them against false results. In the estimation of tension it was found that air-free alcohol "bumped" seriously; consequently, it having been found that the error introduced by the employment of alcohol containing air was infinitesimal, the remaining densities, &c., were determined without freeing the alcohol from air. An abstract of the result of the vapour-tension determinations is given in the following table; in the original memoir, figures are given for every degree.

Table of Vapour-tension of Methyl Alcohol in Millimetrès of Mercury at 0°.

Temp.	Tension.	Temp.	Tension.	Temp.	Tension.
0°	29·7	30°	158·9	60°	624·3
10	53·8	40	259·4	64·96	760·0
20	94·0	50	409·4		

The methods, apparatus, and calculations employed in the estimation of the specific gravity are most fully detailed in a table, of which the following is an abstract, figures being given in the original for each percentage :—

Per cent. of $CH_3 \cdot OH$.	Sp. gr. at 0°.	Sp. gr. at 15·96°.	Per cent. of $CH_3 \cdot OH$.	Sp. gr. at 0°.	Sp. gr. at 15·96°.
0	999·87	999·07	60	909·17	897·98
10	984·29	982·62	70	886·87	874·87
20	972·33	968·08	80	863·14	850·35

Products of the Slow Combustion of Ethyl Ether. By L. Legler (*Chem. Centr.*, 1888, 1604).—The solid substance obtained by the author by the slow combustion of ethyl ether is *hexaoxymethylene peroxide*, $C_6H_{12}O_8,3H_2O$. When treated gradually with ammonia, *hexaoxymethylenediamine*, $C_6H_{12}O_6N_2$ is formed. The oxide is decomposed by alkalis into formic acid and hydrogen. With gaseous ammonia, it explodes ; with bromine water, it forms an orange-yellow precipitate, which gives off bromine when exposed to the air, with formation of *hexamethyleneamine dibromide*, $C_6H_{12}N_4Br_2$.

J. W. L.

Products of Alcoholic Fermentation, with Special Reference to the Formation of Glycerol. By V. Thylmann and A. Hilger (*Chem. Centr.*, 1889, 260; from *Arch. Hygiène*, 8, 451—467).—From a series of experiments on alcoholic fermentation, the authors have deduced the following results :—(1.) Slow fermentation at a low temperature reduces the formation of glycerol. In one case the fermentation lasted 25 days at 15°, when the proportion of alcohol to glycerol was 100 : 1·638. (2.) The minimum relation of 100 parts of alcohol to 7 parts of glycerol in the case of the fermentation of the juice of the grape, is not at all applicable to a solution of pure sugar. The average ratio in 21 fermentations of pure sugar solutions with ordinary beer yeast was 100 : 4·6. (3.) The addition to sugar solutions of other food, results in the formation of a high proportion of glycerol. (4.) The presence or absence of air during fermentation appears to have no influence on the result. (5.) A temperature of 35° reduces the rate of fermentation, and at the same time the proportion of glycerol is diminished. The rate of fermentation may be reduced by using a concentrated solution of sugar, but in this case the proportion of glycerol is increased. J. W. L.

Combination of Mannitol with Aldehydes of the Acetic Series. By J. Meunier (*Compt. rend.*, **108**, 408—410).—If aldehyde vapour is passed into a solution of mannitol in sulphuric or hydrochloric acid, the aldehyde is absorbed. The same reaction takes place if similar solutions of mannitol are agitated with paraldehyde, and the liquid becomes semisolid, owing to the separation of small, white, silky needles.

The product is the same in both cases, and forms slender, white needles which melt at 174° if rapidly heated, but sublime at a much lower temperature if gradually heated. Sublimation is rapid at 100—110°, and the product condenses in long, flexible needles. It is insoluble in cold water, but dissolves in 100 parts of water at 95°, it is only slightly soluble in cold alcohol, but dissolves readily in boiling alcohol. When it is suspended in water containing 2 per cent. of sulphuric acid and steam is passed into the liquid, the compound is decomposed into mannitol and aldehyde. When heated with water containing a higher proportion of acid, it decomposes below 100° into mannitol and other products which have not yet been investigated. The quantity of mannitol is greater the lower the temperature at which decomposition takes place, and the smaller the proportion of acid present.

This compound is an acetal formed by the union of mannitol with paraldehyde with elimination of 3 mols. H_2O. When the acetal is formed from gaseous aldehyde, the conditions are identical with those under which aldehyde changes into paraldehyde.

When an acid solution of mannitol is agitated with a mixture of acetaldehyde and benzaldehyde in equal proportions, the ethyl compound is formed first. C. H. B.

Sorbite and its Occurrence in the Fruits of Rosaceæ. By C. Vincent and Delachanal (*Compt. rend.*, **108**, 354—356).—The sorbite was separated in the form of the dibenzoic acetal from concentrated solutions which had previously been fermented with beer yeast, and treated with basic lead acetate. Unlike mannitol (preceding Abstract), it yields no acetal with the aldehydes of the acetic series. Sorbite was obtained from pears, apples, medlars, the fruit of the evergreen thorn, and Brittany cider. With a Laurent's shadow polarimeter and a tube 50 cm. long, it was found that the rotatory power is $[\alpha]_D = -1°73'$, so that sorbite, like mannitol, is lævogyrate, and contains asymmetrical carbon-atoms. The rotatory power is increased, but its direction is changed by the addition of sodium borate. In a liquid which contains in 100 c.c. 40 grams of crystallised borax, 30 grams of sodium hydroxide solution of 36°, and 10 grams of sorbite, the rotatory power of the latter at 15° is $[\alpha]_D = +12° 33'$.

When a dilute solution of sorbite is oxidised in the cold with a limited quantity of potassium permanganate, it yields a reducing sugar and an acid. If the product is warmed with potassium hydroxide solution, an intense yellow coloration is produced. The oxidised solution reduces ammoniacal silver nitrate and Fehling's solution energetically even in the cold.

If 1 part of sorbite is added to 2 parts of fuming nitric acid, or to a mixture of 4 parts of nitric acid and 10 parts of sulphuric acid, no nitrogen oxides are evolved, but an oil separates and rises to the top. The product is poured into a large quantity of water, the oil separated by treatment with ether, the ethereal solution agitated first with a solution of potassium carbonate, then with the solid salt and the ether expelled by slow evaporation. The yellow oil thus obtained is a nitro-derivative, which takes fire in contact with a burning substance and detonates violently when struck with a hammer.

C. H. B.

Quercitol. By H. KILIANI and C. SCHEIBLER (*Ber.*, **22**, 517—520).—When finely divided quercitol (5 grams) is treated with nitric acid of sp. gr. 1·39 (15 grams) first at 20° for about 12 hours and then at about 30° until evolution of gas ceases, mucic acid (5 to 6 per cent.) separates from the solution in the form of a colourless, crystalline powder. The colourless mother-liquors on neutralisation with calcium carbonate gradually become deep-red, and on mixing the filtered solution with alcohol, impure calcium trihydroxyglutarate is precipitated. This acid, which is only formed in very small quantities, was identified by means of the normal calcium salt (this vol., p. 32).

These results seem to show that Kanonnikoff's constitutional formula for quercitol is not correct. F. S. K.

Saccharification of Dextrin by Diastase. By L. LINDET (*Compt. rend.*, **108**, 453—455).—The author has reinvestigated the influence of maltose in checking the conversion of dextrin into sugar by the action of diastase. Phenylhydrazine was used to completely or partially remove maltose from the liquid. In an ordinary wort or must, saccharification stops when the maltose reaches a maximum, but recommences if the maltose is removed by alcoholic fermentation or by precipitation. These results confirm the earlier experiments of Payen. C. H. B.

Formation of Saccharoses from Formaldehyde. By O. LOEW (*Ber.*, **22**, 470—478).—As has been previously stated (compare Abstr., 1888, 358), some bases have the power of causing the condensation of formaldehyde to a far greater extent than others; lead oxide, for example, although without action in the cold, has a remarkably powerful action at a moderately high temperature even when present in very small quantities. Lime is a better agent than baryta, and both are far more powerful than soda or potash. A 3 per cent. solution of formaldehyde was shaken with a little lime; after half an hour the solution was filtered and divided into two portions, to one of which concentrated sodium carbonate solution was added as long as a precipitate of calcium carbonate was produced. After keeping for four days in closed vessels, condensation was at an end in the portion containing lime, but in the solution containing soda not a trace of sugar was formed, even after six days, the aldehyde having been partially converted into formic acid, but the greater part remaining unchanged. On warming this solution, a small quantity of sugar was formed, but it was immediately decomposed again, the solution becoming yellow. In other experiments with potash and soda, 1 per cent. of the alkali was added to a 1 per cent. solution of formaldehyde and kept at the ordinary temperature; the results were as unsatisfactory as before. When a 0·1 per cent. solution of formaldehyde is gently warmed with a 0·1 per cent. solution of potassium carbonate for several hours, a product similar to crude formose is obtained. As a rule the more concentrated the formaldehyde solution and the stronger the base, the larger the quantity of formic acid produced and consequently the smaller the quantity of sugar. Magnesia produces no condensation in a 1 per cent. or even in a 0·1 per cent. solution of formaldehyde, even on heating at 80—90° for several days; the solution obtained by shaking lead oxide with magnesium sulphate (*loc. cit.*) contains a small quantity of lead oxide, and it is to this base alone that condensation is due. The production of sugar which is observed when dilute formaldehyde solutions are treated with metallic lead is also due to the formation of lead oxide or hydroxide. When a solution of formaldehyde is heated at 80—90° with granulated metallic lead, slight evolution of gas occurs, and the solution becomes turbid owing to the separation of lead hydroxide; only traces of sugar are formed during the first hour, but at the end of the third hour condensation is complete. In presence of sulphates, the lead is attacked much more slowly, no turbidity is produced, and the condensation takes 6 to 10 times as long. The condensing action of commercial tin (*loc. cit.*) is due to the presence of small quantities of lead, and the sugar (pseudo-formose) which is formed is a mixture of several isomeric saccharoses.

The condensing action of bases is doubtless due to the intermediate formation of some unstable compound of formaldehyde with the base, as is shown by the fact that a solution of formaldehyde, free from formic acid, dissolves more lime than water does.

When litharge (about 15 grams) is warmed with a 16—20 per cent. solution of formaldehyde (25 c.c.), the oxide increases considerably in volume and becomes converted into a white, spongy mass, a small portion being reduced to metal. This powder, after washing with water, pressing, and drying over sulphuric acid, contains unchanged lead oxide, probably also hydroxide, but on heating, it blackens with separation of metallic lead and is then immediately converted into the yellow oxide. It has no smell, but when heated alone, or with water, or with dilute sulphuric acid, the penetrating odour of formaldehyde is perceptible. It reduces silver nitrate solution at the ordinary temperature, the metal being deposited. This white powder is, therefore, a compound of lead oxide and formaldehyde, and its formation is distinct evidence in favour of the glycol formula for the latter.

Numerous experiments were made under varying conditions with bases, compounds of bases (amongst others calcium and magnesium acetate), and salts with an alkaline reaction, but no naturally occurring saccharose was obtained. A feeble electric current passed through the mixture was also without effect on the result. It was noticed, however, that seemingly inconsiderable alterations in the mode of condensation often influenced the relative quantities of the various sugars produced, and it was found that by diminishing the quantity of the condensing agent the proportion of the more stable sugars could be augmented. Formose, on the other hand, is formed when condensation takes place easily and rapidly.

The author gives hypothetical graphic formulæ for formose and levulose, and also attempts to show by graphic formulæ in what manner the condensation of formaldehyde by lime may be supposed to take place. According to these views a base containing more than two hydroxyl-groups would limit the freedom of rotation of the carbon-atoms, and would lead to an increased formation of those sugars analogous to the natural saccharoses. The striking energy of lead oxide may, therefore, be due to the existence of a hydrate, $Pb_2(OH)_4$, and with this base the author succeeded in obtaining a mixture of sugars, amongst which is one (*methose*) which ferments with yeast. The method which yields the largest proportion of this sugar (about 20 per cent.) was found to be the following:—Formaldehyde (40 grams) in aqueous solution of known strength is added to water (4 litres), the solution mixed with magnesia (0·5 gram) and magnesium sulphate (2 to 3 grams), and then warmed at about 60° with granulated lead (350—360 grams) in a flask, which the solution fills almost entirely. The reaction is at an end when a small portion, on boiling, no longer smells of formaldehyde, which is the case after about 12 hours. The almost colourless syrup which remains when the solution is evaporated at 50°, is boiled with 80 per cent. alcohol, the cold solution mixed with ether to precipitate magnesium sulphate, and most of the sugar then precipitated by adding ether and light petroleum. The product is again dissolved in absolute alcohol, the solution mixed with ether, the precipitated syrup dissolved in water, and the alcohol driven off by evaporation. The yellowish, extremely sweet syrup which is thus obtained reduces Fehling's solution very energetically, and is less readily attacked by bromine than is dextrose; it yields humous substances when warmed with hydrochloric acid, gives a yellowish-brown colour with alkalis, and shows all the most important properties of a natural saccharose. It enters into lively fermentation when treated with yeast in aqueous solution, but a large quantity of the sugar, probably formose, remains unchanged even when left in contact with yeast for eight days; the ethyl alcohol produced was identified by its smell, by the iodoform reaction, and by oxidation to acetaldehyde. The crude syrup is almost completely decomposed when warmed for three hours with 7·5 per cent. hydrochloric acid, yielding humous substances and furfuraldehyde, so that the sugar which ferments resembles levulose rather than dextrose. (Compare Sieber, *Zeit. anal. Chem.*, **24**, 137.) The crude syrup yields an oily mixture of osazones from which, by washing with cold 96 per cent. alcohol and recrystallising the residue, an osazone, $C_{18}H_{22}N_4O_5$, melting at 205—206°, can be isolated. This compound crystallises in yellow needles, and in appearance and solubility in absolute alcohol is very similar to phenylglucosazone. That this osazone is a derivative of the fermenting sugar is shown by the following experiments:—Two equal portions (10 c.c.) of the crude syrup were taken; one was mixed with 8 vols. of water and fermented with yeast for one day at the ordinary temperature. The osazones were then prepared from the two portions separately, and treated in the same way with benzene, ether, and cold absolute alcohol. The weight of the residual sparingly soluble osazone obtained from the non-fermented portion was 26 per cent. of the total mixture of osazones, in the other case it only amounted to 11·5 per cent. The osazone (0·4 gram) was reconverted into sugar by Fischer's method (*Ber.*, **22**, 87); the sugar fermented with yeast, but only slowly, and was not entirely decomposed until the third day, perhaps owing to the diluteness of the solution. F. S. K.

Formose. By O. Loew (*Ber.*, **22**, 478—482).—The mixture of osazones which is obtained from the crude formose, prepared by treating a 3·5—4 per cent. solution of formaldehyde with lime, consists principally of three compounds (compare Fischer, Abstr., 1888, 590):—(1) Formosazone, which constitutes 75—82 per cent., or probably more, of the crude product; this compound is readily soluble in ether, and thereby differs from all other known osazones; (2) an osazone (16—20 per cent.), probably a mixture, which is sparingly soluble in ether, but very readily soluble in absolute alcohol; (3) an osazone (3—4 per cent.) insoluble in ether and very sparingly soluble in cold, absolute alcohol. The relative quantity of formose in the crude product is considerably diminished when more dilute solutions of formaldehyde are employed, and when a large quantity of thin milk of lime is used instead of a thick paste; with a 1 per cent. solution the formosazone only forms 48—53 per cent. of the total osazone weight.

Pure formose, prepared from the osazone, is a syrupy sugar, readily soluble in strong alcohol and very easily changed by acids or alkalis. When warmed with hydrochloric acid it yields humous substances, but no levulose, and when heated at about 100° it turns brown, and is converted into a substance with a bitter taste. It undergoes the lactic fermentation, but does not ferment with yeast. Bromine acts on it more rapidly than on levulose, but much more slowly than on dextrose, converting it into oxalic acid and another acid, probably trihydroxybutyric acid; it is also oxidised by nitric acid, but no acid containing six atoms of carbon is produced. Its reducing power for Fehling's solution is about the same as that of dextrose, but when treated with nascent hydrogen it is converted into a syrupy substance which has no reducing action. It combines readily with hydrocyanic acid, but the product is easily decomposed by concentrated mineral acids. The osazone (see above) begins to melt at about 130°.

The article concludes with a reply to Fischer (*loc. cit.*) in which the author claims that he himself, and not Butlerow, first showed that several saccharoses could be obtained from formaldehyde.

F. S. K.

Conversion of Ketones into Nitrosoketones. By L. Claisen and O. Manasse (*Ber.*, **22**, 526—530).—Nitrosoketones can be obtained, as has been previously shown (Abstr., 1887, 944), by treating ketones with amyl nitrite in presence of sodium ethoxide or hydrochloric acid. Further investigations have shown that with some ketones sodium ethoxide, with others hydrochloric acid, gives the best results. Diethyl ketone and benzalacetone belong to the second category, nitrosomesityl oxide, on the other hand, can only be obtained by using sodium ethoxide. The nitroso-derivative of methyl propyl ketone and phenyl ethyl ketone can be prepared by either method, but the yield is better when hydrochloric acid is employed.

In preparing nitrosoketones by means of amyl nitrite and hydrochloric acid, it is best to proceed as follows:—A small quantity of amyl nitrite is added to the ketone, then a little hydrochloric acid, and as soon as, but not before, the yellow coloration has disappeared, the calculated quantity of amyl nitrite is gradually added in small portions to the well-cooled mixture, care being taken that the yellow colour has disappeared before each fresh addition of the nitrite. After keeping for a short time, the product is extracted with dilute soda, the alkaline solution shaken with ether to remove amyl alcohol, acidified with acetic acid or dilute hydrochloric acid, and the nitrosoketone extracted with ether. In the case of benzalacetone and propiophenone, it is not necessary to extract with soda, as the product can be precipitated at once, and almost entirely by adding excess of light petroleum. The yield varies considerably, being in many cases 30—40 per cent., in others as much as 70 per cent. of the calculated quantity. Excess of amyl nitrite should never be present during the reaction, as the nitrosoketones are thereby readily decomposed. Nitrosoethyl phenyl ketone (*loc. cit.*) is decomposed by amyl nitrite, yielding benzoyl acetyl, amyl alcohol, and nitrous oxide; nitrosoacetone and nitrosoacetophenone are decomposed when warmed with amyl nitrite, but the reaction seems to take place in a different manner.

Propyl nitrosomethyl ketone, $COPr\cdot CH\colon NOH$, crystallises from light petroleum in small, nacreous plates, melting at 48—51°. The *osazone*, $N_2HPh\colon CH\cdot CPr\colon N_2HPh$, crystallises in needles and melts at 162—163°. The *glyoxime*, $CPr(NOH)\cdot CH\colon NOH$, melts at 168°.

Nitrosodiethyl ketone, $OH\cdot N\colon CMe\cdot COEt$, crystallises in colourless plates melting at 59—62°. The *osazone*, $N_2HPh\colon CEt\cdot CMe\colon N_2HPh$, melts at 166—169°. The *glyoxime* is a crystalline powder melting at 170—172°.

These two nitrosoketones are isomeric with methyl nitrosopropyl ketone, prepared by Meyer and Züblin (Abstr., 1878, 659) from ethyl ethylacetoacetate.

Nitrosomesityl oxide, $CMe_2\colon CH\cdot CO\cdot CH\colon NOH$, crystallises from benzene and light petroleum in colourless prisms melting at 102°.

Nitrosopropiophenone, $COPh\cdot CMe\colon NOH$, crystallises from alcohol and water in small, colourless needles melting at 108—110°.

Nitrosobenzalacetone, $CHPh\colon CH\cdot CO\cdot CH\colon NOH$, can be prepared as described above, or by gradually adding a mixture of nitrosoacetone, benzaldehyde, and ether, to well-cooled ether containing sodium ethoxide in suspension, and decomposing the ice-cold solution of the resulting sodium salt with acids. It crystallises well from water, benzene, ethyl acetate, and chloroform, melts at 143—144°, and gradually decomposes with evolution of hydrogen cyanide.

F. S. K.

Decomposition of Fats by Heating under Pressure. By C. Engler (*Ber.*, **22**, 592—597; compare Abstr., 1888, 928).—Two series of experiments with fish oil and oleïc acid showed that when such compounds are distilled under increased pressure, the quantity of methane produced is increased and the quantity of carbonic anhydride diminished.

When fish oil is heated under the ordinary atmospheric pressure, the greater portion distils between 360° and 420°, but in the closed glass vessels previously described (*loc. cit.*) it passes between 365° and about 425°. In the latter case, the principal portion (63·1 per cent.) distils in the form of liquid hydrocarbons (sp. gr. 0·837), and considerable quantities (8·9 per cent.) of gaseous products, such as methane, olefines, carbonic oxide, and carbonic anhydride, are formed; the residual tarry mass, when heated under the ordinary atmospheric pressure, yields liquid hydrocarbons (16·5 per cent.) and coke or asphalte (11·6 per cent.). Trioleïn, when treated in like manner, yields liquid hydrocarbons (69·8 per cent., sp. gr. 0·845) and gaseous products (10 per cent.); the residue, on further distillation under the ordinary pressure, yields liquid hydrocarbons (14·1 per cent.) and coke or asphalte (6·1 per cent.). If the small quantity of water which is formed and the undecomposed oil or trioleïn in the distillate is taken into account, the yield of crude oily hydrocarbons is 69·5 per cent. in the case of fish oil, and 73·7 per cent. in case of trioleïn; the conversion into paraffins is almost complete with one distillation. The following paraffins were isolated from the distillate of fish oil:—Secondary hexane (diisopropyl), boiling at 57—59°; sp. gr. 0·6677 at 21°. Secondary heptane (ethylisoamyl), boiling at 88—91°, sp. gr. 0·6918 at 18°. Normal octane, boiling at 123—125°; sp. gr. 0·7044 at 19°. Secondary octane (diisobutyl), boiling at 107—109°; sp. gr. 0·702 at 17·5°. Normal nonane, boiling at 148—151°; sp. gr. 0·729 at 20·5°.

The fraction 140° to 300° of the crude distillate obtained from fish oil, after purifying, burns in an ordinary petroleum lamp with a highly luminous flame.

The crude product, which is obtained when trioleïn is distilled under pressure (10 atmos.), is a mobile, brownish-black, fluorescent oil of sp. gr. 0·780, and very similar to that obtained from fish oil. It contains 2·5 per cent. of ethereal salts, and yields to water 1·6 per cent., to soda 2 per cent., to concentrated sulphuric acid 15 per cent., and to fuming sulphuric acid 10 per cent. of its weight. From the residue, normal hexame and normal heptane were isolated.

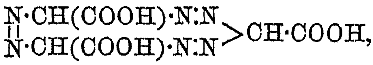
Constitution of Diazo- and Azo-compounds of the Fatty Series, and of Hydrazine (Diamide) and its Derivatives. By T. Curtius (*J. pr. Chem.* [2], **39**, 107—139).—The author discusses these questions in the light of his recent researches on the subject (this vol., pp. 340, 369, 376, 393). The constitution of ethyldiazoacetate is $\overset{N}{\underset{N}{\|}}>CH\cdot COOEt$, containing the group $\left(\overset{N}{\underset{N}{\|}}>C\right)''$, which characterises the diazo-compounds of the fatty series.

Triazoacetic acid has the constitution



$$\left.\begin{array}{l} N\cdot CH(COOH)\cdot N{:}N \\ \| \\ N\cdot CH(COOH)\cdot N{:}N \end{array}\right> CH\cdot COOH,$$

which explains its splitting up under the action of water into hydrazine, $H_2N\cdot NH_2$, and oxalic acid (or formic acid and carbonic anhydride).

Hydrazine hydrate is $H_2N\cdot NH_3\cdot OH$; it evaporates completely in a vacuum over caustic potash, and solidifies in a mixture of solid carbonic anhydride and ether to a crystalline mass, which melts below —40°. A. G. B.

Bromine Additive Products of Angelic and Tiglic Acids. By M. Pückert (*Annalen*, **250**, 240—250).—Angelic acid is best prepared by shaking a mixture of oil of Roman camomile (100 grams) with potassium hydroxide (51 grams) and water (51 grams), until the whole solidifies. After a few days a small quantity of water is added, and the layer of alcohol which rises to the surface is removed. The aqueous solution is acidified with sulphuric acid and extracted with ether. The residue which remains after evaporating the ethereal solution is pressed between bibulous paper and distilled. It melts at 45—46°, and boils at 185°. 100 grams of oil of camomile yield 15 grams of angelic acid. Tiglic acid can be most economically prepared by slowly adding 150 grams of 2 per cent. sodium amalgam to 10 grams of ethyl methylacetoacetate dissolved in 30 grams of water and a sufficient quantity of alcohol to yield a clear solution; during the operation, sulphuric acid is added so as to keep the mixture slightly acid, and from time to time the liquid mercury must be run off, and crystals of sodium sulphate removed. When all the amalgam is added, the solution is neutralised, evaporated to dryness, and extracted with absolute alcohol. The alcoholic solution is evaporated, the residue acidified with sulphuric acid and extracted with ether; the ethereal extract is evaporated, and the residue on distillation yields tiglic acid. The dibromides are formed by slowly adding bromine diluted with carbon bisulphide to a solution of the acids in carbon bisulphide. *Tiglic dibromide* melts at 86—87°, and is insoluble in cold water, in which it remains in the crystalline state. *Angelic acid dibromide* melts between 50° and 57°, but after fusion it melts constantly at 64°. It is hygroscopic and liquefies in water. Tiglic acid dibromide is decomposed by sodium carbonate, yielding crotonylene hydrobromide. Under similar conditions angelic dibromide yields monobromopseudobutylene. The crotonylene hydrobromide is more easily reduced by an alcoholic solution of sodium ethoxide than the isobromopseudobutylene from angelic dibromide. These results indicate that angelic and tiglic acids are geometric isomerides, having respectively the constitutions represented by the following formulæ:—

$$\begin{array}{l} CH_3\cdot C\cdot H \\ \quad\ \ \| \\ CH_3\cdot C\cdot COOH \end{array} \text{ and } \begin{array}{l} H\cdot C\cdot CH_3 \\ \quad\ \| \\ CH_3\cdot C\cdot COOH \end{array}$$

W. C. W.

Ethyl Monochloracetoacetates. By A. HALLER and A. HELD (*Compt. rend.*, **108**, 516—518).—Ethyl γ-monochloracetoacetate was obtained by the direct action of chlorine on the acetoacetate at a low temperature. On fractionation, the chlorine-derivative boiled at 188—189°. A solution of the monochloracetoacetate in anhydrous ether or benzene was allowed to act on half its weight of pure potassium cyanide, the product was filtered, the filtrate treated with a further quantity of the cyanide, and the process repeated a second time. The formation of a certain quantity of insoluble ethyl acetocyanacetate showed that some α-monochloracetoacetate was present. The ether was expelled from the filtrate and the residue was fractionated; unaltered chloracetoacetate passed over, and the remaining cyanogen-derivative boiled at 145—160° in a vacuum. The latter was treated with an alcoholic solution of hydrogen chloride, the precipitate of ammonium chloride separated, and the ethereal salt treated with hydrocyanic acid, and afterwards with an alcoholic solution of hydrogen chloride. After removal of ammonium chloride and ether and distillation in a vacuum, a small quantity of liquid was obtained which boiled at 200°, and when saponified yielded a solution which with lime-water gave the reaction for citric acid.

C. H. B.

Syntheses by means of Ethyl Cyanosuccinate. By L. BARTHE (*Compt. rend.*, **108**, 297—300).—The hydrogen of the CH group in ethyl cyanosuccinate is readily displaced by metals or by alkyl radicles. The substitution of metals is effected by treatment with alkyl-metallic oxides; the substitution of alkyl radicles is accomplished by mixing the ethyl cyanosuccinate with a solution of an equivalent quantity of sodium in the particular alcohol and boiling the mixture with the corresponding alkyl iodide. The excess of alcohol is distilled off, the residue diluted with water, extracted with ether, the ethereal solution dried over calcium chloride, and the ether distilled off. The products are colourless, oily liquids, of the general formula

$$COOEt{\cdot}CH_2{\cdot}CR(CN){\cdot}COOEt.$$

Ethyl methylcyanosuccinate boils at 183—186° under a pressure of 3·5 mm.; *ethyl ethylcyanosuccinate* boils at 170—180° in a vacuum; *ethyl propylcyanosuccinate* boils at 204—206° under a pressure of 45 mm.

If ethyl ethylcyanosuccinate is allowed to remain for several weeks in contact with alcohol saturated with hydrogen chloride, it yields *ethyl ethylethenyltricarboxylate*, $COOEt{\cdot}CH_2{\cdot}CEt(COOEt)_2$; this boils at 187° under a pressure of 50 mm. C. H. B.

Action of Bromine on Aconitic and Carballylic Acids. By E. GUINOCHET (*Compt. rend.*, **108**, 300—302).—Aconitic acid, when heated in sealed tubes at 115—120° for several hours with four molecular proportions of bromine, yields tribromocarballylic acid, $C_6H_5Br_3O_6$, which separates from alcohol of 90° in colourless crystals, very soluble in ethyl alcohol, methyl alcohol, ether, and acetone, but insoluble in cold water and in chloroform. It decomposes slowly at 100°, and dissolves rapidly in hot water with decomposition and liberation of hydrogen bromide. When boiled with barium hydroxide, it yields a considerable proportion of oxalic acid. The potassium salt of tribromocarballylic acid forms a crystalline powder containing 1·5 mols. H_2O; the ammonium salt crystallises in prisms very soluble in water; and the barium salt crystallises with 12 mols. H_2O in colourless prisms which are very soluble in water, but do not dissolve in ethyl alcohol. The barium salt loses 9 mols. H_2O in a dry vacuum or when exposed to air, and then undergoes no change at 100°, but begins to decompose at 115°. Cold aqueous solutions of all these salts give no precipitate with silver nitrate, but a hot solution gives an immediate precipitate of silver bromide.

The action of bromine on carballylic acid yields the same derivative. In the first case, the tribromocarballylic acid is formed from the aconitic acid by direct addition of two atoms of bromine and substitution of one atom of bromine for an atom of hydrogen, the change being analogous to the formation of carballylic acid by direct union of aconitic acid with two atoms of hydrogen. C. H. B.

Oxidation of Galactosecarboxylic Acid. By H. Kiliani (*Ber.*, **22**, 521—524).—Galactosecarboxylic acid (Abstr., 1888, 581) is best prepared in large quantities by boiling the crude product of the action of hydrocyanic acid on galactose with lime; the lime is precipitated in the cold with oxalic acid, the filtered solution boiled with lead carbonate and concentrated, crystallisation being promoted by rubbing with a small quantity of the crystalline lead salt. The latter is obtained from a small quantity of the pure acid, which is prepared by the method previously described (*loc. cit.*). The crystals are separated after one to two days, and purified by crystallising twice from boiling water (4 parts) with addition of animal charcoal. The pure salt is dissolved in water (5 parts), treated with hydrogen sulphide, and the filtered solution evaporated under diminished pressure to avoid the formation of the lactone.

Carboxygalactonic acid, $C_7H_{12}O_9$, is formed when galactosecarboxylic acid (1 part) is heated at 50° for about 24 hours with nitric acid of sp. gr. 1·2 (1½ parts). The solution is evaporated until free from nitric acid, taken up with water, the oxalic acid precipitated with the requisite quantity of calcium carbonate, and the filtered solution neutralised with potash, evaporated to a syrup, and mixed with a large excess of acetic acid. *Potassium hydrogen carboxygalactonate*, $2C_7H_{11}O_9K + 3H_2O$, separates on stirring, the whole becoming solid after 12 to 24 hours. It is purified by recrystallisation from water, from which it separates in aggregates of silky needles; it readily forms supersaturated solutions, from which it can be separated by adding alcohol or stirring. The *cadmium* salt, $C_7H_{10}O_9Cd,2H_2O$, prepared by decomposing a solution of the neutral potassium salt with cadmium nitrate, crystallises in colourless, nodular masses, consisting of small, slender needles. The free *acid* is obtained in microscopic prisms when a solution of the cadmium salt is treated with hydrogen sulphide, filtered and evaporated in a partial vacuum. It sinters together at 168°, melts at 171° with decomposition, and is sparingly soluble in cold water, although more readily than mucic acid. The neutral potassium and sodium salt could not be obtained in crystals. The *barium* salt, $(C_7H_{10}O_9)_2Ba + 3H_2O$, crystallises in small prisms or needles. F. S. K.

Metasaccharic Acid. By H. Kiliani (*Ber.*, **22**, 524—525).—Maquenne (Abstr., 1888, 677) has observed that the diphenylhydrazide of ordinary saccharic acid has the same melting point as that of metasaccharic acid, and resembles the latter in being almost insoluble in water, alcohol, and ether. The author finds by direct comparison that these two compounds can hardly be distinguished one from the other.

The diacetyl-derivative of the double lactone of metasaccharic acid can be prepared by treating the anhydrous double lactone (2 grams) with acetic anhydride (3 grams) and concentrated sulphuric acid (3 drops). It melts at 155°, and is readily soluble in hot, glacial acetic acid, from which it crystallises in well-defined prisms. This compound is therefore quite different from the corresponding derivative of saccharic acid (compare Maquenne, *loc. cit.*), which crystallises in small rhombic plates melting at 188°. F. S. K.

Preparation of Glycocine. By S. Gabriel and K. Kroseberg (*Ber.*, **22**, 426—428).—Glycocine is best prepared by heating potassium phthalimide (100 grams) with ethyl chloracetate (65 grams) at 140—150° (compare Goedeckemeyer, Abstr., 1888, 1294). The product is poured into a dish, the powdered cake recrystallised from boiling 50 per cent. alcohol, and washed first with dilute alcohol and then with water. The yield of ethyl phthalylglycollate is about 97 per cent. of the theoretical quantity. This compound is then decomposed by heating with concentrated hydrochloric acid at 200° (compare Goedeckemeyer, *loc. cit.*), when it yields about 96 per cent. of the theoretical quantity of glycocine hydrochloride.

In preparing glycocine in large quantities, the phthalyl-derivative (1 mol.) is hydrolysed by boiling for a short time with alcoholic potash (10 per cent., 2 mols.). The clear liquid is mixed with fuming hydrochloric acid (2 mols.) and the glycocinephthaloylic acid, which crystallises from the cold solution, is separated and washed with ice-cold water. The yield is about 85·5 per cent. of the theoretical quantity. The acid is then boiled for about two hours with twice its weight of pure hydrochloric acid (20 per cent.) with constant shaking, and the diluted solution is separated from the phthalic acid by filtration and evaporated. The residue is extracted with a small quantity of ice-cold water, the extract evaporated, and the residual glycocine hydrochloride washed with absolute alcohol.

Glycocinephthaloylic acid, $COOH\cdot C_6H_4\cdot CO\cdot NH\cdot CH_2\cdot COOH$, softens at about 100° and melts at 105—106° (compare Beese, Abstr., 1888, 148). F. S. K.

Ethylfumarimide. By A. Piutti (*Chem. Centr.*, 1888, 1529).—If ethylamine hydrogen malonate is heated at 160—200°, water and an oil distil over. The latter, *ethylfumarimide*,  $\begin{matrix}CH\cdot CO\\ \| \\ CH\cdot CO\end{matrix}\!\!>\!NEt$, solidifies in crystals, is volatile and caustic, and the vapours cause a flow of tears. It is little soluble in water, very soluble in alcohol and ether, considerably soluble in benzene; from the latter it may be obtained in thick, lustrous crystals. It forms two compounds with bromine in ethereal solution, a liquid and a solid derivative; the latter is little soluble in ether, and does not melt at a high temperature. When heated with zinc-dust, ethylfumarimide emits vapours which, when brought into contact with a splinter of pinewood moistened with hydrochloric acid, give the pyrroline reaction. When reduced with sodium amalgam, an oil is formed. With aqueous or alcoholic alkali solutions, a beautiful purple colour is obtained; by heating with solid potassium hydroxide, a violet substance is formed, which evolves ethylamine at a higher temperature. From the aqueous solution of the fused mass, hydrochloric acid precipitates fumaric acid. If ethylfumarimide is dissolved in somewhat concentrated potassium hydroxide solution, *potassium ethylfumaramate* is formed; the free acid may be obtained from this on the addition of a mineral acid.

Ethylfumaramic acid, $NHEt·CO·CH{:}CH·COOH$, melts at 125—126°, crystallises in lustrous, pearly scales, is very readily soluble in hot water and alcohol, fairly soluble in ether, insoluble in benzene. When heated, ethylfumarimide is regenerated. It combines directly with bromine. The copper salt is a blue, amorphous precipitate; the silver salt crystallises from water in microscopic needles.

J. W. L.

Substituted Asparagines. By A. PIUTTI (*Chem. Centr.*, 1888, 1530—1531).—*β-Ethylasparagine*, $NH·Et·CO·CH_2·CH(NH_2)·COOH$, is prepared by the action of a solution of ethylamine in alcohol on ethyl β-aspartate. An ethylamine salt first crystallises out, which melts at about 255° with decomposition. It reacts with cupric acetate to form the copper salt of β-ethylasparagine, which crystallises out in light-blue, pearly flakes, nearly insoluble in water. Hydrogen sulphide decomposes this, and the precipitated β-ethylasparagine is purified by recrystallisation from water. It forms thin, lustrous flakes melting at 258—260° with decomposition. It is not decomposed by magnesia, but with 30 per cent. potassium hydroxide it yields ethylamine and inactive aspartic acid. β-Ethylasparagine is optically inactive.

β-Allylasparagine, $C_3H_5·NH·CO·CH_2·CH(NH_2)·COOH$, is prepared in an exactly similar manner to the foregoing. It crystallises from water in lustrous, pearly flakes, melting at 258° with decomposition. It is anhydrous, readily soluble in hot water, but little soluble in cold water, and very sparingly soluble in alcohol and ether. It is optically inactive.

J. W. L.

Attempts to prepare Titanium Ethyl. By E. PATERNÒ and A. PERATONER (*Ber.*, 22, 467—470). The compound $TiCl_4,2ZnEt_2$ is obtained when titanium chloride (1 mol.) is gradually added to well-cooled zinc ethyl (2 mols.). An energetic reaction occurs, but no gas is evolved, and as soon as all the chloride has been added the whole solidifies to a brown mass which is not changed even on heating. It is decomposed with violence when mixed with water, yielding metallic zinc and a small quantity of an oil which can be separated by distilling with steam. This oil has no constant boiling point, but it can be separated into two fractions, namely, a portion boiling at 120—130°, which was proved to be octane, and a portion boiling at 220—270°, which contains considerable quantities (7·72 per cent.) of titanium, and is probably a mixture of octane and titanium ethyl.

F. S. K.

Condensation of β-Ketonic Ethers with Bibasic Acids. By R. Fittig (*Annalen*, **250**, 166—178).—A discussion of the constitution of the condensation products of succinic and pyruvic acids with ethyl acetacetate and ethyl benzoylacetate, described in the following Abstracts. All these compounds are derived from the compound

$CO<\begin{matrix}CH:CH\\ CH_2\cdot CH_2\end{matrix}$ or $OH\cdot C<\begin{matrix}CH:CH\\ CH\cdot CH_2\end{matrix}$.

W. C. W.

Condensation of Ethyl Acetoacetate and Succinic Acid. By F. v. Eynern (*Annalen*, **250**, 178—192).—*Ethyl hydrogen methronate*, $C_8H_7O_5Et$, is prepared by heating for 10 hours a mixture in molecular proportions of ethyl acetoacetate, acetic anhydride, and powdered sodium succinate which has been dried at 150°; the product is dissolved in water and extracted with ether. The liquid which is left on evaporating the ethereal extract is rendered alkaline with sodium carbonate, and again treated with ether to remove any unaltered ethyl acetoacetate; the alkaline solution is acidified with hydrochloric acid, and the new acid dissolved out with ether. Ethyl hydrogen methronate crystallises in needles and melts at 75·5—76°; it is freely soluble in alcohol, ether, chloroform, and benzene. The calcium and barium salts crystallise in needles containing 2 mols. H_2O. The silver salt, $C_{10}H_{11}O_5Ag$, crystallises in needles and is soluble in hot water. Ethyl hydrogen methronate resembles ethyl hydrogen carbuvate in many respects. It is decomposed by boiling with baryta-water, yielding the barium salt of methronic acid.

Methronic acid,

$\begin{matrix}CH(COOH)\cdot CH_2\\ CMe\cdot C(COOH)\end{matrix}>CO$, melts at 204—205°, decomposes at a higher temperature, forming uvitic acid and carbonic anhydride, and dissolves in alcohol, benzene, and in hot water. The acid calcium salt, $(C_8H_7O_5)_2Ca$, is very sparingly soluble in water. The acid barium salt is much more freely soluble. The normal barium salt, $C_8H_6O_5Ba$, is amorphous. In analyses of silver methronate, the percentage of silver is invariably found too low for some unknown cause. *Diethylmethronate*, $C_8H_6O_5Et_2$, is prepared by saturating an alcoholic solution of ethyl hydrogen methronate with hydrogen chloride; it boils at 300—305°. Phenylhydrazine unites with ethyl hydrogen methronate, forming a crystalline compound of the composition $C_{16}H_{18}N_2O_4$; this melts at 133—134°, and is freely soluble in hot alcohol, but is insoluble in cold solutions of sodium carbonate or sodium hydroxide.

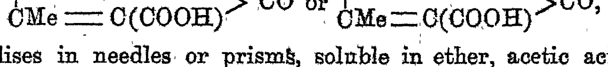
Phenylhydrazine and methronic acid unite together, forming a neutral compound of the composition $C_{14}H_{14}N_2O_4$; it melts at 211—212°

with decomposition, and is freely soluble in alcohol. Methronic acid is not attacked by nascent hydrogen. W. C. W.

Barium and Calcium Salts of Uvic, Carbuvic, and Ethylcarbuvic Acids. By P. Feist (*Annalen*, **250**, 192—195).—*Barium uvate*, $(C_7H_7O_3)_2Ba + 4H_2O$, crystallises in flat needles, soluble in hot water; the water of crystallisation is expelled at 120°. The *calcium* salt is deposited from a cold saturated solution in thick prisms containing 2 mols. H_2O, and from a hot solution in needles containing 4 mols. H_2O. *Carbuvic acid* is less soluble in water than methronic acid, but it is freely soluble in alcohol; it melts at 230°, and decomposes at a slightly higher temperature. *Barium carbuvate*, $C_8H_6O_5Ba + \frac{1}{2}H_2O$, is deposited as a crystalline precipitate when barium chloride is added to ammonium carbuvate. The calcium salt is anhydrous, and is less soluble than the barium salt. These salts do not resemble the salts of methronic acid. *Ethyl hydrogen carbuvate* is freely soluble in alcohol, chloroform, benzene, and in warm carbon bisulphide and in light petroleum. The barium salt, $(C_{10}H_{11}O_5)_2Ba + 4H_2O$, is soluble in hot water and crystallises in needles. The calcium salt, $(C_{10}H_{11}O_5)_2Ca + 3H_2O$, is also more soluble in hot than in cold water. These salts are quite distinct in their properties from those of ethyl hydrogen methronate. W. C. W.

Ethyl Acetoacetate and Pyruvic Acid. By A. Dietzel (*Annalen*, **250**, 195—211).—Ethyl hydrogen methylmethronate is formed by heating a mixture of equivalent quantities of ethyl acetoacetate, sodium pyruvate, and acetic anhydride in a large flask fitted with a reflux condenser. The temperature is gradually raised from 70° to 140°. The product is poured into a shallow basin and heated at 100°, with the occasional addition of small quantities of water in order to remove ethyl acetate, ethyl acetoacetate, and acetic acid; the residue is diluted with ether or chloroform and filtered, and after removing the ether or chloroform from the filtrate by evaporation, the residue is dissolved in boiling water and the solution energetically shaken. It is then treated with animal charcoal and extracted with ether. On evaporating the ether, ethyl hydrogen methylmethronate remains as a yellowish-red hygroscopic syrup. It is insoluble in water and carbon bisulphide, but is freely miscible with the usual solvents. It is decomposed by solutions of sodium hydroxide or baryta, forming the sodium or barium salt of methylmethronic acid. The acid is almost completely precipitated from these solutions by the addition of hydrochloric acid.

Pure *methylmethronic acid*,



$$\left.\begin{array}{l}\mathrm{CH(COOH){\cdot}CHMe}\\ \mathrm{CMe{=\!=}C(COOH)}\end{array}\right>\mathrm{CO}\ \text{or}\ \left.\begin{array}{l}\mathrm{CMe(COOH){\cdot}CH_2}\\ \mathrm{CMe{=\!=}C(COOH)}\end{array}\right>\mathrm{CO},$$

crystallises in needles or prisms, soluble in ether, acetic acid, hot alcohol, and in hot water. It melts at 198°. The barium salt, $C_9H_8O_5Ba + 2H_2O$, is deposited from its aqueous solution as a hygroscopic, amorphous mass, but it may be obtained in crystals by the cautious addition of alcohol to the aqueous solution. The calcium salt, $C_9H_8O_5Ca + 3H_2O$, resembles the barium salt in its properties. The silver salt, $C_9H_8O_3Ag_2$, is crystalline and sparingly soluble in hot water. No acid salts of methyl methronic acid are known.

Diethyl methylmethronate, $C_9H_8O_5Et_2$, boils with slight decomposition at 279—280° (uncorr.). It is insoluble in water, but miscible with other solvents. It is decomposed by boiling with an alcoholic solution of potassium hydroxide, yielding ethyl hydrogen methylmethronate, $C_9H_9O_5Et$, and by an aqueous solution of potassium carbonate, yielding potassium methylmethronate. The ethyl barium salt, $(C_{11}H_{13}O_5)_2Ba + H_2O$, is amorphous. The calcium salt, $(C_{11}H_{13}O_5)_2Ca + 2H_2O$, crystallises in needles which are soluble in water and in hot alcohol. The silver salt, $C_{11}H_{13}O_5Ag$, is freely soluble in alcohol and ether. The salts of the heavy metals are as a rule insoluble in water, and freely soluble in alcohol and ether.

Methyluvic acid,  $\mathrm{CO}<\begin{matrix}\mathrm{CH{=}CMe}\\ \mathrm{CHMe{\cdot}CH{\cdot}COOH}\end{matrix}$ or  $\mathrm{CO}<\begin{matrix}\mathrm{CH{:}CMe}\\ \mathrm{CH_2{\cdot}CMe{\cdot}COOH}\end{matrix}$, is prepared by heating methylmethronic acid in an atmosphere of carbonic anhydride. It is less soluble in water than methylmethronic acid, but dissolves freely in alcohol, light petroleum, chloroform, benzene, ether, and acetic acid. The acid is reprecipitated from concentrated aqueous solutions by sulphuric acid, and from its alcoholic solution by hydrochloric acid. Methyluvic acid melts at 98° and sublimes at 100°, but melts under water at 85—86°. The barium salt, $(C_8H_9O_3)_2Ba + 4H_2O$, crystallises in rhombic prisms. The calcium salt also crystallises with 4 mols. H_2O in plates. It is insoluble in alcohol. The crystalline silver salt melts at 150°, decomposing into silver and methyluvic acid. The ethyl salt, $C_8H_9O_3Et$, boils at 218—219° (uncorr.), and is miscible with the usual solvents, excepting water; it is slowly decomposed by water, and rapidly by an alcoholic solution of potassium hydroxide, yielding alcohol and methyluvic acid.

Methyluvic acid is decomposed by prolonged boiling, yielding *dimethylketopentene*, $\mathrm{CO}<\begin{matrix}\mathrm{CH{=}CMe}\\ \mathrm{CHMe{\cdot}CH_2}\end{matrix}$ or  $\mathrm{CO}<\begin{matrix}\mathrm{CH{:}CMe}\\ \mathrm{CH_2{\cdot}CHMe}\end{matrix}$, and on one occasion the author also observed the occurrence of a crystalline compound, which he regarded as an analogue of uvinone described by Paal and Dietrich (Abstr., 1887, 658). Dimethylketopentene boils at 118—119°; it is not miscible with water. W. C. W.

Succinic Acid and Ethyl Benzoylacetate. By A. SCHLOESSER (*Annalen*, **250**, 212—223).—Ethyl hydrogen phenythronate, $C_{13}H_9O_5Et$, is prepared by heating at 100° for 15 hours ethyl benzoylacetate (1 mol.), dry sodium succinate (1 mol.), and acetic anhydride (2 mols.). It crystallises in needles freely soluble in alcohol, ether, benzene, and chloroform, and melts when dry at 112·5°, but under water its melting point lies below 100°. The *calcium* salt, $(C_{15}H_{13}O_5)_2Ca + 3H_2O$, is deposited from alcohol in beautiful needles. It is less soluble in water than in alcohol. The *barium* salt, $(C_{15}H_{13}O_5)_2Ba + H_2O$, crystallises in rhombic plates, and is more soluble in water than the calcium salt.

The silver salt is amorphous. The salts of this acid are decomposed by boiling with baryta-water, yielding *barium phenythronate*, $C_{13}H_8O_5Ba + H_2O$. This salt is very soluble in water, but insoluble in alcohol. *Phenythronic acid*,  $\begin{matrix}\mathrm{CH(COOH)\cdot CH_2}\\ |\\ \mathrm{CPh : C(COOH)}\end{matrix}>\mathrm{CO}$, melts at 192—193°, and crystallises in silky needles. It is soluble in alcohol and in boiling water. The calcium salt contains 3 mols. H_2O. About 20 parts of water are required to dissolve one of the salt. The silver salt, $C_{13}H_8O_5Ag_2$, is an amorphous powder insoluble in water, but it becomes crystalline when rubbed with a glass rod. *Diethyl phenythronate*, $C_{13}H_8O_5Et_2$, melts at 44·5°, and forms rhombic crystals. When phenythronic acid is rapidly heated in a bent tube, a mixture of phenuvic acid and phenylketopentene distils over. *Phenuvic acid*,  $\mathrm{CO}<\begin{matrix}\mathrm{CH{:}CPh}\\ |\\ \mathrm{CH_2\cdot CH\cdot COOH}\end{matrix}$, melts at 144—145°, and is freely soluble in alcohol, benzene, and light petroleum. The *calcium* salt, $(C_{12}H_9O_3)_2Ca + 2H_2O$, forms colourless needles. *Barium phenuvate*, $(C_{12}H_9O_3)_2Ba + H_2O$, dissolves more freely in water than the calcium salt. The silver salt is amorphous. *Phenylketopentene*,  $\mathrm{CO}<\begin{matrix}\mathrm{CH{:}CPh}\\ |\\ \mathrm{CH_2\cdot CH_2}\end{matrix}$, crystallises in colourless prisms soluble in alcohol, ether, benzene, chloroform, and carbon bisulphide. It melts at 40°, and is identical with Paal's phenylmethylfurfuran (Abstr., 1885, 248).

W. C. W.

Effect of Thiophen and its Homologues on the Colour of the Derivatives of Benzene and its Homologues. By A. Bidet (*Compt. rend.*, **108**, 520—522).—The yellow tint of nitrobenzene and nitrotoluene, which becomes darker on exposure to light, is due to the presence of small quantities of nitrothiophen and its homologues, and if these are removed the nitrobenzene and nitrotoluene are practically colourless, and are not affected by light. They have, moreover, a much pleasanter odour than the ordinary preparations. Phenols free from thiophen-derivatives remain white. Pure aniline and its homologues are colourless when freshly distilled, and become yellow after some days, but never acquire the dark tint of ordinary aniline and toluidine. Pure aniline and toluidine mixed in the proportions necessary to give magenta, yield only a very small quantity of this dye when heated with arsenic acid. If, however, a small quantity of nitrothiophen is added, the ordinary yield is obtained.

The effect on the colour and other properties of the benzene compounds is a much more delicate test for thiophen than the ordinary isatin reaction.

Thiophen and its homologues may be removed by very careful fractionation, by repeated crystallisation, or by treatment with sulphuric acid. If nitrobenzene is dissolved in sulphuric acid, gently heated, and poured into water, and this process is repeated several times, the nitrothiophen remains in the aqueous acid. C. H. B.

Aromatic Nitriles. Benzyl Cyanide and Hydratroponitrile. By V. Meyer (*Annalen*, **250**, 118—125).—In benzyl cyanide, $CH_2Ph{\cdot}CN$, one hydrogen-atom can be displaced by benzyl, and in diphenylacetonitrile, $CH{\cdot}Ph_2CN$, the substitution can be even more easily accomplished, but in benzylphenylacetonitrile, $CHPhBz{\cdot}CN$, the hydrogen-atom cannot be displaced by benzyl. The hydrogen can also be displaced by benzyl in hydratroponitrile (methylbenzyl cyanide). Hydratroponitrile is most conveniently prepared by mixing benzyl cyanide with an equivalent quantity of freshly fused and powdered sodium hydroxide, methyl iodide is added, and the mixture gently warmed. The crude product of the reaction is distilled to separate benzyl cyanide and hydratroponitrile from the bye-products. When the nitriles are mixed with sodium ethoxide and benzaldehyde, the benzyl cyanide forms α-phenylcinnamonitrile which boils at 360°, and the benzylmethyl cyanide remains unaltered, and can easily be obtained in a pure state by fractional distillation.

Phenylcinnamonitrile is formed when a mixture of benzyl cyanide and benzyl chloride is boiled with solid sodium hydroxide.

W. C. W.

Replacement of the Methylene Hydrogen-atoms in Benzyl Cyanide. By H. Janssen (*Annalen*, **250**, 125—140).—By the action of benzyl cyanide (1 mol.) on solid sodium hydroxide (1 mol.) and benzyl chloride, a good yield of benzylbenzyl cyanide is obtained, but if the proportions of benzyl cyanide and sodium hydroxide are doubled, phenylcinnamonitrile, $CH{\cdot}Ph{:}C{\cdot}Ph{\cdot}CN$, is the chief product of the reaction. This nitrile is also formed when benzylbenzyl cyanide is treated with benzyl chloride and sodium hydroxide in molecular proportions. The conversion of benzylphenylacetonitrile into benzylphenylacetic acid by the action of strong hydrochloric acid at 130° is quantitative.

The cyanides obtained synthetically by the action of phosphorus pentachloride on benzylphenylacetamide from dibenzylcarboxylic acid and from α-phenylhydrocinnamic acid are identical with benzylbenzyl cyanide derived from benzyl cyanide.

Hydratropic acid can be prepared from acetophenone. For this purpose, strong hydrochloric acid (44 grams) is very slowly dropped on to pure potassium cyanide (30 grams) moistened with 30 drops of water, and covered with 50 grams of acetophenone. After an interval of 24 hours, the cyanhydrin, $OH{\cdot}CMePh{\cdot}CN$, is treated with hydriodic acid in sealed tubes at 150—160°. 30 grams of hydriodic acid and 1·7 grams of amorphous phosphorus are required for 10 grams of the cyanhydrin. The crude product is mixed with dilute sodium hydroxide solution, and on the addition of an acid to the alkaline solution, hydratropic acid is precipitated. The *amide* crystallises in plates, and melts at 91—92°. The nitrile boils at 230—232° without decomposition, and is soluble in alcohol and ether. The methine hydrogen-atom can be displaced by benzyl, yielding *benzylhydratroponitrile*, a yellow oil boiling at 335—337°. When heated with hydrochloric acid, it is converted into *benzylhydratropic acid*; this is freely soluble in alcohol and ether, crystallises in colourless needles, and melts at 126°. The *sodium* salt, $C_{16}H_{15}O_2Na + 7H_2O$, crystallises in needles, and melts in its water of crystallisation at 45°. It is soluble in alcohol. The silver and copper salts are insoluble in water, but the copper salt is soluble in alcohol and ether.

W. C. W.

Substituted Benzyl Cyanides. By K. NEURE (*Annalen*, **250**, 140—146).—Diphenylacetonitrile may be conveniently prepared from diphenylacetic acid obtained by the reduction of benzilic acid with hydriodic acid. The ammonium salt of diphenylacetic acid is prepared by passing dry ammonia gas into an ethereal solution of the acid. The ammonium salt is heated at 230° in sealed tubes to convert it into the amide, which is converted into the nitrile by the action of phosphorus pentachloride dissolved in phosphorus oxychloride. Benzyl chloride acts on an alcoholic solution of sodium and diphenylacetonitrile, yielding *benzyldiphenylacetonitrile*, $CPh_2Bz\cdot CN$. The new nitrile is freely soluble in chloroform, ether, benzene, and hot alcohol, and crystallises in plates or needles. It melts at 126°.

Methyldiphenylacetate is decomposed by sodium ethoxide with the formation of benzyl ethyl ether, methyl diphenylacetate, and diphenylacetic acid. Attempts to displace hydrogen by benzyl in benzophenone and triphenylacetonitrile led to negative results.

Benzyldiphenylacetonitrile is decomposed with difficulty, but by the action of a mixture of strong hydrochloric acid and acetic acids at 200—220°, it is partly converted into benzyldiphenylacetic acid. *Benzyldiphenylacetic acid* is soluble in ether, alkalis, and in hot alcohol, but it is very sparingly soluble in hot water, and is reprecipitated from alkaline solutions by the addition of an acid. It crystallises in needles, and melts at 162°. The author regards the compound which Meyer (Abstr., 1888, 702) obtained by the action of nitrous acid on diphenylacetonitrile as a polymeride of diphenylacetonitrile. This substance melts at 200—202°, and crystallises in needles.

Paratolylphenylacetonitrile, prepared by the action of phosphorus pentachloride on the amide of paratolylphenylacetic acid, crystallises in needles, melts at 59°, and is freely soluble in ether and in hot alcohol. It is converted into *benzyltolylphenylacetonitrile* by treatment with benzyl chloride and sodium ethoxide. The new nitrile melts at 121°, and is deposited from its alcoholic solution in white needles. The preparation of methylbenzyl cyanide has been described by V. Meyer (see preceding page). It is converted into methylphenylacetic acid, identical with hydratropic acid, by boiling with dilute sulphuric acid. *Ethylbenzyl cyanide* boils at 243—245°. On hydrolysis, it yields *ethylphenylacetic acid*, which melts at 42° and boils at 270—272°. The calcium salt crystallises in needles containing 2 mols. H_2O. The methyl salt boils at 228°.

Phenylcinnamonitrile is formed by the action of benzal chloride on benzyl cyanide in the presence of solid sodium hydroxide.

W. C. W.

Condensation of Benzyl Cyanide and its Substitution Products with Aldehyde and with Amyl Nitrite. By H. V. FROST (*Annalen*, **250**, 156—166).—*α-Phenylcinnamonitrile* is deposited as a crystalline mass when an alcoholic solution of sodium ethoxide is added to a mixture of benzyl cyanide (10 grams) and benzaldehyde (9·5 grams); it crystallises from boiling alcohol in white plates, melts at 86°, boils at 359—360° (corr.), and dissolves freely in ether, chloroform, benzene, carbon bisulphide, and in hot alcohol. It unites directly with two atoms of chlorine or bromine, forming compounds melting respectively at 129—130° and at 167—168°. *α-Phenylfurfuracrylonitrile*, $C_4H_3O{\cdot}CH{:}CPh{\cdot}CN$, prepared by the action of an alcoholic solution of sodium ethoxide on a mixture of benzyl cyanide and furfuraldehyde, melts at 42—43°; it unites with bromine to form a dibromide; this compound crystallises in six-sided plates of an orange colour, and melts at 113—114°. *α-Phenylanisacrylonitrile*, prepared from anisaldehyde and benzyl cyanide, forms white, needle-shaped crystals and melts at 93°.

The condensation product of benzyl cyanide with metanitrobenzaldehyde melts at 133—134°, and yields an unstable dibrom-additive product melting at 128°. The corresponding ortho-compound forms yellow needles and melts at 127—128°. The dibromide is unstable and melts at about 129° with decomposition. α-Phenylparanitrocinnamonitrile melts at 117—118°. It does not form additive compounds with chlorine and bromine. Parabromobenzyl cyanide forms crystalline condensation products with benzaldehyde, furfuraldehyde and anisaldehyde. These compounds melt at 111—112°, 65°, and 135° respectively. Substitution takes place when bromine is added to a solution of α-parabromophenylanisacrylonitrile, and a compound is formed of the composition $C_{16}H_{11}NOBr_2$. It is probably either $OMe{\cdot}C_6H_3Br{\cdot}CH{:}C(C_6H_4Br){\cdot}CN$ or $OMe{\cdot}C_6H_4{\cdot}CH{:}C(C_6H_3Br_2){\cdot}CN$.

The sodium salt of isonitrosobenzylcyanide is deposited as a crystalline mass, on mixing together equivalent quantities of benzyl cyanide, amyl nitrite, and an alcoholic solution of sodium ethoxide. Isonitrosobenzyl cyanide has been recently described by A. Meyer (Abstr., 1888, 693). Parabromisonitrosobenzyl cyanide crystallises in plates and melts at 131—132°. It forms amorphous sodium, silver, and copper salts. W. C. W.

Action of Chlorine and Bromine on Benzyl Acetate and similar Substances. By E. Seelig (*J. pr. Chem.* [2], **39**, 157—187).—78 per cent. of the theoretical yield of benzyl acetate is obtained by heating benzyl chloride (150 grams) with fused sodium acetate (97·6 grams) and glacial acetic acid (200 grams) for 25 hours. With ammonia, benzyl acetate forms benzyl alcohol and acetamide; chlorine acts on it between 130° and 170°, forming acetic and benzoic chlorides; in the presence of powdered ferric chloride, parachlorobenzyl chloride is obtained in the cold. Bromine decomposes benzyl acetate in the cold, forming para- and ortho-bromobenzyl bromide, and the substance $C_2H_4O_2Br_2$, described by Mühlhäuser and Hell (Abstr., 1879, 705); near the boiling point, acetic and benzoic bromides are formed.

Parabromobenzyl acetate melts at 32° and boils at 260—263°; bromine acts on it near the boiling point, forming bromobenzyl bromide.

Neither chlorine nor bromine act on ethyl benzoate or ethyl acetate below 100°; at higher temperatures the latter yields, with chlorine, benzoic and acetic chlorides respectively, together with aldehyde.

With chlorine, in the cold, phenyl acetate yields acetic chloride, chlorophenol, and chlorophenyl acetate; when heated, dichlorophenyl acetate is the chief product; in the presence of ferric chloride, trichlorophenyl acetate is also formed in the cold. The action of bromine is analogous.

Benzyl acetate is converted into acetic acid and benzyl chloride by hydrogen chloride at 180°, and ethyl benzoate into benzoic acid and ethyl chloride.

The author has already discussed the action of chlorine on toluene (Abstr., 1887, 362); he concludes with some general deductions as to the position in organic compounds of the hydrogen which is most easily attacked by the halogens. A. G. B.

Action of Chlorine on Catechol and Orthamidophenol. By T. Zincke and F. Küster (*Ber.*, 22, 486—497). The hexachlorodiketohexene obtained from catechol or orthamidophenol (compare Abstr., 1888, 1277) is identical with the compound formed when tetrachlororthoquinone is treated with chlorine. The difference in the melting points which was previously observed is due to the presence of varying quantities of water; the compound $C_6Cl_6O_2,2H_2O$ readily loses water when recrystallised from a mixture of ether and benzene, its melting point being thereby raised and only becoming constant when the compound $C_6Cl_6O_2,H_2O$, which does not lose water when recrystallised from hot benzene, is formed.

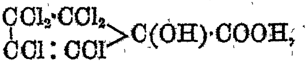
Propylideneacetic acid is obtained when pentachlorobutenecarboxylic acid is dissolved in dilute alkali and treated with 40 to 50 times its weight of 4 per cent. sodium amalgam, the whole being warmed for a long time to complete the reaction; the alkaline solution is first shaken with ether, then acidified and the acid extracted with ether and purified by fractional distillation. The yield is about 50 per cent. of the calculated quantity. It combines with bromine, yielding an oily bromide, and is identical with the propylideneacetic acid prepared by Komnenos (Abstr., 1884, 422). The *barium* salt, $(C_4H_7\cdot COO)_2Ba$, melting at 265—270°, and the *calcium* salt, with $1H_2O$, are readily soluble in water, alcohol, and ether. The *copper* salt is a greenish, crystalline compound, melting at 91°. The *silver* salt separates from hot water in moss-like crystals. The *mercuric* salt crystallises in needles.

The reduction of pentachlorobutenecarboxylic acid to propylideneacetic acid shows that the constitution of the former is

$$CCl_2{:}CCl\cdot CCl{:}CCl\cdot COOH,$$

the constitution of hexachloroketopentene is therefore  $\begin{matrix}CCl_2\cdot CCl_2\\ |\\ CCl:CCl\end{matrix}\!>\!CO$,

that of hexachlorohydroxypentenecarboxylic acid,



$$\begin{matrix}CCl_2\cdot CCl_2\\ |\\ CCl:CCl\end{matrix}\!>\!C(OH)\cdot COOH,$$

and that of hexachlorodiketohexene,  $CCl_2\!<\!\begin{matrix}CCl_2\cdot CO\\ CCl{:}CCl\end{matrix}\!>\!CO.$

The conversion of catechol and orthamidophenol first into tetrachlororthoquinone and then into propylideneacetic acid proves that orthoquinone has the diketone constitution, and is also evidence in support of Kekulé's benzene formula. F. S. K.

Orthonitroethylaniline and its Derivatives. By A. HEMPEL (*J. pr. Chem.* [2], **39**, 199—200).—*Orthonitroethylaniline*,

$$NO_2 \cdot C_6H_4 \cdot NHEt,$$

is obtained by heating orthonitrophenyl ethylene ether with alcoholic ethylamine at 140°; it is an orange-red oil, distilling with decomposition and is precipitated unchanged on adding water to its solution in acids. *Dinitroethylaniline*, $C_6H_3(NO_2)_2 \cdot NHEt$, is obtained by the action of nitrous acid on an ethereal solution of orthonitroethylaniline; it forms lemon-yellow needles melting at 113—114°. *Orthonitronitrosoethylaniline* is formed when sodium nitrite is added to a hydrochloric acid solution of orthonitroethylaniline; it crystallises in long, yellow needles melting at 32°. *Orthamidoethylaniline*, $NH_2 \cdot C_6H_4 \cdot NHEt$, is a colourless oil boiling at 249° and becoming dark-red in air. *Orthamidoethylacetanilide*, $C_6H_4 \cdot N_2H_2EtAc$, obtained when acetic anhydride acts on an ethereal solution of orthamidoethylaniline, forms white crystals melting at 104°. *Ethenylorthoethylphenylenediamine*,

$$C_2H_3 < \begin{matrix} N— \\ NEt \end{matrix} > C_6H_4,$$

crystallises from alcohol in slender, colourless, rhombic tables or prisms, melting at 178°. A. G. B.

Last Runnings obtained in the Purification of Aniline and Toluidine. By C. HELL and T. ROCKENBACH (*Ber.*, **22**, 505—514). —The dark oil which is obtained when the last runnings in the purification of aniline are acidified with hydrochloric acid and distilled with steam, consists of a variety of compounds which cannot be separated by fractional distillation. When boiled with a 5 per cent. solution of potassium permanganate, it yields various organic acids which remain in solution, and an oily product insoluble in water. After removing the supernatant oil and adding excess of sulphuric acid, a mixture of acids is precipitated from which by repeated fractional crystallisation of the lead and silver salts, terephthalic acid and a small quantity of an acid melting at 228—232° were isolated. The latter crystallises in shining needles, and probably has the composition $C_{10}H_{10}O_4$. The mother-liquors from these acids contain small quantities of acetic acid and its next higher homologues, which can be separated by distilling with steam; in one experiment, paratoluic acid was isolated from the non-volatile residue. The oily oxidation product yielded, on keeping, a crystalline substance, from which, by recrystallising from ether and absolute alcohol, two compounds, one melting at 122·5°, probably a sulphone or sulphone-derivative, the other melting at 66°, were isolated. The mother-liquors from the crystalline products can be separated by fractional distillation into a large portion boiling at 255—259°, and a somewhat smaller fraction boiling at 259—264°, The fraction 255—259° consists of a *hydrocarbon*, $C_{14}H_{22}$, in an almost pure condition. This hydrocarbon becomes gelatinous when cooled with a mixture of ether and solid carbonic anhydride, and when heated at 220° with concentrated nitric acid, it yields terephthalic acid. When boiled with a mixture of nitric acid and sulphuric acid, it yields a brown, oily nitro-compound, together with small quantities of a colourless, crystalline substance melting at 228°. The oily nitro-compound, when reduced with tin and hydrochloric acid, is converted into a white, amorphous *base*, which rapidly darkens in colour and is soluble in ether. The *hydrochloride* of this base is a semi-crystalline compound, which quickly turns dark violet; the *platinochloride*, $(C_{14}H_{21}NH_2)_2,H_2PtCl_6$, is a brown powder.
